This class of social influences is concerned with the concept of strategic uncertainty (Van Huyck et al. 1990), in which players’ outcomes depend on the choices of other players. The stag hunt game discussed above is an example. More generally, coordination games where the optimal social outcome provides no incentive for deviation, but players cannot make binding agreements, are a widely studied group of games involving such social risk. In economics, an important application of such coordination games concern depositors’ decisions on whether to keep their money in a distressed bank. If all depositors stay calm, the bank will survive. If a few depositors withdraw their money prematurely, however, the bank will fall and the remaining depositors lose their money. From a game theoretic perspective, all depositors staying calm as well as all depositors withdrawing (a bank-run), both constitute Nash equilibria. Game theory makes no prediction which equilibrium will obtain, and equilibrium selection in such settings therefore creates strategic uncertainty.

Empirical evidence has shown that, although seemingly obvious, the coordination problem is often too difficult for players to solve. After a few rounds of repeated play (with new pairings), the game usually converges to the Pareto-dominated equilibrium of all players withdrawing. The result suggests that strategic uncertainty may be difficult for people to deal with. In a comprehensive study, Heinemann et al. (2009) investigated risk taking in coordination games. Two important results were obtained. First, they found a strong correlation between risk taking in a simple gambling task, and coordination (and thus the acceptance of strategic uncertainty). Second, the authors showed that coordination was more likely the smaller the percentage of people necessary for successful implementation of the Pareto-efficient outcome. Note that because of the multiplicity of equilibria, it is not theoretically the case that a smaller percentage implies a higher chance of an efficient outcome. People seem to perceive it as such, however. Another interesting finding shows that risk-averse people also expect others to be risk averse (see also Kocher and Trautmann (2010) for a similar effect for ambiguity attitude in a market setting). This finding helps explain the poor outcomes of coordination games. In a risky decision, attitudes toward risk should be independent of the perception of the lottery itself. Due to the above-stated correlation, however, in a coordination game, the expected probabilities of the favorable outcome are reduced inasmuch as the decision maker’s own risk aversion creates an expectation of others also shying away from the risk of coordinating on a superior equilibrium.

The conclusion of increased risk aversion under strategic uncertainty compared with the risk due to nature is not unchallenged. Fox and Weber (2002) let subjects choose between either playing a two-player coordination game, or making a risky coin flip. The game is similar to the one described above with two pure equilibria, and with a mixed equilibrium in which both strategies are played with equal probability. Most subjects preferred to play the game rather than flipping a coin. Obviously, the expected probability of successful coordination can be larger than 50%, such

that even if risk aversion is stronger under strategic uncertainty than under pure randomization, subjects may still opt for playing the coordination game. In a slightly different game, called the matching pennies game, the same authors found a preference for the coin flip, however, replicating a finding in Camerer and Karjalainen (1994). In this game, there exists only a mixed equilibrium within which both the strategies are played with equal probability: this is the case because for each event where player 1 wins money, player 2 loses the same amount, and vice versa. Fox and Weber (2002) also found that the perceived competence of the opponent/partner affected the choice between the game and the risky lottery. A similar result is reported in Eichberger et al. (2008) for more complex games played against opponents with a different perceived degree of rationality. These findings imply that the perception of the game structure and the perception of the opponent strongly influence attitudes toward strategic uncertainty, showing the importance of subtle social influences.

The situation of strategic uncertainty is common to other games as well. Two-player examples include the ultimatum game and the trust game, also known as investment games. In the ultimatum game, an endowment is given to one player, called the proposer, whose task it is to propose a division of the endowment between herself and the second player, called the responder. Given this proposal, the responder has to make a binary decision between accepting and rejecting the proposal. In the former case, each player receives her share as specified in the proposal. In the latter case, both players receive nothing. Assuming pure self-interest, any positive amount is preferable to a zero payoff, and the subgame perfect Nash equilibrium therefore predicts that the responder accepts any positive amount. Hence, the proposer proposes the smallest positive unit to the responder, keeping the rest of the endowment to herself. If players have distributional or reciprocal preferences, however, proposers may offer significant amounts to the responder. Similarly, responders may reject small offers because of such preferences. The proposer obtains a risky decision situation because of the uncertainty regarding social preferences of the responder, and thus the possibility of rejection and loss of the endowment. Bellemare et al. (2008) show that proposers perceive the situation as a risky decision problem, and make proposals according to their beliefs about the probability of a rejection by the responder for each potential proposal of shares. This implies that proposers will offer more in situations where the responder is able to reject offers as described above, compared with situations where the responder is forced to accept any proposal (i.e., a dictator game). This prediction is empirically confirmed by Bellemare et al. (2008, see also Bolton and Zwick 1995).

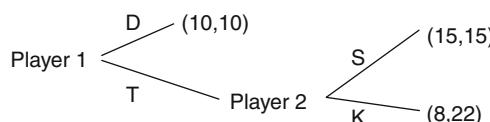

The above evidence from coordination games that a risk-averse person may be even less inclined to take social risk than an equivalent lottery risk has been tested intensively in the trust game. In the trust game, the first player receives an endowment  $e$  and can submit any part  $x$  of it to the second player, the trustee. The remaining amount  $(e - x)$  she keeps for herself. For any amount  $x$  that is entrusted to her, the trustee then receives an amount  $b \times x$  from the experimenter, with  $b$  typically set equal to 2 or 3 in experiments. The real-world equivalent for the multiplication factor  $b$  is that the trustee may have access to more profitable investment opportunities than the first player, but she does not have enough funds to make the investment with her own money. After receiving  $b \times x$ , the trustee in turn decides how much to send back to the first player, denoted  $y$ . The final payoffs for the first and the second player are, respectively,  $e - x + y$  and  $(b \times x) - y$ . The game is either played with  $x$  and  $y$  to be freely picked by the players, or in a binary form with only two possible amounts for  $x$  and  $y$ , respectively. In the latter case, for example, the first player can submit either the full

endowment or zero, and the second player may either keep the full amount  $b \times x$  or send back the equal split ( $b \times x/2$ ).

The decision to trust by player 1 in the trust game is a decision implying social risk, and the relevant payoff probabilities depend on her beliefs about the trustee's behavior. A variety of studies tried to identify whether first players in the trust game indeed perceive the game as a simple decision under risk, or whether there is an additional, social component. Using behavioral measures of trust game choices and risk-decision behavior, Eckel and Wilson (2004) find no correlation between various measures of risk attitude from lottery choices, and the trust game behavior. Schechter (2007) finds evidence of a positive correlation between trusting and risk seeking, using a risky decision task that matches the structure of the trust game as closely as possible. Schechter's results show that the relation between trusting and risk seeking is far from one to one: one unit invested in a risky lottery increases the amount submitted in the trust game by 0.28 units. Kosfeld et al. (2005) study the trust game from a biological perspective. They administer either the peptide oxytocin or a placebo to first players in the trust game. They find that oxytocin increases trust behavior, but does not affect risk-seeking behavior in a matched risky decision lottery task. Their result thus shows that trust includes an additional social risk component that is not related to risk seeking in uncertainty deriving from nature, and is uniquely affected by the administered hormone.

Bohnet and Zeckhauser (2004) and Bohnet et al. (2008) devise a clever experimental design to clearly separate the pure risk aspect from the additional social component using behavioral data. They call the latter component *betrayal aversion*, and show that it is substantial and that it exists across a wide range of cultural groups. Bohnet and Zeckhauser separate betrayal aversion from risk aversion by the following task. Given a certain payoff structure in the trust game (see Fig. 22.3), they ask player 1 to indicate the lowest acceptable probability of a randomly matched trustee playing equal split (instead of keeping most of the pie) such that she (player 1) would choose trusting. Given the same game structure, in a control group, player 2's choice is replaced by a random lottery draw with unknown probability. Here, they ask first movers what the lowest probability of the equal split is that would make them choose the risky strategy.

Clearly, the more risk averse a subject is, the higher will be the lowest acceptable probability of the good outcome. If trust is simply determined by risk attitude, this probability should be equal in both questions. In fact, Bohnet and coauthors find that people require much higher probabilities in the trust game than in the pure risk game to make them accept the more risky trust option. The difference between a typical minimum acceptable probability in the trust

**Fig. 22.3**

**Trust game used to identify betrayal aversion.** Notes: The game is played sequentially. Player 1 either distrusts (D) or trusts (T). Conditional on strategy T by player 1, player 2 either shares equally (S), or betrays the trust, keeping (K) most of the pie for herself.  $(x,y)$  indicate a payoff of  $x$  for player 1 and  $y$  for player 2

game and in the risk game measures betrayal aversion. The authors report probability differences in the range of 10–20% points more requested in the trust game, indicating a much stronger aversion to social risk than to natural risk from an impartial random device.

In sum, there is clear evidence that people perceive strategic uncertainty as a risky decision problem. Attitudes toward this uncertainty deviate strongly from individual choice setting, however, and depend on the social content of the game. There is some indication that risk attitudes and beliefs are correlated, amplifying risk aversion in social contexts.

## Further Research

---

The previous sections have explored recent research efforts in economics that bring social factors to the forefront of decision making under risk. While we have seen many interesting findings that increase the realism and descriptive power of traditional theories of decision making under risk and uncertainty, one element that has become apparent is the many contradictions between different studies. Since effects may often be subtle and this literature is still in its infancy, this is not surprising: as the research field becomes more mature, more of these contradictions will be explained, and the discovery of the underlying causes will greatly improve our understanding of social influences in risk taking. Beyond resolving the underlying controversies in the baseline research, there is also a wealth of applications to real-world phenomena to be explored. Since such real-world applications may be more interesting – and are generally the drivers behind the baseline research we have already discussed – the present section will pay heed to the latter in order to pinpoint lacunae that remain in our understanding of social influences on risk attitudes. We will thereby focus on two areas that are currently highly debated – financial agency and climate change.

Principal–agent relationships in financial markets constitute an especially promising terrain for future research. As discussed briefly earlier, such relationships can be complex, involving potentially different payoff mechanisms for the agent and the principal. A better empirical understanding of such asymmetric compensation mechanisms seems fundamental for the design of agency contracts, in which the principal tries to induce an agent to represent her interests. Influencing the agent's risk attitude in such a way as to be aligned with the interests of the principal can be quite challenging and the mechanisms needed to achieve this are still poorly understood, as shown by the results of Lefebvre and Vieider (2010) discussed above. Many other – even more involved – relationships exist in the real world, which we are only starting to study and understand. One important question that has emerged from the recent financial turmoil is, for instance, how the principal–agent relationships can be reformed in cases where agents are employed by one principal (e.g., a bank or a financial advisor), but take decisions for or provide advice to another principal (e.g., a private investor). Indeed, incentives of such agents to act exclusively in the interest of the permanent employer have been blamed for advice that has often been excessively risk-laden from the point of view of clients, and which is at least partially to blame for the escalating risk spiral culminating in the 2008 financial crisis. While models and theories on how to fix such relationships do exist, it seems crucial to obtain empirical evidence to test such models and investigate subtleties that may have been missed in the deductive process of their construction.

The imitation of others around us is one of the most natural and common ways of learning about the world and improving oneself. This imitation may however take very different forms.

One could learn from someone else how to better perform a given task – or one could learn how not to perform a task from observing somebody else's success or failure (Offerman and Schotter 2009 and references therein). Since actual decision-making processes are rarely observable in sufficient detail, a focus on the outcomes of such decision-making processes can generally be considered a more accessible substitute. Problems may arise from this approach, however, when outcomes are largely dependent on chance, and observers are more likely to observe successful decision makers than the unsuccessful ones. This is sometimes known as a *survivor bias*, whereby only successful actors may stay in the market long enough to be observed, while the unsuccessful ones tend to drop out and disappear from sight relatively quickly. When survival depends largely on chance, imitating the behavior of survivors may not lead to better decision-making processes, and may sometimes lead to worse decisions. A typical example of this may be bubble formation in financial markets. When markets get artificially inflated, observers may imitate the behavior of early movers and buy increasing amounts of stocks, thus pushing their price even higher and thus increasing the risk of a painful burst. Unfortunately, the social element in these types of behavior is still poorly understood, such that it is unclear what part of such behavior is due to uninformed following, and which part is instead caused by rational speculation (as long as this self-enforcing mechanism continues, the price will continue going up, even though the asset is already overpriced).

Whenever the linkage between actions and outcomes is poorly understood, delegating decisions involving risk or uncertainty creates complex issues of incentives and accountability of agents. This derives at least in part from the fact that in an uncertain world it is often difficult to determine what outcomes result from skill and what outcomes result from pure luck (Maboussin 2010), with consequent difficulties for the establishment of effective incentive and responsibility mechanisms. Moreover, perceptions by the principal of the control that agents have over outcomes in different contexts and the subsequent preferences for accountability regimes resulting from such perceptions may depend crucially on the principal's ideological worldview (Tetlock and Vieider 2010). Bartling et al. (2009) gave principals a choice between a low-trust strategy leaving little room for employee discretion and a high-trust strategy that gave employees substantial freedom, but also provided the possibility of substantial rent sharing. They found that the trust strategy resulted in substantial benefits for both employers and employees when there was competition between employees who could build up reputations. Notwithstanding this clear advantage, some employers never switched to the trust strategy, thus sacrificing potential payoffs. These employers may have been deterred by the risk that employees may turn out to be untrustworthy and shirk.

While the latter examples show how important social perceptions and mechanisms can be, they also provide an indication of how poorly understood some of the mechanisms involved still are. Reputation formation, different accountability regimes, reporting requirements, etc., all play into the equation and interact with the pure incentive mechanisms on which economic theory has classically focused. Expanding the traditional focus and allowing for more complex interactions, which are generally present in the real world, promise to improve our understanding of the existing processes as well as opening up new directions for contract design. In this sense, integrating the variety of findings from different social science literatures seems a promising direction for moving forward. Huge parallel literatures on principal-agent relationships exist in economics and organizational science, and even sociology and organizational and social psychology. To mention, but one example, organizational scientists have long called for abandoning the simplistic assumption of invariant risk aversion by agents still central to the

agency literature in economics (Wiseman and Gomez-Mejia 1998) – an assumption whose anachronism has been dramatically unveiled by recent events. Unfortunately, such communication between different disciplines in the social sciences is still rather the exception than the rule, be it because of the different taxonomies or methodologies adopted that make their integration arduous work, or because of turf wars between scientific communities driven by narrow self-interest.

Financial markets are by no means the only real-world phenomenon on which a better understanding of social aspects of decision making under uncertainty promises to shed some light. Let us take another issue that currently occupies a prominent position in international policy agendas: climate change. It is often repeated how humanity's failure to control emissions of greenhouse gases constitutes a classic tragedy of the commons problem (Hardin 1968). Such problems have been intensively studied in economics under the label of public good games, and the large body of evidence clearly rejects the economically selfish prediction of zero contributions to the common good (Andreoni 1995). Nevertheless, this large body of knowledge only offers poor guidance for the complex phenomenon of emission reductions, for the simple reason that the issue differs from the classic public good problem on several dimensions that may be expected to be relevant for the decision-making process.

First of all, climate change is a public bad rather than a public good, and there is solid evidence that different frames significantly influence people's decisions. Perhaps more importantly from the point of view of the present chapter, the public bad of climate change – or alternatively, the public good of emissions reductions – involves risks that do not derive only from the possible failure of other group members to contribute. Mounting levels of greenhouse gas concentrations in the atmosphere increase global average temperatures. In turn, such mounting temperatures produce changes in global weather patterns, resulting in increased likelihoods of catastrophic events such as prolonged droughts, floods, increased storm frequency and intensity, and even potential migrations and wars resulting from such events. Finally, the likelihoods of different events themselves are often poorly understood because of previously unexperienced feedback cycles such as the recession of the permafrost zones in northern Siberia, etc.

All this shows the point that we are here considering a risky public good involving unknown and highly uncertain probabilities – a type of phenomenon on which virtually no evidence exists (Zeckhauser 2006). To this, one needs to add the social connotations of the problem that go far beyond the classical social issues involved in public good games as studied in the experimental economics literature. The asymmetric wealth of the actors involved (with some of the poorer actors also being the largest emitters of greenhouse gases; see Reuben and Riedl (2009) for the effects of such asymmetries on public good contributions), the fact that some of the largest emitters are unlikely to face the highest risks (Sunstein 2008), different historical responsibilities for stocks of greenhouse gases present in the atmosphere, and different cultural backgrounds all constitute social elements that complicate the process, and which are still often poorly understood in isolation, let alone combined. For instance, how may risk attitudes – and hence the willingness to reduce existing or future risks – depend on income or wealth of the involved actors? And how does this dependency interact with historical responsibility for current risks by the richest actors, combined with a power for stopping increases in risk level that rests mainly with relatively poor actors? Obtaining better evidence on the drivers of decision-making processes in situations that have complex social and risk dimensions appears to be crucial for a better understanding of involved decision-making processes and international coordination on these complex issues.

While the examples provided here are by no means exhaustive, they seem apt at providing a snapshot of how more evidence on the social drivers of decision-making processes under risk can help us better understand – and thus potentially improve – complex real-world interactions. The challenge will be to dissect these complex issues in such a way as to be able to draw causal inferences on single aspects in isolation, as well as to later reassemble the collected evidence in order to understand their interaction. One discipline or research methodology will hardly be able to rise to this challenge. Classical laboratory experiments from economics aimed at understanding basic decision-making processes will need to be integrated with evidence from more complex decision environments in the field. A better understanding of social interactions from social psychology will be just as important as a solid underpinning from organizational science, and deeper insights into the legal aspects necessary for binding international agreements and their implementation into national law. Finally, philosophy can come into the picture by highlighting the intercultural common ground of ethical thought and shared principles on which the indispensable closer international cooperation can be founded. Paraphrasing a famous scientist from another discipline: everything should be made as simple as possible, but not simpler.

**Abstract:** Risk intelligence is the ability to estimate probabilities accurately. In this context, accuracy does not imply the existence of objective probabilities; on the contrary, risk intelligence presupposes a subjective interpretation of probability. Risk intelligence can be measured by calibration testing. This involves collecting many probability estimates of statements whose correct answer is known or will shortly be known to the experimenter, and plotting the proportion of correct answers against the subjective estimates. Between 1960 and 1980, psychologists measured the calibration of many specific groups, such as medics and weather forecasters, but did not gather extensive data on the calibration of the general public. This chapter presents new data from calibration tests of over 6,000 people of all ages and from a wide variety of countries. High risk intelligence is rare. Fifty years of research in the psychology of judgment and decision-making shows that most people are not very good at thinking clearly about risky choices. They often disregard probability entirely, and even when they do take probability into account, they make many errors when estimating it. However, there are some groups of people with unusually high levels of risk intelligence. Lessons can be drawn from these groups to develop new tools to enhance risk intelligence in others. First, such tools should accustom users to specifying probability estimates in numerical terms. Second, they should focus on a relatively narrow area of expertise, if possible. Thirdly, these tools should provide the user with prompt and well-defined feedback. Regular calibration testing might fulfill all three of these requirements, though training assessors by giving them feedback about their calibration has shown mixed results. More research is needed before we can reach a definitive verdict on the value of this method.

## Introduction

---

Although the term “risk intelligence” has been gaining currency during the past few years, there is still no consensus as to what it means. According to David Apgar, the term denotes “an individual’s or an organization’s ability to weigh risks effectively,” and involves “classifying, characterizing, calculating threats; perceiving relationships; learning quickly; storing, retrieving, and acting upon relevant information; communicating effectively; and adjusting to new circumstances” (Apgar 2006). According to Frederick Funston, coauthor of *Surviving and Thriving in Uncertainty: Creating the Risk Intelligent Enterprise* (Funston and Wagner 2010), risk intelligence is “the ability to effectively distinguish between two types of risks: the risks that must be avoided to survive by preventing loss or harm; and, the risks that must be taken to thrive by gaining competitive advantage,” and involves the ability to “translate these insights into superior judgment and practical action to improve resilience to adversity and improve agility to seize opportunity” (Krell 2010). Funston is a principal at Deloitte & Touche LLP, and Deloitte seems keen for people to associate the phrase “risk intelligence” with its brand, to judge by the series of research papers they have published on this topic and their release of an iPhone app which purports to let users create a “risk intelligence map.”

The trouble with both of these definitions is that they are rather vague, and encompass so many abilities as to be practically useless, and certainly immune to any kind of scientific measurement. I prefer a much more restricted definition: risk intelligence is the ability to estimate probabilities accurately (Evans 2012). Not only is this concept simpler to grasp and more precise than those suggested by Apgar and Funston, it is also more susceptible to measurement. Before explaining how to measure risk intelligence as I define it, however, I will first address some common objections I have encountered when explaining my definition.

## Objections to My Definition of Risk Intelligence

---

The most common objection to my proposed definition seems to be that it makes no reference to notions of harm, threat or danger, which some people consider to be central to the concept of risk. The observation is correct, but I regard this feature as a virtue of my approach rather than a fault. While it is true that the term “risk” is intimately associated in the vernacular with undesirable possibilities, those who study the subject largely agree that this restriction is somewhat arbitrary. Risk experts never tire of pointing out that an exclusive focus on “downside risk” tends to encourage a risk-averse attitude and to discourage an awareness of the potential rewards from exploiting risky opportunities. Indeed, Funston goes so far as to make this point central to his definition of risk intelligence, as we have already seen. My definition of risk intelligence avoids value judgments altogether by referring simply to “probabilities,” regardless of whether such probabilities refer to outcomes that we find pleasant or not.

Another objection to my definition comes from those who are fond of the distinction between “risk” and “uncertainty” proposed by the American economist Frank Knight in 1921. In that year Knight published his influential book, *Risk, Uncertainty, and Profit*, in which he argued that:

- ▶ Uncertainty must be taken in a sense radically distinct from the familiar notion of Risk, from which it has never been properly separated. The term “risk,” as loosely used in everyday speech and in economic discussion, really covers two things which, functionally at least, in their causal relations to the phenomena of economic organization, are categorically different. . . . The essential fact is that “risk” means in some cases a quantity susceptible of measurement, while at other times it is something distinctly not of this character; and there are far-reaching and crucial differences in the bearings of the phenomenon depending on which of the two is really present and operating. . . . It will appear that a measurable uncertainty, or “risk” proper, as we shall use the term, is so far different from an unmeasurable one that it is not in effect an uncertainty at all. “We . . . accordingly restrict the term ‘uncertainty’ to cases of the non-quantitative type” (Knight 1921).

This distinction has become so influential that economists now talk about “Knightian uncertainty” when referring to risks that are immeasurable or impossible to calculate, in contrast to risks that can be quantified. This way of explicating the distinction is misleading, however, since both risk and Knightian uncertainty can be measured and quantified. The putative distinction is really about the way in which the probabilities are calculated in each case.

The prototypical case of risk, in Knight’s sense, is a casino game like roulette or blackjack. To work out what the odds of a given bet should be in these games, all you need to know is the rules of the game itself. You do not need to collect any data or observe how the game is actually played. You can just read the rule book in the comfort of your armchair and work it out with pen and paper (though a laptop would often help considerably).

This may be contrasted with, say, working out what the odds of a given bet should be in a horse race. In this case, it will not help much if you simply read the rule book. In addition to this, you also need to gather lots of data about the horses in the race, and the jockeys, and the racetrack, and the likely weather on the day of the race, and who knows what else. You can get these data in all sorts of ways – reading the “form” of the horses as published in newspapers, looking carefully at the horses with your own eyes, talking to tipsters, listening to the weather forecast, and so on. And then you need to crunch all these data and come up with an estimate of how likely it is that this horse will win this race.

One way to crunch the data is to use a computer. Another is to use your brain; first absorb the data by reading, watching, and listening, and then mull them over in your own head and come up with an estimate of how likely it is that the horse will win. Doing that well is what I call risk intelligence.

I'm sticking to my guns, and will continue to refer to this ability as *risk* intelligence (rather than, say, *uncertainty* intelligence) because I do not think the distinction proposed by Frank Knight holds water. For one thing, the mere fact that the odds in a racetrack world cannot be worked out from first principles does not mean they cannot be measured or quantified. On the contrary, when gamblers or bookmakers estimate the chances of a horse winning a race or a team winning a basketball match, what else are they doing if not quantifying uncertainty?

More importantly, pure casino worlds do not exist – except in the pages of economics textbooks. In this respect, I agree with maverick trader Nassim Nicholas Taleb, who wrote in his bestselling book, *The Black Swan*, that:

- ▶ In real life you do not know the odds; you need to discover them, and the sources of uncertainty are not defined. Economists, who do not consider what was discovered by noneconomists worthwhile, draw an artificial distinction between Knightian risks (which you can compute) and Knightian uncertainty (which you cannot compute), after one Frank Knight, who rediscovered the notion of unknown uncertainty and did a lot of thinking but perhaps never took risks, or perhaps lived in the vicinity of a casino. Had he taken financial or economic risk he would have realized that these “computable” risks are largely absent from real life! They are laboratory contraptions! (Taleb 2007).

When Taleb states that computable risks are “laboratory contraptions,” he means that casino worlds are artificial entities which have to be deliberately manufactured under sterile conditions, like an unstable element that only exists for a few brief moments in a physics lab. It took thousands of years for the irregular-shaped knucklebones used in ancient Rome, and the Vibhīdaka nuts used in ancient India, to evolve into the precision dice used in modern casinos, with their pips drilled and then filled flush with a paint of the same density as the acetate, such that the six numbers are equally probable. It takes even greater engineering prowess to produce a fair roulette wheel. The manufacturers of roulette wheels perform elaborate tests to ensure that the numbers generated are truly random, and even then the wheels still have flaws, allowing some cunning players to make a fortune with a “biased wheel attack.” In 1873, for example, a mechanic from Lancashire called Joseph Jagger identified a biased wheel in Monte Carlo and won the equivalent of \$70,000 in one day.

Taleb tells a lovely story to illustrate the unreality of casino worlds. A casino in Las Vegas thought it had all the bases covered in risk management. It was sufficiently diversified across the various tables to not have to worry about taking a hit from lucky gamblers. It had a state-of-the-art surveillance system to catch cheats. But the four largest risks faced by the casino in the past few years lay completely outside its risk management framework. For example, it lost around \$100 million when an irreplaceable performer in the main show was maimed by his tiger. In other words, even casinos are not pure casino worlds.

A third objection to my proposed definition is that it makes no reference to the concept of risk appetite. Again, I think this is an advantage rather than a defect. Risk intelligence is a cognitive capacity, a purely intellectual ability to estimate probabilities accurately. It involves gauging the extent of one's knowledge on a given topic, and can be objectively assessed to distinguish between those with high risk intelligence and those with low RQ. Risk *appetite*, on the other hand, is an emotional trait. It has to do with preferences. Some people enjoy taking on

risk, and other people avoid risk like the plague; some people are willing to expose themselves to danger, while others prefer to shield themselves from as many losses as possible. Unlike risk intelligence, there's no right or wrong about risk appetite; it's just a matter of taste.

## Measuring Risk Intelligence

---

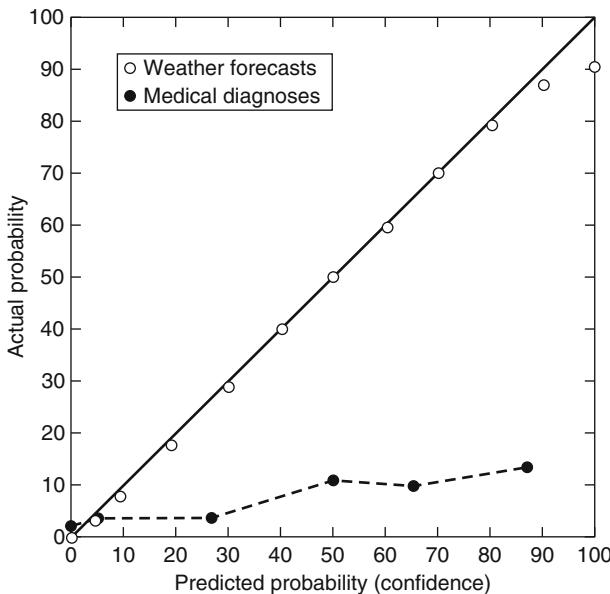

How do we judge the accuracy of probability estimates? One way is to compare subjective probability estimates to objective statistics. For example, one can ask people to estimate the probability of death from various causes for some particular demographic group, and compare these estimates to the mortality data. This method is restricted, of course, to subject areas for which data are readily available.

Another way to measure a person's ability to provide accurate probability estimates is calibration testing (Lichtenstein et al. 1982). This involves collecting many probability estimates about statements whose correct answer is known or will shortly be known to the experimenter, and plotting the proportion of correct answers against the subjective estimates. For example, suppose that every day you estimate the probability that it will rain in your neighborhood the following day, and then you note whether or not it did, in fact, rain on each day. To simplify things a little, let us assume that you can only choose from a discrete set of probability values, such as 0, 0.1, 0.2, etc. Over the course of a year, you collect 365 estimates, for each of which you have also indicated whether it did, in fact, rain or not. Suppose that you estimated the chance of rain as 0 on 15 days. If you are well calibrated, it should have rained on none of those days. Again, if there were 20 days which you assigned a 0.1 probability of rainfall, it will have rained on 2 of those days if you are well calibrated. Perfect calibration, in other words, would be shown by all points falling on the identity line.

The nice thing about this method is that, unlike comparing subjective estimates to objective statistics, it does not take objective probabilities to be conceptually prior. Throughout this chapter, I use numerical probabilities to express degrees of belief – or, to put it another way, to quantify subjective uncertainty. For the sake of fairness, however, I should point out that this is a minority view. A rival school of thought holds that numerical probabilities refer to objective facts about the world, namely, long run frequencies. According to this view, the statement that “there is a 50% chance of this coin landing on heads” does not have anything to do with anyone’s beliefs; rather, it means that, in the long run, the coin will land heads up on half of all the times it is tossed.

These two schools of thought are happy to use the same mathematical tools; the probability calculus is uncontroversial. They differ only in their interpretation of what the math means. The subjectivist school is the older one; when Jacob Bernoulli first showed how any probability could be represented as a number, it was degrees of belief that he had in mind. During the twentieth century, however, the frequentist approach became more popular, and this is now the dominant view. For reasons I do not have time to go into here, I think the frequentist view is fundamentally flawed.

According to the subjectivist view, there is no such thing as a “true” probability, in the sense of some objective fact existing out there in the world; probabilities are just numerical expressions of our subjective degree of belief. I suppose a subjectivist could say that a probability estimate is “true” when it accurately expresses the strength of one’s conviction – indeed, that is a vital aspect of risk intelligence – but that is a far cry from the frequentist view of probabilities as facts.

**Fig. 23.1**

Calibration curves for US weather forecasters and for doctors. (Data are from Murphy and Winkler 1977 and Christensen-Szalanski and Bushyhead 1981)

Calibration tests might be seen as incorporating something of the frequentist approach, in the sense that they plot probability estimates (subjective probabilities) against the proportion of correct predictions (an objective measure). But the proportion of correct predictions is not the same thing an “objective probability.” So while I sometimes talk loosely of “making accurate probability estimates,” strictly speaking this phrase is incoherent. The accuracy of an estimate can only be measured by comparing it to some objective fact, and such facts do not exist in the case of probabilities. This is why experts who study risk intelligence usually prefer to speak of “well-calibrated” probability estimates rather than of accurate ones.

Nobody is perfectly calibrated, but as you can see from [Fig. 23.1](#), US weather forecasters are pretty close. However, as the same figure also shows, doctors are very badly calibrated.

The doctors whose data are shown in [Fig. 23.1](#) were asked estimate the probability that real patients had pneumonia after taking a medical history and completing a physical examination. When these doctors estimated that there was about a 5% chance that a patient had pneumonia, they were about right. But only about 15% of the patients to whom these doctors assigned a 90% chance of pneumonia turned out to have the disease. In other words, these doctors had much more faith in the accuracy of their diagnoses than was justified by the evidence.

## The Distribution of Risk Intelligence in the General Population

Between 1960 and 1980, psychologists measured the calibration of many specific groups, such as medics (Christensen-Szalanski and Bushyhead 1981) and weather forecasters (Murphy and

Winkler 1977), but did not gather extensive data on the calibration of the general public (the data from these two groups are shown in Fig. 23.1, above). In their survey of the research up to 1980, Lichtenstein and colleagues report studies of hospital patients, psychologists, military personnel, engineering students, and other groups, but no large cross-sectional studies of the general population (Lichtenstein et al. 1982). One reason for this was no doubt because the testing was done with pen and paper, which made data collection and processing a time-consuming process. It appears that interest in calibration testing began to decline after 1980, and has not progressed much since then. This area of research is ripe for revival, especially now that the Internet allows testing and data collection to be automated.

In this section I present data from calibration tests of over 6,000 people of all ages and from a wide variety of countries. I was able to collect such a large amount of data by using an online calibration test rather than a pencil-and-paper version.

In December 2009 my co-investigator Benjamin Jakobus and I created an online calibration test (<http://www.projectionpoint.com>), and promoted the site through press releases, media interviews, blogs, and Internet discussion forums. The test consisted of 50 statements (see Appendix), below each of which were 11 buttons indicating percentage values ranging from 0 to 100 in increments of ten. Visitors to the site were instructed to indicate how likely they thought it was that each statement was true according to the following rules:

- If you are absolutely sure that a statement is true, you should click on the button marked 100%.
- If you are completely convinced that a statement is false, you should click on the button marked 0%.
- If you have no idea at all whether it is true or false, you should click on the button marked 50%.
- If you are fairly sure that it is true, but you are not completely sure, you should click on 60%, or 70%, or 80%, or 90%, depending on how sure you are.
- If you are fairly sure that it is false, but you are not completely sure, you should click on 40%, or 30%, or 20%, or 10%, depending on how sure you are.

After participants had answered all 50 questions in the test, they were asked if they would like to take part in our study. If they declined, they were given their test results, and then their data were deleted from the server. If they agreed, they were asked to specify the following demographic details: gender, nationality, age, highest level of academic education, and profession. They were then given their test results.

The test results were calculated as follows. First, all the times that the participant assigned a likelihood of 0% to a statement were counted, and then we counted how many of those statements were actually true. We proceeded in the same way for each of the other likelihoods and plotted each data point on a graph with the probability estimates on the  $x$ -axis and the proportion of correct answers in each category on the  $y$ -axis. We always plotted the points for the categories of 0% and 100% (if a participant never used the 100% category, we plotted that as 100% correct), but we only plotted points for the other categories if the participant had used them at least three times. We then connected the points by a continuous line. This line is henceforth referred to as the participant's calibration curve.

As already noted, a perfect calibration curve would lie on the identity line  $x = y$ . The further away from that diagonal line the curve lies, the poorer the calibration is. We created a simple index of a participant's calibration by calculating the area between their calibration curve and

the identity line and scaling the result to a number between 0 and 100, where 100 = perfect calibration (i.e., this number is inversely proportional to the size of the area between the calibration curve and the identity line). Henceforth we refer to this number as the “RQ score.”

We chose to use this measure, rather than using the better-known Brier score (Brier 1950) for three reasons. Firstly, our approach is much easier to understand for a lay audience. Secondly, we find some of the statistical properties of the Brier score to be unsatisfactory. Suppose a person chooses  $p_i$  for  $n_i$  questions, of which  $k_i$  are correct. The Brier score would yield  $(p_i - k_i/n_i)^2$ , which implies that it is irrelevant whether  $k_i = 1$  and  $n_i = 2$  or  $k_i = 1,000$  and  $n_i = 2,000$ . We object to this because we believe that the scores should be weighted by the number of answers. We could remedy this by adjusting the Brier score as follows:  $n_i \times (p_i - k_i/n_i)^2$  (Aaron Brown, personal communication), but again we prefer a simpler approach. Finally, the Brier score is a composite measure of calibration, resolution, and knowledge (Murphy 1973), whereas we wish to measure only calibration.

Some people realize fairly quickly that there is an easy way to game this test. If a participant always selects the 50% category – and if the test contains equal numbers of true and false statements – they will obtain an RQ score of 100. The high score generated by this strategy does not reflect good calibration, however, so to remedy this we created a second indicator which we call the “K factor” (for Keynes and Keats). To calculate the K factor, each time that a participant uses the categories 10%, 20%, 30%, 40%, 60%, 70%, 80%, or 90%, they get one point. When they use 0%, 50%, or 100% they get zero. The maximum K factor is therefore 50 for a fifty-question test. The K factor gives an indication of how reliable a participant’s RQ score is as an indicator of their calibration.

Between December 10, 2009, and February 6, 2010, a total of 21,910 people visited the web site, of whom 10,187 took the online calibration test and gave us permission to use their data in our research. We removed all participants with an RQ score of 0 ( $N = 30$ ) on the grounds that this was probably due to error. We then removed all those with a K score of less than 10 ( $N = 3,295$ ) on the grounds that in such cases the RQ score would not be a good indicator of calibration. We then removed all those who did not specify their gender ( $N = 154$ ) or their educational achievement ( $N = 10$ ). After these adjustments, a total of 6,698 participants remained in our sample.  [Table 23.1](#) shows the composition of this sample by gender and educational achievement.

The participants’ ages ranged from under 10 to over 80, though most participants were aged either 21–30 ( $N = 2,242$ ) or 31–40 ( $N = 1,852$ ). Participants came from every continent,

 **Table 23.1**  
**Composition of the sample by gender and educational achievement**

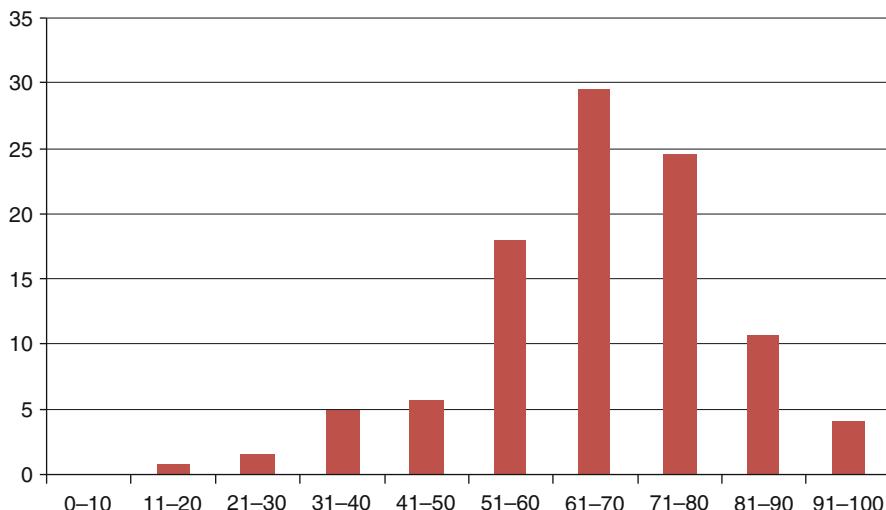

Education	Men	Women	Total
Primary or less	37	10	47
Secondary	974	223	1,197
First degree	2,617	675	3,292
Masters	1,113	338	1,451
Ph.D.	567	144	711
Total	5,308	1,390	6,698

with over 20 nationalities, with the most well-represented countries being (in order): the USA ( $N = 2,633$ ), the UK ( $N = 1,118$ ), Ireland ( $N = 1,023$ ), Canada ( $N = 402$ ), Australia ( $N = 343$ ), and Germany ( $N = 188$ ).

The mean RRQ score for the sample of 6,698 was 65.02. ► *Figure 23.2* shows the distribution of RQ scores in this sample.

As shown in ► *Table 23.2*, the mean RQ score of the men in our sample was significantly higher than the mean RQ score of the women (two-tailed  $t$ -test for independent samples, not assuming equal variance,  $p < .0001$ ; similar results were found with a Mann–Whitney rank sum test). When analyzed according to educational achievement, however, the difference between the mean RQ scores of the men and women in our sample is only significant in those whose highest level of educational achievement is a first degree or masters. As the graph in ► *Fig. 23.3* makes clearer, education seems to make little or no difference to the calibration of women until they achieve a Ph.D., while every increase in educational achievement seems to improve calibration in men. It is this “education effect” that explains the higher mean RQ score of men in our sample, since it contains a high proportion of people whose highest level of educational achievement is a first degree or masters (70.7%). It is only at this level of achievement that the education effect produces a clear difference in calibration between men and women. Something about university education seems to boost calibration in men to levels significantly higher than those in women, and this gap only closes when people have attained the highest level of educational achievement – the Ph.D.

Previous studies have not found differences in calibration between men and women (Lichtenstein and Fischhoff 1981) or between people with different levels of education (Lichtenstein and Fischhoff 1977). However, this may be due to the fact that most studies have typically involved fewer than 200 participants, and participants have generally been required to provide a smaller number of probability estimates – both of which have severely

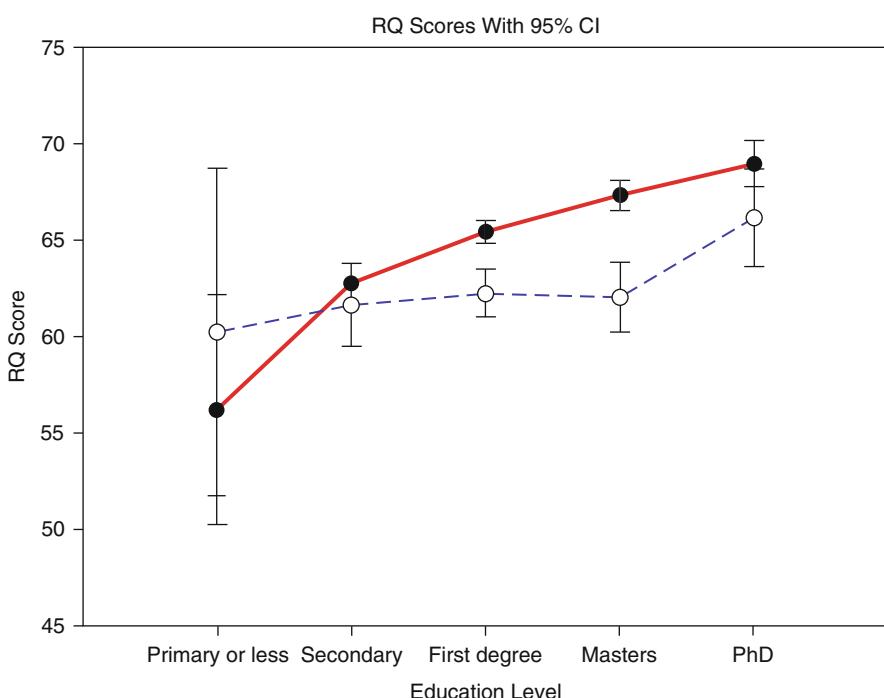

► **Fig. 23.2**

The distribution of RQ scores in the sample of 6,698 people reported here. The x-axis shows the RQ score, and the y-axis the percentage of the sample in each category

**Table 23.2**Mean RQ scores by gender and educational achievement (\*=significant at  $p < .05$ )

Education	Men		Women		Standard error difference	95% CI of the difference		<i>p</i>

**Fig. 23.3**

Effect of education on calibration in men and women (dashed line=women)

limited the capacity of previous research to detect individual differences with a high enough degree of statistical significance. Our sample of 6,698 people, in which each participant provided 50 probability estimates, provides a dataset which is an order of magnitude larger than any previous study, and this may have permitted us to detect patterns which were previously invisible.

## The Dunning–Kruger Effect

---

Calibration tests measure the extent to which one is able to gauge how much one knows, not knowledge per se. The extent of one's knowledge should, therefore, make no difference to one's score on a calibration test, and empirical research seems to bear this out (Lichtenstein and Fischhoff 1977). If education improves calibration in men, as it seems to, this effect must therefore be due to something other than the greater knowledge that greater education typically bestows. A possible candidate for this other factor is enhanced metacognition. Metacognition refers to “the ability to know how well one is performing, when one is likely to be accurate in judgment, and when one is likely to be in error” (Kruger and Dunning 1999). Kruger and Dunning (1999) have argued that the skills that engender competence in a domain are often the very same skills necessary to *evaluate* competence – including one's own competence – in that domain. Education may therefore make people not only more knowledgeable, but also more aware of the limits of their knowledge. Contrary to what Lichtenstein and Fischhoff (1977) concluded, then, it does appear that “those who know more also know more about how much they know,” but as Fig. 23.3 shows, this dictum seems to apply more to men than to women. Conversely, as Charles Darwin noted, “ignorance more frequently begets confidence than does knowledge” (Darwin 1871).

If education has this effect in men, why does it not also have this effect in women? I confess that I am at a loss to explain this apparent sex difference. In the rest of this section, I will limit myself to some general remarks about the Dunning–Kruger effect and risk intelligence in both sexes.

Like the Roman god Janus, risk intelligence has two faces looking in opposite directions. One looks outward at the external world, and attempts to gather objective data that will throw light on the matter at hand. The other looks inward and attempts to assess how much relevant knowledge one really has. Good probability estimates require that both faces see clearly – in other words, risk intelligence requires both objective and subjective knowledge (cognition and metacognition).

To change the metaphor, picture your mind as a light bulb shining in an otherwise darkened room. Some nearby objects are fully illuminated; you can see them in every detail, present and identifiable. These are the things you know very well – the names of your friends, what you had for breakfast this morning, how many sides a triangle has, and so on. The objects on the other side of the room are completely shrouded in darkness. These are the things about which you know nothing – the five thousandth digit of pi, the composition of dark matter, or King Nebuchadnezzar's favorite color. Between the light and the darkness, however, lies a gray area in which the level of illumination gradually shades away. In this twilight zone, the objects are not fully illuminated, but neither are they completely invisible. You know something about these things, but your knowledge is patchy and incomplete – the law of the land (unless you are a lawyer), the evidence for climate change (unless you are a climatologist), and the causes of the

credit crunch (even economists are still arguing about this). Risk intelligence involves gauging exactly how illuminated the objects in this twilight zone really are.

Nothing in our education system or our culture prepares us to operate in the twilight zone. If we are cautious, we relegate everything beyond the zone of complete illumination to complete obscurity, not daring to venture an opinion on things of which we do, in fact, have some inkling. If we are overconfident, we do the opposite, expressing views about things in the twilight zone with more conviction than is justified. It is hard to steer between these two extremes; daring to speculate, but with prudence. Yet that is what risk intelligence is all about.

This is why calibration tests which require users to estimate the likelihood of general knowledge statements are a perfectly acceptable way to measure risk intelligence. When putting a probability value on these statements, one is required to weigh up all the relevant evidence that one possesses and gauge one's true level of uncertainty on the matter. There is no reason to restrict the content of these statements to threats, dangers, and other concepts generally associated with the vernacular view of risk.

Nor should it matter if a calibration test is dominated by questions that refer to a particular area of knowledge or a particular part of the world. A number of people in the study reported in section ➤ [The Distribution of Risk Intelligence in the General Population](#) complained that they thought the test had a “US bias.” However, since the test measures how well one is able to gauge how much one knows, rather than knowledge per se, any such bias is irrelevant.

Of course, if a calibration test contained too many questions about which a user knew absolutely nothing, and which the user should therefore use the 50% category many times, the result would not be an accurate measure of the person’s level of risk intelligence. To provide a good measure of risk intelligence, it is necessary to gather probability estimates across the whole range of possible values from 0% to 100%. This is what the K-factor described in section ➤ [The Distribution of Risk Intelligence in the General Population](#) was intended to capture.

## Why Is Risk Intelligence Important?

---

The doctors whose data are graphed in ➤ [Fig. 23.1](#) were extremely overconfident in their diagnoses. When a patient had a 15% chance of having pneumonia, they would give them a 90% chance. That meant they were likely to recommend more tests than were strictly necessary, prescribe more treatments than were warranted, and cause their patients needless worry.

It is not always true to say “better safe than sorry,” either. Some tests are invasive and painful, and there are many cases where the treatment prescribed for an ailment that is not present can be harmful to the patient. It is always better to make a choice on the basis of accurate information than the basis of error, no matter what the context. And the data clearly show that these diagnoses are full of error.

Doctors are not the only professionals who require good risk intelligence. Finance professionals are also required to estimate probabilities as a regular part of their work. Yet as the recent financial crisis has shown us, bankers and those who work at credit rating agencies can make basic errors when assessing the likelihood of certain outcomes. What would happen if trading desks implemented some kind of regular calibration testing, or if a requirement for calibration training were incorporated into new financial regulations? The Basel Committee on Banking Supervision, which formulates broad supervisory standards for financial

institutions around the world, is currently working on a new update to the Basel Accords. Basel II required numerical assessments of both the probability of default and the expected loss given default, and it specifically forbade relying on rating agency assessments to estimate these, but these estimates were typically produced by computer models. What if future rounds of the Basel Accords were to include some provision for testing risk intelligence? The head of a prop desk in a bank, for example, could ask each trader to estimate the probability that each trade will make a profit and keep track of each trader's calibration.

The commitment, detection, and investigation of crime also offer many opportunities for the exercise of risk intelligence. For example, when police officers question suspects, they must judge whether the responses they receive are truthful or not. It is rarely the case that such judgments are clear cut; more typically, the officer has some index of suspicion which lies somewhere between complete confidence and absolute distrust. In other words, the question of whether a suspect is lying usually demands a probability estimate rather than a simple yes or no. As with all probability estimates, their accuracy may be measured by means of a calibration test when the true answers are known. Psychologists have carried out many such tests, and the results all point to the same conclusion; police officers and other professional investigators are all massively overconfident about their ability to discern lies. Although they are convinced they can spot deception, their real ability to sift fact from fiction is scarcely better than flipping a coin. One reason for this is that most police officers look at the wrong signals; shifty eyes, for example, are not a good signal of deception, and yet it is one that many investigators rely on. This has serious consequences for the criminal justice system, and law enforcement officials should therefore be trained in risk intelligence if we are to reduce miscarriages of justice.

High levels of risk intelligence will also be required among the general population if we are to deal effectively with any of the big challenges that humanity faces in the twenty-first century. Climate change is a case in point. Nobody knows precisely how increasing levels of greenhouse gasses in the atmosphere will affect the climate in different regions around the globe. The Intergovernmental Panel on Climate Change (IPCC) does not make definite predictions; instead, it sets out a variety of possible scenarios and attaches different probabilities to them to indicate the level of uncertainty associated with each one. Knowing how to make sense of this information is crucial if we are to allocate resources sensibly to the various alternative solutions, from carbon trading schemes to the development of alternative energy sources, or even planetary-scale geo-engineering. How can citizens make informed decisions about such matters if they are not equipped to think clearly about risk and uncertainty? Too often, the public figures who take opposite views about climate change make exaggerated claims which convey greater certainty than is warranted by the evidence. Critics dismiss the claims of the IPCC out of hand, while believers in climate change proselytize with equal dogmatism. Both kinds of exaggeration seriously hamper informed debate; the latter kind also terrifies kids. One survey of 500 American preteens found that one in three children between the ages of 6 and 11 feared that the earth would not exist when they reached adulthood because of global warming and other environmental threats (Lomborg 2009). We see the same pattern in the UK, where a survey showed that half of young children aged between seven and eleven are anxious about the effects of global warming, often losing sleep because of their concern. Without the tools to understand the uncertainty surrounding the future of our climate, we are left with a choice between two equally stupid alternatives – ignorant bliss or fearful paralysis.

## Methods for Increasing Risk Intelligence

---

Leading medical schools around the world are beginning to wake up to the problem of low risk intelligence among doctors. Something called “confidence-based assessment” is increasingly being used in these schools. In this form of assessment, students must not only give the right answer, but also assess the confidence with which they give each answer. If a student gives the wrong answer confidently, that receives the worst possible grade; if they give the wrong answer but are not confident, then they get a better grade; giving the right answer but without confidence is OK, but not ideal, as in reality it could end up with them wasting time having to consult others; and the best answer is that which is correct and made with confidence. This form of assessment is intended to help students know when to consult others (or text books etc) and when to act independently.

All well and good, but how do you prepare students for this kind of test? Nothing in our current repertoire of educational tools and methods seems well designed to equip someone with the skills to be confident when justified but doubtful when necessary. In medical schools in particular, doubt has often been perceived as a sign of weakness.

The same could be said of the financial sector, where similar macho attitudes played no small part in stoking the bubble that burst in late 2007. What if the bankers who were making all those dubious loans in the preceding decade had undergone regular calibration testing, of the sort described here? It is an interesting thought.

The fact that weather forecasters are so much better calibrated than doctors suggests that one's level of risk intelligence is not relatively fixed like IQ, but susceptible to improvement given the right conditions. Sarah Lichtenstein, an expert in the field of calibration testing, speculates that several conditions favor the weather forecasters (Lichtenstein et al. 1982). First, they have been expressing their forecasts in terms of numerical probability estimates for many years; since 1965, US National Weather forecasters have been required to say not just whether or not it will rain the next day, but how likely they think this is in actual percentage terms. They have got used to putting numbers on such things, and as a result are better at it. Doctors, on the other hand, are under no such obligations. They remain free to be as vague as they like.

Second, the task for weather forecasters is repetitive. The question to be answered (“Will it rain?”) is always the same. Doctors, however, must consider all sorts of different questions every day: “Does he have a broken rib?” “Is this growth malignant?” “How will she respond to a different type of antidepressant?”

Finally, the feedback for weather forecasters is well defined and promptly received. This is not always true for doctors. Patients may not come back, or may be referred elsewhere. Diagnoses may remain uncertain. Most theories of learning emphasize the need for rapid feedback; the longer the delay between an action (or, in this case, a prediction) and a corrective signal, the lower the chance that the later information will enable the recipient to profit from it.

These speculations could assist the development of tools to enhance risk intelligence. First, such tools should accustom users to specifying probability estimates in numerical terms. Second, they should focus on a relatively narrow area of expertise, if possible. Thirdly, these tools should provide the user with prompt and well-defined feedback. Regular calibration testing might fulfill all three of these requirements, though training assessors by giving them feedback about their calibration has shown mixed results. It should be pointed out however, that only a few studies have been carried out in this area, and they are now several decades old. More research is needed before we can reach a definitive verdict on the value of this method.

Another approach to improving calibration involves requiring people to think of reasons why they might be wrong. In one study, subjects took two calibration tests similar to the one described in section [The Distribution of Risk Intelligence in the General Population](#). In the second test, one group was asked to write down a reason supporting each of their answers, another group was asked to write down a reason contradicting each answer, and a third group wrote down two reasons, one supporting and one contradicting. Only the group asked to write down contradicting reasons showed improved calibration in the second test. This suggests that one partial remedy for overconfidence is to search for reasons why one might be wrong (Koriat et al. 1980).

## Further Research

---

As already noted, it appears that interest in calibration testing began to decline after 1980, and research in this area has not progressed much since then. I believe this area is ripe for revival, especially now that the Internet allows testing and data collection to be automated. The study reported in section [The Distribution of Risk Intelligence in the General Population](#) is ongoing, and a further 25,000 people have taken the online calibration test between the date when the dataset reported there was collected and the present time of writing (April 2011), bringing the total sample size to over 35,000 participants so far. Analysis of this growing dataset is ongoing, and further features are being added to the calibration test, including the measurement of time taken to complete the task.

In a study of horse handicappers, Steven Ceci and Jeffrey Liker found that handicapping expertise had zero correlation with IQ (Ceci and Liker 1986). IQ is the best single measure of intelligence that psychologists have, because it correlates with so many cognitive capacities. Indeed, it is this very correlation that underpins the concept of “general intelligence.” The discovery that expertise in handicapping does not correlate at all with IQ means that, whatever cognitive capacities are involved in estimating the odds of a horse winning a race may be, they are not a part of general intelligence. Or, to put it the other way round, IQ is unrelated to some real-world forms of cognitive complexity that are clear-cut cases of intelligence.

Of course, not everyone is comfortable with blanket terms like “general intelligence.” One of its most high-profile critics, the psychologist Howard Gardner, prefers to conceive of intelligence as consisting of multiple, special-purpose skill sets (Gardner 1983). It was Ceci and Liker’s paper that first led me to wonder if the ability to estimate probabilities accurately, and make wise decisions under uncertainty, might constitute a special kind of intelligence to be added to Gardner’s list.

Gardner identifies eight different kinds of intelligence: bodily-kinesthetic, interpersonal, verbal-linguistic, logical-mathematical, naturalistic, intrapersonal, visual-spatial, and musical. None of these involves an ability to estimate probabilities accurately, and yet the study of Ceci and Liker shows that this is a complex cognitive skill that some people are very good at, and this suggests that it could constitute a ninth kind of intelligence that Gardner had not considered.

To clinch this argument, I would have to show that risk intelligence is typically implemented in the brain by a specific set of neural pathways, for Gardner’s framework restricts intelligences to cognitive capacities that can be localized neurologically. Linguistic intelligence, for example, is rooted in certain structures in the brain’s left hemisphere. I believe that recent

neuroscience imaging studies would also support a distinct neural architecture for risk assessment, but further research is needed to confirm this.

High risk intelligence is rare. Fifty years of research in the psychology of judgment and decision-making shows that most people are not very good at thinking clearly about risky choices. They often disregard probability entirely, and even when they do take probability into account, they make many errors when estimating it. Like most psychologists, I had assumed that these patterns of bias were universal – until I read the paper by Ceci and Liker. These two young psychologists seemed to have stumbled on a rare breed of individuals who had somehow escaped the influence of the well-known cognitive biases that affect most peoples' ability to judge risk – expert gamblers.

As has already been noted, it appears that US weather forecasters form another group with unusually high levels of risk intelligence (Murphy and Winkler 1977). Further research might identify yet more such groups. For example, finance professionals are probably too diverse and heterogeneous to constitute such a group, but there may be particular kinds of finance professional who display higher than average risk intelligence. I suspect that hedge fund principals may be one such subgroup.

Risk intelligence differs utterly from what we normally consider intelligence to be – which is why, when we get it wrong – when banks fail, doctors misdiagnose, and weapons of mass destruction turn out not to exist in a country we have invaded – we are in such a bad position to understand the reasons. We need gamblers and weather forecasters – because we can learn an enormous amount from them, not just about money and rainfall, but about the way we make decisions in all aspects of our lives.

## Appendix

---

The 50 true/false statements in the online calibration test were as follows:

A one followed by 100 zeros is a Googol	T
Africa is the largest continent	F
Alzheimer's accounts for under half the cases of dementia in the USA	F
An improper fraction is always less than 1	F
Armenia shares a common border with Russia	F
There have been over 40 US Presidents	T
In 1994, Bill Clinton was accused of sexual harassment by a woman called Paula Jones	T
Canberra is the capital of Australia	T
Cats are not mentioned in the Bible	T
Christianity became the official religion of the Roman empire in the third century AD	F
Commodore Matthew Perry compelled the opening of Japan to the West with the Convention of Kanagawa in 1870	F
El Salvador does not have a coastline on the Caribbean	T
Gout is known as "the royal disease"	F
Harry Potter and the Goblet of Fire tells the story of Harry Potter's third year at Hogwarts	F

Humphrey Bogart had two wives before Lauren Bacall	F
In 2008 the population of Beijing was over 20 million people	F
In the Old Testament, Jezebel's husband was Ahab, King of Israel	T
Iron accounts for over 30% of the Earth's composition	T
It is possible to lead a cow upstairs but not downstairs, because a cow's knees cannot bend properly to walk back down	T
Lehman Brothers went bankrupt in September 2008	T
LL Cool J got his name from the observation "Ladies Love Cool James"	T
Male gymnasts refer to the pommel horse as "the pig"	T
Mao Zedong declared the founding of the People's Republic of China in 1949	T
More than 10 American states let citizens smoke marijuana for medical reasons	T
More than 8 out of 10 victims infected by the Ebola virus will die in 2 days	T
Most of the terrorists who carried out the attacks on 9/11 were from Saudi Arabia	T
Mozart composed over 1,000 works	F
Natural gas has an odor	F
Of all Arab nations, Lebanon has the highest percentage of Christians	T
Over 40% of all deaths from natural disasters from 1945 to 1986 were caused by earthquakes	T
Over 50% of Nigeria's population lives on less than \$1 per day	T
Stalagmites grow down, and stalactites grow up	F
The Italian musical term adagio means that the music should be played quickly	F
The Euphrates river runs through Baghdad	F
The face on a \$100,000 bill is that of Woodrow Wilson	T
The Islamic Resistance Movement is better known to Palestinians as Hizbollah	F
The Japanese were largely responsible for building most of the early railways in the US West	F
The last Inca emperor was Montezuma	F
The most frequently diagnosed cancer in men is prostate cancer	T
The only stringed symphonic instrument that has a pedestal and a crown is a double bass	F
The president of Russia is Vladimir Putin	F
The San Andreas Fault forms the tectonic boundary between the Pacific Plate and the North American Plate.	T
The US civil war broke out the same year the federal government first printed paper money	T
The US Declaration of Independence begins: "We the People of the United States..."	F
The word "robot" was coined by the American science fiction writer, Isaac Asimov	F
The world's highest island mountain is Mauna Kea	T
The Taj Mahal was built by Emperor Shah Jahan in memory of his favorite wife	T
There are more people in the world than chickens	F
There are no diamond fields in South America	F
Wikipedia was launched in 1999 by Jimmy Wales and Larry Sanger	F
Number of True Statements	25

**Abstract:** Policy makers, health professionals, and patients have to understand health statistics to make informed medical decisions. However, health messages often follow a persuasive rather than an informative approach and undermine the idea of informed decision making. The current practice of health risk communication is often biased: Risks are communicated one sided and in nontransparent formats. Thereby, patients are misinformed and misled. Despite the fact that the public is often described as lacking basic statistical literacy skills, statistics can be presented in a way that facilitates understanding. In this chapter, we discuss how transparent risk communication can contribute to informed patients and how transparency can be achieved. Transparency requires formats that are easy to understand and present the facts objectively. For instance, using statistical evidence instead of narrative evidence helps patients to better assess and evaluate risks. Similarly, verbal probability estimates (e.g., “probable,” “rare”) usually result in incorrect interpretations of the underlying risk in contrast to numerical probability estimates (e.g., “20%,” “0.1”). Furthermore, we will explain and discuss four formats – relative risks, conditional probabilities, 5-year survival rates, and single-event probabilities – that often confuse people, and propose alternative formats – absolute risks, natural frequencies, annual mortality rates, and frequency statements – that increase transparency. Although research about graphs is still in its infancy, we discuss graphical visualizations as a promising tool to overcome low statistical literacy. A further challenge in risk communication is the communication of uncertainty. Evidence about medical treatments is often limited and conflicting, and the question arises how health professionals and laypeople deal with uncertainty. Finally, we propose further research to implement the concepts of transparency in risk communication.

## Introduction

---

Understanding health statistics is one basic prerequisite for making health decisions. Policy makers evaluate health statistics when implementing health programs, insurance companies assess the cost-effectiveness of health interventions, and doctors and patients need to know the chances of harms and benefits of different treatment alternatives. The channels available to inform decision makers about risks are manifold, and so are the ways risks can be framed. A widespread phenomenon is what we call biased reporting in risk communication. By biased, we mean two things: First, information is incomplete and one sided. For instance, benefits of a health treatment are reported, while drawbacks are omitted. Second, the continuous use of nontransparent and incomprehensible risk communication formats misleads decision makers. In this chapter, we discuss the interaction between the fact that most people have difficulties with statistical information and the way health risks can be represented. The chapter is organized as follows:

1. *What constitutes “good” risk communication?* We start this chapter by discussing the objective of risk communication.
2. *Current practice in health risk communication.* We describe current drawbacks in the practice of risk communication.
3. *How good are experts and laypeople at dealing with risks and uncertainties?* We present evidence about the public’s problems in adequately interpreting statistical information.
4. *The role of numbers and words in risk communication.* We discuss the role of narrative and verbal information, in comparison to statistical information.

5. *Transparent risk communication: How to overcome statistical illiteracy and innumeracy.* We present alternative formats that improve statistical comprehension, in contrast to those frequently used in practice.
6. *Further research.* We point out important directions for future research to make our society more risk literate.

## What Constitutes “Good” Risk Communication?

---

Of central importance, but at the same time the subject of much controversy, is the issue of what the goal of risk communication ought to be. To put it differently, what is the standard by which risk communication should be evaluated? There are at least two different perspectives a communicator can adopt: one is persuasive, the other informative (or educative). Despite commonalities between these two perspectives, there is an area of tension resulting from the different objectives each of the views follows. Let us first discuss persuasion.

The press release of the first European Randomized Study of Screening for Prostate Cancer (ERSPC) stated, “Screening for prostate cancer can reduce deaths by 20%. ERSPC is the world’s largest prostate cancer screening study and provides robust, independently audited evidence, for the first time, of the effect of screening on prostate cancer mortality” (Wilde 2009). This news was celebrated as a successful demonstration of the benefits of prostate-specific antigen (PSA) screening. Based on this statement, policy makers and doctors could argue for regular PSA tests, and men might express their willingness to participate in the screening program. However, the actual benefits of screening for prostate cancer with PSA tests are not as clear as they seem, as we will demonstrate later in this chapter. Similarly, health advertisements usually promote behavioral change. For example, an advertisement for screening for vascular diseases appeals with the admonition, “Don’t be a victim” (see Gigerenzer et al. 2007).

More extreme attempts to change people’s attitudes and intentions are fear appeals (for a meta-analysis, see Witte and Allen 2000). For instance, antitobacco campaigns show pictures of smokers’ lungs or mouth cancer to demonstrate the consequences of smoking. The aim of fear appeals is less to educate the public about health interventions than to promote and encourage health behavior change. Frosch et al. (2007) evaluated health advertisements and found that the vast majority of those aired on TV made emotional appeals, and only about one-fourth gave explicit information about risk factors, prevalence, and condition causes. These campaigns are not solely run by the pharmaceutical industry, but also by health authorities and health associations. The term “social marketing” has been coined to describe the application of “marketing principles and techniques to create, communicate and deliver value in order to influence target audience behaviors that benefit society (public health, safety, the environment, and community development) as well as the target audience” (Kotler and Lee 2007, p. 7).

The underlying assumption of the persuasive approach is that people’s motivation and ability to engage in health decisions is rather low in the first place and hence deviate from a “normative” standard – however that might be defined. From this point of view, the key measure for successful risk communication is behavioral change that is reflected in more favorable attitudes toward health (prevention) programs, higher intentions to participate, and finally higher attendance rates.

The alternative perspective – that is, the informative approach – begins with the assumption that people are able to take responsibility for their health and make individual and

informed health decisions. A decision per se is not right or wrong – it always depends on the patient's personal preferences, values, and needs. Some patients prefer watchful waiting to invasive treatments; others prefer rapid treatment of abnormalities. Some patients accept severe side effects of treatments if the benefit is high, while others do not. For instance, it has been reported that patients are willing to accept higher risks of severe side effects than their physicians (Heesen et al. 2010). The concept of health communication as information is related to the paradigm shift from the classic notion of a paternalistic doctor–patient relationship to one of shared decision making and informed consent – a mutual, interactive process between the doctor and the patient, who jointly make health decisions (e.g., Edwards and Elwyn 2009). With this in mind, the main evaluation principles in risk communication should be transparency and (gained) knowledge. Risk communication requires comprehensible, unbiased, and complete information to educate doctors and patients and provide a basis for shared decision making. Informed decisions require facts about etiological factors, epidemiological data, treatment benefits and side effects, uncertainties, and potential costs. Without knowing the risk of developing a particular disease, the chance that a treatment will lead to success, or the risk of side effects, neither policy makers nor doctors and patients can effectively make informed health decisions.

We consider ourselves proponents of the latter approach and argue that the major objective of risk communication should be informing and educating rather than persuading. However, we do not aim at discussing the “persuasion” approach.

An example contrasting the two different approaches in risk communication is given in Fig. 24.1. While the flyer “mammograms save lives” encourages women to participate in mammography screening and convey an illusion of certainty (“mammograms save lives – there's no doubt about it (...) Hope for a cancer-free future starts with you”), the facts box summarizes current scientific evidence and compares 2,000 women in a mammography group with 2,000 women not attending the screening.

## Current Practice in Health Risk Communication

Consider the following fictive example: An urologist offers a 57-year-old patient a PSA test – the previously mentioned screening test to detect early stages of prostate cancer. The patient, who has never heard of this test, says to his doctor, “Well, I don't really know. What do you think I should do?” The urologist hesitates and then answers, “I think you should do the test.” The patient agrees without knowing his baseline risk of prostate cancer or the benefits and harms of the PSA test. The patient trusts the doctor's recommendation and believes the doctor's decision was based on the best medical knowledge. However, this does not need to be true.

Doctors often practice what is called defensive decision making: They prescribe treatments that may not be best for their patients but that reduce their own risk of facing legal consequences. In our example, the doctor could have recommended not participating, because current scientific evidence does not show a benefit of PSA screening in the reduction of prostate cancer mortality (Djulbegovic et al. 2010; Sandblom et al. 2011). But even if the doctor did not believe in the efficacy of PSA screening, not urging the patient to have the test might cause trouble if the patient is later diagnosed with prostate cancer. Daniel Merenstein, an American urologist, informed his patient about the pros and cons of PSA screening, and the patient decided not to participate. Later, the patient developed prostate cancer and sued Merenstein, whose residency had to pay compensation of US\$1 million (see Gigerenzer and Gray 2011).

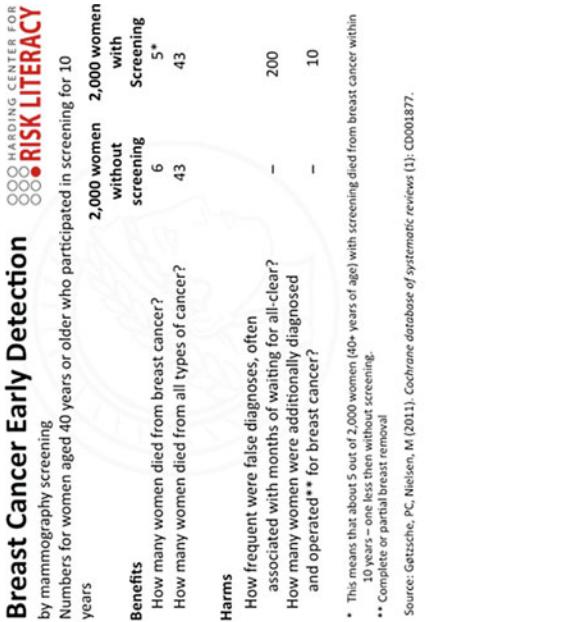

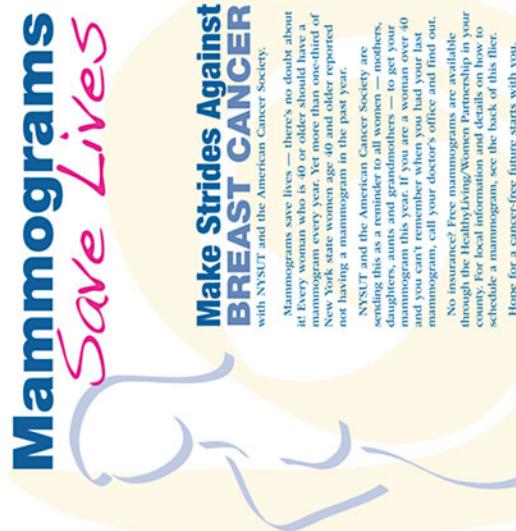

Fig. 24.1

Two different ways to inform women about mammography screening. The flier on the left side by the American Cancer Society (Retrieved from [www.nysut.org/files/makingstrides\\_070921\\_poster.pdf](http://www.nysut.org/files/makingstrides_070921_poster.pdf) in April 2011) encourages women to participate in regular mammography screening without providing information about benefits and harms of the screening program. It states that "mammograms save lives – there's no doubt about it (...) Hope for a cancer-free future starts with you." The facts box on right side (Retrieved from [www.harding-center.com/fact-boxes/](http://www.harding-center.com/fact-boxes/) in April 2011) summarizes the most important results based on the current scientific evidence and informs rather than persuades. It contrasts 2,000 women aged 40 and older who participate in mammography screening over 10 years with 2,000 of the same age who do not. Besides the benefits of the screening program, the facts box also includes information about potential harms like overtreatment

Such decisions have far-reaching consequences for doctors' behavior as well as the entire health system. For instance, many doctors in Switzerland order PSA tests for their patients but would not participate themselves (Steurer et al. 2009).

## The Seven Sins in Health Care

---

Defensive decision making is just one of seven "sins" in health care that Gigerenzer and Gray (2011) identified. They have called for the "century of the patient" to demonstrate the importance of a radical change in health policy. This change centers on fostering patients who understand health risks and who are willing to take responsibility for their own health decisions based on transparent and unbiased information. A misinformed patient is the result of the seven sins: biased funding in medical research, biased reporting in medical journals, biased reporting in pamphlets, biased reporting in the media, conflicts of interests, defensive decision making, and last but not least, doctors' lack of fundamental health literacy skills (see ➤ *Table 24.1*). Although these sins are more or less linked to each other, we will primarily address the issues of biased reporting and the lack of statistical literacy in health professionals. Surprisingly, even doctors have trouble understanding medical evidence and are prone to being deceived by statistics, as we will demonstrate later.

### Biased Reporting in the Medical Literature

To explain what is meant by biased reporting in the medical literature, let us again take the example of the press release of the European trial for PSA screening. It stated that PSA testing reduces the risk of dying from prostate cancer by 20%. What does this number mean? It means that out of every 1,410 men who regularly participated in prostate cancer screening, one less died of prostate cancer than in an equally sized group of men who did not participate (Schröder et al. 2009). Additionally, 48 of the 1,410 men were unnecessarily treated and hence subjected to potential incontinence and impotence and that overall mortality was also unaffected. Communicating risk as a 20% risk reduction or as the number of men needed to screen to save one life makes quite a difference.

Evaluations of abstracts in leading medical journals have shown that the majority of reports fail to report absolute risks in addition to relative numbers (Schwartz et al. 2006; Sedrakyan and Shih 2007; Gigerenzer et al. 2010). Another form of biased risk communication in the medical literature is mismatched framing: Benefits are presented in relative risk reduction formats and appear rather large, whereas side effects are presented in absolute terms and appear smaller. Thereby benefits are overestimated, side effects underestimated. An even more extreme way to misinform is the omission of any side effects.

### Biased Reporting in the Media and Pamphlets

In contrast to presenting deceiving numbers, many health pamphlets do not present any numbers at all. A pamphlet informing the public about the human papillomavirus (HPV) vaccine – an innovative vaccine to prevent the risk of cervical cancer – states the following: "For two years,

**Table 24.1**

**The seven sins in health care:** The table summarizes the seven factors that contribute to misinformed patients identified by Gigerenzer and Gray (2011)

The seven sins	Example
<i>Biased funding of research</i>	Out of estimated US\$160 billion spent on research and development in health in the United States, more than half was sponsored by the pharmaceutical, biotechnical, and medical technology industry (see Gigerenzer and Gray 2011)
<i>Biased reporting in medical journals</i>	Out of 222 articles published in leading medical journals between 2003 and 2004, 150 failed to report the underlying absolute risk in the abstract (see Schwartz et al. 2006)
<i>Biased reporting in health pamphlets</i>	Out of 27 pamphlets informing about breast cancer screening in Germany, only ten informed about lifetime risk of developing breast cancer, two reported about risk reduction of death from breast cancer in relative formats, two in absolute formats, and one presented number needed to treat (see Kurzenhäuser 2003)
<i>Biased reporting in the media</i>	Out of 202 German Web sites and newspaper reports informing the public about HPV vaccination, 116 reported information about baseline risk of developing cervical cancer (96 gave correct estimates); 102 out of the 202 reports reported about pros and cons of the vaccination in a balanced way. Correct estimates of risk reduction were provided in 14 articles only (see Bodemer et al. submitted)
<i>Commercial conflicts of interest</i>	After a drug has been approved, doctors are offered money for each patient they put on the drug by companies (between 10 and 1,000€ per patient in Germany). In 2008, out of 150,000 private medical practices, about 85,000 participated in such programs (see Gigerenzer and Gray 2011)
<i>Defensive medicine</i>	In Switzerland, 41% of the general practitioners and 43% of internists reported that they sometimes or often recommend PSA tests for legal reasons. In other words: They order a test for patient which they would not order for themselves (see Steurer et al. 2009)
<i>Doctor's lack of understanding health statistics</i>	Ninety-six out of 160 gynecologists overestimated the positive predictive value of mammography and 29 underestimated the value, despite the fact that all relevant information was available (see Gigerenzer et al. 2007)

young women have had the possibility to get vaccinated against HPV. Worldwide, 50 million vaccines have been administered. In Germany, the media has reported controversy about the vaccine, while doctors and scientists are convinced of the certainty and efficacy of the vaccine.” What does this statement tell a young girl or her parents who are considering having her vaccinated? Does it mean that the vaccine reduces the risk of suffering from cervical cancer by 100%? Does the vaccine cause no side effects? Does the protection last a lifetime?

The case of the HPV vaccine is exemplary and of particular interest for two reasons: First, vaccination campaigns affect large parts of the population, primarily young girls between the ages of 12 and 16. Second, the HPV vaccine has prompted extensive media coverage, because some researchers have questioned whether it has been sufficiently evaluated (Dören et al. 2008). While the pamphlet conveys certainty and cites trustworthy and convinced experts, this

only reflects half the story. We conducted a media analysis in two countries – Germany and Spain – to evaluate media coverage and how the public was informed about the HPV vaccine in Web sites and newspapers. Most of the media reports did not provide any information about the prevalence, etiology, efficacy, or uncertainties of the vaccine (Bodemer et al. [submitted](#)). It is clear through content analyses of other health communications, such as pamphlets about mammography (Kurzenhäuser [2003](#)) or colon cancer screening (Steckelberg et al. [2001](#)) as well as media reports about medications (Moynihan et al. [2000](#)), that the media lack complete and balanced statistical information about risks, benefits, harms, and costs. Numbers are either not provided at all or are provided in nontransparent formats that mislead the public. This is alarming, since the mass media constitute the most prominent channels of communication about health innovations and treatments to the public (Grilli et al. [2009](#)).

## **Consequences of Biased Reporting**

Biased reporting undermines shared decision making and has consequences for the individual patient as well as for the health system. When the UK Committee on Safety for Medicine stated that the risk of life-threatening blood clots in legs or lungs is increased by 100% when using the third generation of the oral contraceptive pill, the public was appalled. As a consequence, many women stopped taking the pill, which resulted in unwanted pregnancies and abortions. But what did this 100% actually mean? Studies revealed that instead of 1 in 7,000 women who took the second generation of the contraceptive pill suffering blood clots, 2 in 7,000 who took the third generation pill did. This is equivalent to a relative increased risk of 100%, which in absolute numbers corresponds to a risk increase in 1 in 7,000 (example taken from Gigerenzer and Gray [2011](#)).

Another example is the fact that treatment benefits are often overestimated. When women and men in nine European countries were asked to estimate the effect of PSA screening and mammography on prostate cancer and breast cancer mortality reduction, respectively, they highly overestimated the benefits. Especially those who consulted their doctors or health pamphlets were particularly prone to overestimation (Gigerenzer et al. [2009](#)).

Another example is the consequence of false-positive test results, the fact that a test can erroneously signal a disease. False-positive tested patients often receive follow-up care despite the absence of disease, a phenomenon called overtreatment. Lafata et al. ([2004](#)) estimated incremental costs for false-positive results averaged over different screenings to be \$1,024 for men and \$1,171 for women, respectively, in the year following diagnosis. Moreover, besides unnecessary costs, false-positives create unwarranted anxieties and fears among patients.

These are just three examples that illustrate the dramatic consequences of biased reporting for health decisions. We will use these and other examples to better demonstrate and contrast the influence of different formats of risk communication.

## **How Good Are Experts and Laypeople at Dealing with Risks and Uncertainties?**

---

The public is often described as lacking the fundamental skills to deal with numerical information. Two terms have been coined to illustrate this phenomenon: (collective) “statistical illiteracy” (Gigerenzer et al. [2007](#)) and “innumeracy” (Paulos [1988](#)). Both concepts refer

to the widespread inability to understand quantitative information and to perform basic mathematical operations. But why is statistical literacy and numeracy so important for health decisions? Lipkus and Peters (2009) defined six main functions of numeracy that directly affect health decisions: Numeracy facilitates computation, encourages information search, improves interpretation of numerical information, facilitates the assessment of likelihood and value, can increase or decrease involvement in numerical data, and can consequently promote behavioral change.

## Statistical (Il-)literacy in Health

Gigerenzer et al. (2007) defined 13 principles of minimal statistical literacy. One of the key competences is the ability to deal with uncertainty. People tend to sustain an illusion of certainty – an ignorant perspective in a world that cannot guarantee any certainty at all (Gigerenzer 2002). For instance, when people rated which of five tests (DNA, fingerprint, HIV, mammography, expert horoscope) yield absolutely certain results, the majority (78%) believed that DNA tests do so. Furthermore, 63% believed in the certainty of fingerprint and HIV-test results, 44% stated that mammography leads to certain outcomes, and 4% even believed in horoscopes (Gigerenzer et al. 2007). One might think that experts are not prone to this illusion, but the opposite is true. In an undercover study, a client, who was explicit about not belonging to a risk group, asked 20 professional AIDS counselors the following questions in the mandatory pretest counseling session: Could I possibly test positive if I do not have the virus? And if so, how often does this happen? The vast majority stated that the test could not err and that it was absolutely impossible to receive false-positive results, which is, of course, not true, even though false-positives are rare (Gigerenzer et al. 1998).

Therefore, the first step to becoming statistically literate is to abandon this illusion and accept living with uncertainty. Minimal statistical literacy in health also subsumes an understanding of basic statistical concepts such as sensitivity, specificity, transforming conditional probabilities into natural frequencies, and the possibility of false alarms in medical screening tests as well as an understanding of the magnitude of treatment effects. All these concepts will be explained in this chapter. In addition, statistical literacy encompasses a grasp of the quality of scientific evidence and potential underlying conflicts of interests in medical research. For instance, the gold standard for evaluating a medical treatment is a randomized control trial (RCT). However, for many medical treatments no RCT is available and scientific evidence is inconclusive or even conflicting. Patients need to distinguish between different qualities of medical evidence. Another crucial distinction for decision making in health addresses the perspective from which a risk is evaluated. First, imagine a woman who knows that of 100,000 like her, 15 will have cervical cancer. She might decide not to participate in pap smear screening to identify early stages of cervical dysplasia since her baseline risk is rather low. Now, imagine a health policy decision maker: The pap smear screening reduces the annual incidence of cervical cancer in Germany by a total 10,400 women (Neumeyer-Gromen et al. *in press*). In this case, a national program to implement pap smear screening might be appreciated. Thus, depending on which perspective is taken, the evaluation of a treatment has different implications.

## The Concept of Numeracy

---

The second approach to assessing people's ability to deal with mathematical concepts is numeracy. In a broader sense, numeracy is defined as "the aggregate of skills, knowledge, beliefs, dispositions, and habits of mind – as well as the general communicative and problem-solving skills – that people need in order to effectively handle real-world situations or interpretative tasks with embedded mathematical or quantifiable elements" (Gal 1995, cited in Reyna et al. 2009). A more concrete definition of health numeracy is given by Golbeck et al. (2005): "the degree to which individuals have the capacity to access, process, interpret, communicate, and act on numerical, quantitative, graphical, biostatistical, and probabilistic health information needed to make effective health decisions." Some also subsume the ability to read and understand graphs under the term "health numeracy" (e.g., Ancker and Kaufman 2007), but we use the term "graph literacy" to define the ability to use visualizations (Galesic and Garcia-Retamero 2010). Moreover, Golbeck et al. (2005) differentiate four levels of health numeracy: Basic health numeracy encompasses the ability to identify numbers and correctly interpret quantifications. Computational health numeracy includes the ability to count and to conduct simple manipulations of numbers and quantities. Concepts of inference, estimation, proportions, frequencies, and percentages are represented on an analytical level of health numeracy. Finally, statistical health numeracy involves an understanding of biostatistics, the ability to compare numbers on different scales, and the critical analysis of risk ratios or life expectancy. Similar to statistical literacy, health numeracy also incorporates the understanding of scientific concepts, such as randomization and the double-blind study. Likewise, Reyna et al. (2009) reviewed the literature on numeracy and defined three levels of numeracy: The lowest level covers concepts of the real number line, time, measurement, and estimation. The middle level requires simple arithmetic operations and the comparison of magnitudes, while the highest level consists of an understanding of ratios, fractions, proportions, percentages, and possibilities.

## Measuring Numeracy

Different measures have been developed to assess people's numeracy skills. Objective scales assess competence with items that measure basic, computational, analytical, or statistical abilities. For example, a simple three-item scale by Schwartz et al. (1997) requires the conversion of percent into proportion and vice versa and the estimation of the expected numbers of heads in 1,000 coin tosses. This scale was the basis for an 11-item numeracy scale developed by Lipkus et al. (2001). An alternative way to measure numeracy is with the Subjective Numeracy Scale, which asks subjects to indicate their confidence in their own mathematical skills and preferences for numerical versus verbal risk information (Fagerlin et al. 2007). Subjects have to rate how easily they can calculate a 15% discount on a T-shirt or whether they prefer weather forecasts that state a probability of rain (e.g., 20% chance of rain tomorrow) as opposed to a verbal description (e.g., a small chance of rain tomorrow). The advantage of the Subjective Numeracy Scale is that subjects are not tested but rather are allowed to estimate their own abilities and preferences. The scale showed satisfactory correlations with objective scales and is easy to apply (Zikmund-Fisher et al. 2007; Galesic and Garcia-Retamero 2010).

## Numeracy in Experts and Laypeople

So how widespread is innumeracy? The Programme for International Student Assessment (PISA) in 2003 assessed mathematical and problem-solving skills of 15-year-olds in 24 countries. The results revealed low mathematical literacy skills in the United States and Germany – especially in concepts such as uncertainty and quantity. In 2007, the National Assessment of Educational Progress (NEAP) assessed students' mathematical performance. Only 22% of the students at grade 12 performed at a proficient level or above; 37% performed at basic level, and 41% even below basic level (Grigg et al. 2007; for an overview see Reyna et al. 2009). However, these results are not surprising since statistics and probability calculation are rarely implemented in school curricula. Nor is it surprising that adults have similar major difficulties in performing simple computations. The National Adult Literacy Survey (NALS) includes one scale measuring quantitative abilities. It demonstrated that 47% of the adults surveyed had very low quantitative literacy scores and difficulties in performing simple mathematical operations (Kirsch et al. 2007). These results were replicated by the National Assessment of Adult Literacy in which 36% of the subjects had a maximum of basic quantitative abilities (Kutner et al. 2006). Galesic and Garcia-Retamero (2010) compared numeracy skills in Germany and the United States using national probabilistic samples. On average, numeracy skills were higher in Germany (average proportion of correct items: 68.5% vs. 64.5%) with a greater difference between literate and illiterate in the United States. In other studies, even in well-educated samples only 16–25% of the subjects gave correct answers to all three items of the short numeracy scale (Lipkus et al. 2001; Schwartz et al. 1997). In general, men achieve higher scores than women, younger people higher scores than older people, and more educated people higher scores than those less educated.

## Consequences of Innumeracy

A growing body of literature has revealed consequences of the lack of statistical literacy and numeracy skills. In one study, women read data about mammography screening and breast cancer mortality and assessed their personal risk of dying of breast cancer with and without screening. Women with low numeracy skills (none of the three items in the short numeracy scale answered correctly) had an accuracy rate of 5.8%; in comparison, those women with high numeracy skills (3 of 3 items correct) showed an accuracy rate of at least 40% (Schwartz et al. 1997). In another study, subjects were confronted with the baseline risk of a hypothetical disease and had to choose between two treatments. Benefits of the treatments were presented as number needed to treat, relative risk reduction, absolute risk reduction, or a combination of these formats. Independent of the format, high-numeracy subjects were more successful in identifying the more beneficial treatment and correctly calculating the effect of treatment for a given baseline risk than less numerate subjects (Sheridan et al. 2003). Low-numeracy subjects were also more prone to framing effects (Peters et al. 2006). Treatment effects can either be framed positively by stating that 80 of 100 patients survive a treatment or negatively by stating that 20 of 100 patients actually die. Differences between the two frames affect decisions, more so in less numerate subjects than in highly numerate students. In addition, less numerate people have more difficulties transforming one representation format (e.g., frequency “20 of 100”) into another (e.g., probability “20%”): Whereas highly numerate people give consistent

risk estimations independent of the format, less numerate people give lower risk estimates under probability than frequency formats. People low in numeracy also tend to overestimate their personal risks, which in turn has important consequences for the perception of treatment benefits and treatment decisions (Woloshin et al. 1999; Davids et al. 2004; Dieckmann et al. 2009). Finally, numeracy moderates denominator effects. People low in numeracy tend to ignore the information in the denominator, which leads to the misinterpretation of treatment effects when the sample size in the treatment and control group are unequal (Garcia-Retamero and Galesic 2009).

On a behavioral level, patients show difficulties in disease management. For instance, diabetes patients low in health literacy – the ability to perform the basic reading tasks needed to function in the health-care environment – and numeracy showed a poorer anticoagulation control (Estrada et al. 2004). Rothman et al. (2006) investigated the perception and interpretation of food labels in 200 primary care patients. Even though most patients indicated that they frequently used food labels and stated that these labels are generally easy to understand, many patients misunderstood information about serving size, misapplied extraneous material on the food label, and performed incorrect calculations.

## The Role of Numbers and Words in Risk Communication

---

The communication of risks does not necessarily require an understanding of numerical information. Instead of relying on statistics, information about treatment benefits or harms can be based on the experiences of doctors and patients. Furthermore, verbal probability estimates describe risks without using data. In the following, we will describe the discrepancy between statistical and narrative evidence, and the influence of verbal probability estimates as opposed to numerical probability estimates on risk perception.

### Narrative Versus Statistical Evidence

---

Imagine a woman age 53 must decide whether to participate in mammography screening. She decides to ask her doctor about the test. The doctor gives her the following information: "Here is what we know: Think about two groups of women at age 40 or older. In each group are 2,000 women. Whereas one group receives biannual mammography screening, the other group does not receive any screening. After 10 years, the breast cancer mortality in the two groups is compared. In the screening group, 5 out of 2,000 women died of breast cancer, whereas in the control group, 6 out of 2,000 died of breast cancer. Mammography screening prevented 1 breast cancer death out of 2,000 women." The woman is not convinced to participate in the screening. On her way back home, she meets her neighbor – a 62-year-old woman. She asks her whether she has ever participated in mammography screening and receives the following answer: "Oh, yes, fortunately, I did. About 6 years ago, my doctor advised me to have a mammogram. At that time, I didn't really know what it was and didn't know a lot about breast cancer either. But I thought it couldn't harm and did it. Then, the mammogram turned out to be positive. Of course, I was shocked. But the doctor told me that my chances are very good, since the cancer was detected at an early stage. I had a mastectomy, and since then, I'm doing fine. You can imagine how happy I am that I had the mammogram." After talking to her neighbor, the woman is convinced – she will make an appointment for a mammogram tomorrow.

This example illustrates two different types of evidence a decision maker is often confronted with: statistical evidence and narrative (anecdotal) evidence. Whereas the latter usually encompasses stories and experiences from single cases ( $N=1$ ), the former summarizes data of larger samples ( $N > 1$ ). Which of the two types of evidence is more persuasive? Reinard (1988) reviewed the literature on statistical and narrative evidence and found little support for an advantage of statistical messages over narrative messages. Anecdotes and stories are more vivid, lively, and emotionally charged (Nisbett and Ross 1980; Taylor and Thompson 1982) or in other words, “it is generally accepted that stories are more concrete, more imagery provoking, and more colorful than statistics that are often abstract, dry, and pallid” (Baesler and Burgoon 1994). Consequently, narrative evidence increases personal relevance, especially when the receiver can identify with the narrator – as the 53-year-old woman did with her neighbor. In contrast, the statistical evidence provided by the doctor appears abstract and less imagery provoking. However, statistical evidence offers some advantages over anecdotes that are of particular importance for a decision maker. Statistical evidence provides information about baseline risks and treatment benefits based on a larger sample size. In comparison to stories, statistics are more factual, objective, and scientific and thereby establish a basis for credibility and trust (Baesler 1997). In their meta-analysis, Allen and Preiss (1997) also found a slightly more persuasive effect of statistical evidence than narrative evidence in different settings.

Both statistics and narratives are common in medical decision making. Ubel et al. (2001) asked subjects to choose between two treatments for angina – bypass surgery and balloon angioplasty. Both kinds of evidence were presented to the decision maker: Statistical evidence for bypass surgery showed a 75% success rate and balloon angioplasty a 50% success rate. When the narrative evidence was proportionate – in other words, when it reflected the statistical success rates (i.e., three pro statements and one contra statement for bypass surgery, and one pro and one contra statement for balloon angioplasty), 44% selected bypass surgery. However, when the number of narratives was disproportionate (one pro and one contra statement in both conditions, independent of the success rate), only 33% favored bypass surgery. Even though both conditions included statistical information, the proportion of narrative evidence affected treatment choice. In a second study, four testimonials were always presented, either proportionate or disproportionate. Whereas no significant difference in treatment choice was found between the proportionate and disproportionate format (37% and 34% chose bypass surgery), many more (58%) chose bypass surgery when numerical information was given without narratives.

The use of statistical or narrative evidence also influences risk perception. Subjects receiving a narrative reported higher personal risk than those who received statistical information, as well as higher intentions to get vaccinated, when confronted with a decision about vaccination against the hepatitis B virus (deWit et al. 2008).

In sum, the issue of which kind of evidence is more persuasive is still unresolved. As we pointed out at the beginning of this chapter, persuasion might not be an appropriate goal when conveying health messages. Instead, correct risk estimates as well as trust and credibility reflect more central evaluation measures. Since different evidence formats affect health decisions, it is crucial to understand how people perceive and interpret narrative and statistical information. Let us again consider the example of the woman facing the mammography screening decision. If she ignores the statistical evidence, she might erroneously assume that mammography is certain and prevents breast cancer deaths by 100%. Statistics help to objectively convey treatment benefits and harms and thereby help to inform and educate patients.

## Expressing Probabilities with Words Versus Numbers

Risk information can, but does not necessarily have to include numbers. A meteorologist may predict a “10% chance of rain” or alternatively state that it is “unlikely” to rain tomorrow. Similarly, a physician can tell a patient that it is “very probable” that she will recover from the treatment, instead of stating that her “chances are 80%” (or in other words that 8 out of 10 patients recover). Both formats represent options for risk communication – but which is more transparent and informative? Words are more common in communication than numbers and therefore match people’s internal representation, whereas the concept of probability emerged rather late in human history (Hacking 1975; Zimmer 1983). In addition, verbal probability expressions signal vagueness and uncertainty since words can never be as precise as numerical point estimates. At the same time, the imprecision of a verbal probability is its main flaw: People show immense variation in the interpretation of verbal probabilities (Budescu and Wallsten 1985; Brun and Teigen 1988). Brun and Teigen (1988) investigated how people interpret verbal probabilities and found high between-subject and within-subject variability in different domains. For instance, subjects assigned lower numerical estimates to verbal probabilities in a medical context in contrast to a context-free condition (see also Pepper and Prytulak 1974). One potential explanation of context dependency in the interpretation of verbal probability estimates is perceived base rate (Wallsten et al. 1986). A higher numerical probability estimate was associated with a verbal probability expression when the base rate of the event was high. This effect occurred primarily in verbal expressions of high and medium probability terms (e.g., possible, very likely), less so in low probability terms (e.g., rarely). Likewise, Weber and Hilton (1990) discussed perceived personal base rate and perceived severity as factors that influence the interpretation of verbal probabilities. Probability ratings were higher for more severe events, even when controlled for the base rate effect.

### Verbal and Numerical Probabilities in Health

Verbal probability estimates are common in health, especially in doctor–patient communications. Doctors often describe risks and treatment effects with such verbal expressions as unlikely, probable, or certainly. However, what a doctor means by “probable” is not necessarily what a patient understands by the same term. When ranking eight different probability expressions, mothers showed higher interquartile ranges than doctors, meaning that the range of interpretation of a single expression was larger for laypeople than for experts (Shaw and Dear 1990). Can the implementation of standards in medical risk communication reduce this discrepancy? The European Commission (1998) established guidelines to indicate the frequency of side effects with five verbal terms, each representing a particular frequency (see  Table 24.2). Knapp et al. (2004) compared how laypeople estimated the side effects in a verbal estimate condition and a numerical estimate condition with two different side effects of statins. One side effect, constipation, had a risk of 2.5%, which corresponds to a “common” event according to the guidelines; the other side effect, pancreatitis, had a risk of 0.4%, which is described as “rare.” Subjects had to rate the likelihood that they would experience the side effect. The average estimated probability of occurrence for the common side effect constipation was 34.2% in the verbal condition and 8.1% in the numerical condition. For pancreatitis, the estimates were 18% in the verbal and 2.1% in the numerical condition. In general, patients give

**Table 24.2**

**Verbal versus numerical probability estimates:** Verbal probability estimates and their intended numerical equivalent from the European guideline on the readability of the label and package leaflet of medical products for human use (1998). When verbal probability estimates are presented without numerical information, laypeople tend to overestimate the occurrence of side effects. In other words, the verbal descriptors are interpreted differently by laypeople than intended by the guidelines (see Steckelberg et al. 2005)

Verbal probability estimate (proposed by European guidelines)	Numerical probability estimate (intended by European guidelines)	Estimated probability by laypeople (Mean [SD])
Very common	>10%	65 (24)%
Common	1–10%	45(22)%
Uncommon	0.1–1%	18(13)%
Rare	0.01–0.1%	8(8)%
Very rare	<0.01%	4(7)%

higher estimates for verbal probabilities than actually intended by the guidelines, which in turn influences risk perception and behavior (Berry et al. 2004).

Marteau et al. (2000) tested parents in their understanding of test results for prenatal diagnostics. When a numerical format for the test outcome was used, 97% interpreted the result correctly, whereas only 91% did so when verbal probabilities were given. Gurmankin et al. (2004) compared variations in risk perception when subjects in a hypothetical cancer scenario received either a verbal message only or a verbal message plus numerical information. In general, subjects overestimated their relative risk and showed very high variation in their estimates, within and between subjects.

### Preferences for Verbal Versus Numerical Probabilities

Independent of how people interpret and understand verbal or numerical probability estimates, they might have a preference for one of the two formats. Mazur et al. (1999) confronted male patients with the treatment choice of either watchful waiting or surgery now in a prostate cancer scenario. The treatment effect in the surgery-now option was described as “possible,” whereas side effects were presented in numerical information (i.e., 10–25% chance of total loss of bladder control after surgery). More than half of the patients (56%) preferred numerical information. Those patients who preferred numbers chose watchful waiting more often, compared to those preferring verbal risk information. Similarly, Shaw and Dear (1990) asked parents which format doctors should use to communicate risks and found that 72% felt that they understood the numerical information and 66% actually favored doctors who gave numerical estimates. In general, findings suggest that people tend to prefer probability information in numerical formats when they search for information but use verbal probabilities when they communicate risks to others (see, e.g., Erev and Cohen 1990; Wallsten et al. 1993). Potential reasons for the preference for numerical information is that people trust numerical

information more and feel more comfortable and satisfied than with verbal estimates (Berry et al. 2004; Gurkankin et al. 2004). Despite this general pattern, interindividual differences exist. Some people feel uncomfortable with numbers and shrink from statistics, while others actively search for numerical information.

In sum, statistical and narrative evidence are important sources for decision makers but at the same time affect risk perceptions and decisions differently. People tend to perceive numbers as objective and credible. Verbal estimates lead to high inter- and intraindividual variation in the interpretation of risks. However, the “strength” of statistical evidence depends on two crucial factors. First, we demonstrated that people often lack statistical literacy and numeracy skills. Even if the public prefers to base decisions on statistics, can it adequately understand them? Low numeracy results in misconceptions that undermine informed decisions. The elimination of statistical illiteracy and innumeracy requires educational programs for doctors, patients, and children to establish a risk-literate society.

The second factor refers to a very different problem. The problem of risk communication is not simply in people’s minds – their inability to deal with numbers – but rather in the environment – an environment that is primarily characterized by biased and nontransparent communication formats. Different representation formats exist to express the same (numerical) information, for example, frequencies (20 of 100) and percentages (20%). Some formats mislead people and lead to false expectations. Other formats are rather intuitive and make it easy for recipients to correctly assess a risk. What makes a format transparent is its ecological structure: the match of the external representation format and the mind – that is, the cognitive capacities to recognize relationships in certain representations of complex problems (Gaissmaier et al. 2007). The second part of this chapter will focus on this issue: transparent risk communication formats and how they facilitate the interpretation of numbers.

## **Transparent Risk Communication: How to Overcome Statistical Illiteracy and Innumeracy**

---

The problem of biased risk communication is less in people’s lack of statistical competency, but primarily in the use of nontransparent communication formats. We will present shortcomings of relative risks, conditional probabilities, 5-year survival rates, and their transparent counterparts. Additionally, we will illustrate the potential benefits of graphical representations and discuss approaches to including uncertainty in risk communication.

### **Relative Versus Absolute Risks**

---

Let us refer again to the example of the UK pill scare. When the UK Committee on Safety for Medicine stated that the risk of life-threatening blood clots in lungs and legs increased by 100%, many women stopped taking the pill. The consequences were unwarranted pregnancies and abortions. Although stating a 100% increase is not incorrect, if an absolute instead of a relative format of risk increase is used (the risk increased by 1 in 7,000 women – i.e., instead of one woman, two women in 7,000 had blood clots), the risk appears to be very different.

A relative risk is the ratio of a risk in a treatment group and the risk in a control group who did not receive a treatment (or received only a placebo). The relative risk reduction is simply

calculated by subtracting the relative risk from one. An absolute risk is defined by the difference in absolute magnitudes between the two groups. A third format to express the same information is the number needed to treat, that is, the number of patients who have to be treated to prevent one death (e.g., 100 people have to get vaccinated to prevent one death). In principle, the three measures can be converted into each other if the underlying risk is known. One might think these formats can be interchangeably used in risk communication – but the opposite is true. As the pill scare example demonstrates, the perception of a treatment's risk increase highly depends on the presented format.

Malenka et al. (1993) asked patients to select one of two treatments for a hypothetical disease with equivalent efficacy, side effects, and costs. The only difference was that one medication was framed in terms of relative risk reduction and the other as absolute risk reduction. The majority of patients (56.8%) selected the medication with relative numbers; about 15% were indifferent, and about the same proportion selected the medication with absolute numbers; and 13% could not decide. Similarly, Sarfati et al. (1998) showed subjects three different (fictitious) screening programs, each in a different format – relative risk reduction, absolute risk reduction, or number needed to treat. Depending on the format, subjects' willingness to participate differed substantially. When framed as relative risk reduction, 80% intended to participate, in comparison to only 53% and 43% who did so in the absolute risk reduction and number needed to treat condition, respectively. Additionally, relative risk reduction formats lead to higher deviations in treatment decisions from expected-utility theory assumptions than absolute formats (Hembroff et al. 2004). Does the same hold true when the subjects are medical experts? Naylor et al. (1992) showed that information in the form of relative risk reduction (relative decrease of 34%) led to higher perception of treatment effects in doctors compared with absolute risk reduction (decrease from 3.9% to 2.5%) or number needed to treat (77 persons have to be treated to save one patient). Likewise, doctors' mean ratings for effectiveness of a drug that lowers cholesterol concentration depended on whether relative or absolute risk reductions were presented (Bucher et al. 1994). A diabetes prevention intervention was rated as important or very important by 86% of health professionals under a relative risk format condition, whereas only 39% gave these ratings in an absolute risk reduction condition (Mühlhauser et al. 2006).

Consistent with other reviews (e.g., Edwards et al. 2001; Moxey et al. 2003) a meta-analysis by Covey (2007) supported the conclusion that both laypeople and experts are sensitive to the way risk reduction is framed: People perceive higher treatment effects when relative risk reduction formats are used in comparison to absolute risk reduction and number needed to treat.

As previously mentioned, health reporting is most biased when different formats are used for different effects, known as mismatched framing. Describing treatment benefits in relative numbers and treatment harms in absolute numbers confuses and misleads patients. For instance, a German pamphlet about hormone replacement therapy (HRT) states the following: 60 out of 1,000 women develop breast cancer in their lives. After HRT for 10 years, 66 out of 1,000 women develop breast cancer – the absolute increase is 6 in 1,000. At the same time, only half as many of the women who take HRT develop colon cancer, compared to those who do not take HRT; in other words, HRT reduces the risk of developing colon cancer by 50%. By using two different formats to describe benefits and harms of HRT, the consumer is misled and overestimates the benefits in contrast to the harms.

However, some argue in favor of the use of relative risks and odds ratio, especially in meta-analyses. The rationale is that both formats are supposedly more stable across different

subpopulations than absolute risks (e.g., Smeeth et al. 1999). In any case, this does not have any implications for risk communication, which should always be based on absolute numbers.

Lessons learned: Findings demonstrate that no relative risks should be used in risk communication. Risk reduction or risk increase ought to be presented in absolute numbers only.

## Conditional Probabilities Versus Natural Frequencies

We already mentioned the illusion of certainty and the problem that patients and health professionals often believe in the certainty of medical test results. For instance, 44% in one study stated that the result of a mammogram is absolutely certain (Gigerenzer et al. 2007). But what is actually the probability that a woman has breast cancer given a positive mammogram? To illustrate what a positive mammogram means, look at the following information (Eddy 1982; see Gigerenzer et al. 2007):

- The probability of breast cancer is 1% for a woman at age 40 who participates in routine screening (this is the prevalence or base rate).
- If a woman has breast cancer, the probability is 90% that she will have a positive mammogram (this is the sensitivity or hit rate).
- If a woman does not have breast cancer, the probability is 9% that she will also have a positive mammogram (this is the false-positive rate).

The task is to estimate the probability that a woman at age 40 who had a positive mammogram actually has breast cancer. What is the correct answer? When Eddy (1982) presented a similar scenario to staff at the Harvard Medical School, 95 of 100 physicians gave an answer between 70% and 80%, though the correct answer is about 10% – or in other words, of ten women who had a positive mammogram, only about one actually has breast cancer. Why do people have problems solving this and similar tasks?

The simple answer would be that humans are not “Bayesian” and hence are not capable of calculating posterior probabilities  $P(H|D)$  based on the prior probability  $P(H)$ , the likelihood  $P(D|H)$ , and the probability  $P(D|-H)$ . In the mammography example,  $P(D|H)$  is the sensitivity (90%),  $P(H)$  is the base rate (1%), and  $P(D|-H)$  is the false-positive rate (9%). The computation of the posterior probabilities requires Bayes’s theorem:

$$P(H|D) = \frac{P(D|H) \cdot P(H)}{P(D|H) \cdot P(H) + P(D|-H) \cdot P(-H)} \quad (1)$$

Kahneman and Tversky (1972) stated that humans cannot perform Bayesian reasoning and lapse into cognitive biases. For instance, humans tend to ignore base rates when calculating conditional probabilities. As a consequence of these biases, people’s judgments are often inconsistent with normative “Bayesian” prescriptions (Casscells et al. 1978; Eddy 1982). Erroneously, humans do not differentiate between the probability of a disease given a positive test result (the posterior probability), and the probability of having a positive test result given the disease (sensitivity). Bayes’s theorem is the common formula in most medical and statistical textbooks to calculate posterior probabilities, but still people who should be familiar with the formula seem to have difficulties in its application.

Gigerenzer and Hoffrage (1995) challenged the assumption that people cannot solve Bayesian tasks and proposed an alternative representation format that facilitates the

computational process: natural frequencies. Think again about the mammography example, but this time, the following information is given:

- Ten of 1,000 women at age 40 who participate in mammography screening have breast cancer (prevalence or base rate).
- Of these ten women, nine have a positive mammogram (sensitivity or hit rate).
- Of the 990 women who do not have breast cancer, about 89 will have a positive mammogram nonetheless (false-positive rate).

Now imagine a representative sample of 1,000 women aged 40 who participate in breast cancer screening. How many of these women with a positive test result actually have breast cancer? Of course, the answer is the same: About 1 of 10. Nevertheless, to arrive at the correct solution does not require Bayes's theorem. Instead, the calculation is much simpler: Of 1,000 women, 98 will have a positive mammogram (9 of the 10 women who actually have breast cancer – referred as  $a$  in the formula and 89 of the 990 healthy women, referred as  $b$  in the formula). Of this 98 with a positive test result, only 9 actually have breast cancer, which results in 9.2%, or about 10%.

$$P(H|D) = \frac{a}{a+b} \quad (2)$$

When Gigerenzer and Hoffrage presented the mammography problem in natural frequencies instead of conditional probabilities, about half of the subjects gave the correct solution in comparison to only one-quarter in the probability condition. Since then, many researchers have replicated the results. Cosmides and Tooby (1996) conducted a series of experiments and supported the hypothesis that natural frequencies lead to higher proportions of correct inferences compared to probability formats. For example, they replicated Casscells et al. (1978) study: Only 12% of their subjects arrived at the correct result when confronted with probabilities, but between 56% and 76% did so when confronted with natural frequencies.

Nevertheless, the concept of natural frequencies has aroused controversy about whether and why it facilitates Bayesian reasoning. Some researchers have argued that frequencies per se do not improve people's performances in Bayesian tasks. However, they confused natural frequencies with other kinds of frequencies (for an overview see Hoffrage et al. 2002). For instance, Macchi and Mosconi (1998) demonstrated that not all kinds of frequencies facilitated Bayesian reasoning, and Lewis and Keren (1999) reached a similar conclusion. Gigerenzer and Hoffrage (1995) stated in the original paper that the computational simplification can be obtained only for natural frequencies, not for normalized frequencies, which – just like probabilities – require Bayes's theorem. Further misunderstandings have resulted from proposed alternative explanations for the same phenomenon, for example, that the facilitating effect is based on a “nested-set structure” or on “partitive representations” (Barbey and Sloman 2007), which actually just restate the original argument.

Barton et al. (2007) proposed a statistical taxonomy subsuming three orthogonal dimensions to reduce confusion: First, the information can refer to one event only (single-event probabilities) or a set of events (frequencies). Second, different numerical representations, such as percentages, fractions, real numbers between 0 and 1, and pairs of integers, are differentiated. Third, the information can be presented in normalized formats or nonnormalized (also called conjunctive) formats. Due to the orthogonality of the dimensions, any combination is possible. For instance, expressing the mammography information in chances leads to the same

computational effect as doing so with natural frequencies but refers to a single individual (Brase 2009).

In summary, findings support the conclusion that natural frequencies help people solve Bayesian tasks and understand positive predictive values. Doctors and patients can easily learn what a positive test result means and how prevalence, sensitivity, and false-positives interact. Teaching natural frequencies is also rather simple. Instead of Bayes's rule, which invites learners to forget the actual components of the formula, the principle of natural frequencies is easy to grasp and helps people convert probabilities into natural frequencies. Even children benefit from this representation format and can perform Bayesian tasks (Zhu and Gigerenzer 2006).

We already mentioned the consequences of not understanding positive predictive values in the  [Introduction](#). Imagine a woman aged 56 who has a positive mammogram. Besides being extremely worried and anxious after receiving this result, she has to undergo further examinations and treatments. However, the chances of her result just being a false-positive are 9 out of 10. The terms "overdiagnosis" and "overtreatment" have been coined to call attention to the phenomenon that many people who have a positive screening test result are actually treated, despite the absence of the disease.

Lesson learned: While people have difficulties interpreting and calculating conditional probabilities, natural frequencies facilitate Bayesian reasoning.

## Single-Event Probabilities Versus Frequencies

---

Another advantage of frequency statements is that they always include a reference class. This is not the case for single-event probabilities. A single-event probability is defined as "a probability that refers to an individual event or person" (Gigerenzer et al. 2007). Thus, no reference classes are included, which often leads to misconceptions between a communicator and a receiver. A meteorologist forecasts that the probability of rain tomorrow is 30%. This prediction leaves room for different interpretations. It could mean that it will rain 30% of the time, in 30% of the area, or on 30% of the days like the one tomorrow (Gigerenzer et al. 2005). While the latter interpretation is correct, most people believe the other two options to be true. Similarly, stating that the probability of developing sexual problems as a consequence of a drug is 30% leaves the patient alone to his or her subjective interpretation. Again, the probability could refer to 30 out of 100 sexual encounters of a single person or to 30 out of 100 patients taking the drug. Frequency statements always include a reference class and thereby eliminate misunderstandings.

Lesson learned: Always provide the reference class to which a probability refers.

## Five-Year Survival Rates Versus Mortality Rates

---

When evaluating a health treatment, the first question that comes to mind is whether it saves lives in the long run. Cancer screenings aim at identifying a cancer at an early stage, even before first symptoms occur. Thus cancer screenings usually increase incidence rates – the number of cancers in a given population within a given time frame. This fact prevents us from drawing conclusions about a screening's effects on life expectancy.

Probably the most common unit mentioned when evaluating health treatments is the so-called 5-year survival rate. Survival rates can be defined as the number of patients alive at a specified time following diagnosis (such as after 5 years) divided by the number of patients diagnosed (Gigerenzer et al. 2007).

5-year survival =

$$\frac{\text{Number of persons diagnosed with a specific cancer still alive 5 years after diagnosis}}{\text{Number of persons diagnosed with a specific cancer in the study population}} \quad (3)$$

For example, if a screening detects 100 people who have a positive diagnosis, and 80 of them are still alive after 5 years, the 5-year survival rate is 80%. If only 20 are still alive, the 5-year survival rate is 20%. One might expect that the higher the 5-year survival rate, the better. However, there is an alternative to 5-year survival rates: (annual) mortality rates. And even more surprising, the correlation between changes in 5-year survival rates and changes in mortality rates over time is zero (Welch et al. 2000). The mortality rate is defined as the number of people in a group who die annually from a disease, divided by the total number of people in the group.

$$\text{annual mortality rate} = \frac{\text{number of persons who die from a specific cancer over 1 year}}{\text{number of persons in the study population}} \quad (4)$$

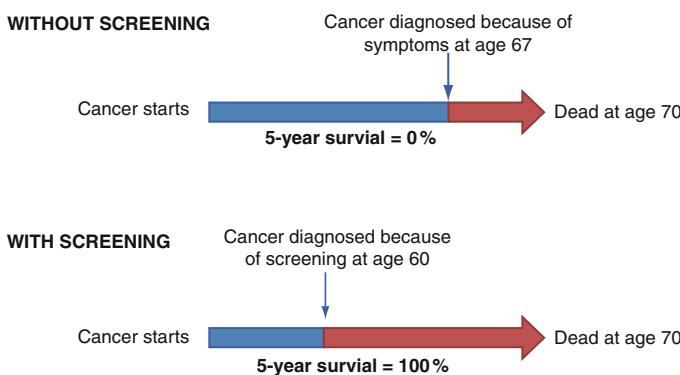

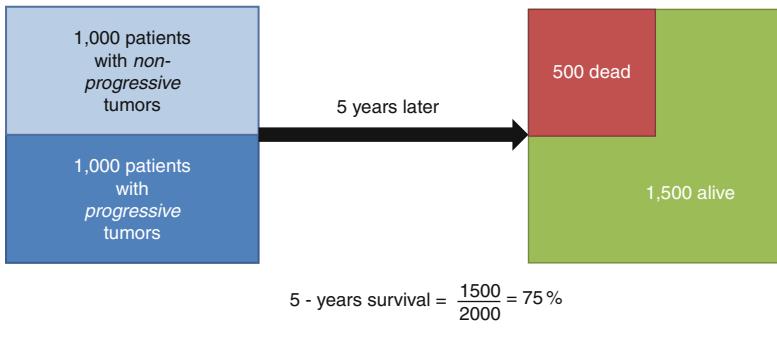

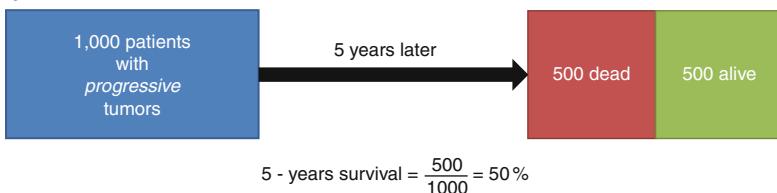

By comparing the two formulas, one thing is apparent: The 5-year survival rate only includes people who are *diagnosed* with disease in the denominator. This fact makes it prone to biases. An annual mortality rate, instead, includes the entire population at risk in the denominator. However, 5-year survival rates are the rule rather than the exception in current risk communication.

## Lead-Time Bias

The first shortcoming of 5-year survival rates is the so-called lead-time bias: A higher proportion of people alive 5 years after screening does not necessarily mean that people actually live longer – it might only be an illusionary extension of life (see Fig. 24.2a). Assume that the 5-year survival rate for a specific cancer was 1% between 1960 and 1965. For the time between 2005 and 2010, the proportion of people alive after 5 years was 80%. The cancer in the 1960s was diagnosed when patients first showed symptoms. In the years 2005–2010, a special screening test was applied for earlier detection, even before first symptoms occurred. Thus the time to diagnosis was reduced. However, this does not necessarily mean that it prolongs life, since patients between 1960 and 1965 and 2005 and 2010, respectively, might die the same number of years after developing the cancer. The difference is that those who lived between 2005 and 2010 knew earlier; in other words, they lived longer with the diagnosis, but in fact their life expectancy was the same.

## Overdiagnosis Bias

The second shortcoming is the so-called overdiagnosis bias. Not every tumor or dysplasia (that is detected) is necessarily fatal. Some tumors would have never been detected without screening, because they would never have caused any symptoms, would have resolved spontaneously,

**a****b****Fig. 24.2**

**Shortcomings of 5-year survival rates:** The figure illustrates the two potential biases of 5-year survival rates (modified from Gigerenzer et al. 2007). (a) *Lead-time bias:* The arrows illustrate the course from the beginning of a disease to death. In the group without screening, cancer is diagnosed at age 67, in the screening group at age 60. However, in both groups, patients die at the same age (age 70). Whereas in the non-screening group the 5-year survival rate is 0%, it is 100% in the screening group. (b) *Overdiagnosis bias:* (1) A group of 1,000 patients with progressive tumors is monitored over 5 years. After 5 years, 500 are still alive; the survival rate is 50%. (2) The same group of 1,000 patients with progressive tumors is monitored over 5 years. Additionally, the screening detects patients with nonprogressive, indolent tumors. Again, after 5 years 500 patients died (500 out of 1,000 with progressive cancer). However, in the calculation of the 5-year survival rate, those 1,000 with nonprogressive tumors are also included hence the 5-year survival rate is 75%

or would not have been detected before the patient died of other causes. To illustrate this example, take a look at the formula 3 for the 5-year survival rates. Assume that we have 1,000 people in a screening with a positive diagnosis of having a progressive tumor based on symptoms. These 1,000 patients form the denominator to calculate the survival rate. After 5 years, half of them are still alive. Hence, the survival rate is 50%. Now imagine that our screening also detects very small and indolent tumors. These tumors are nonprogressive and hence not lethal. To the 1,000 patients with progressive tumors in the denominator, add the 1,000 patients with indolent tumors. However, the number of deaths due to the cancer is still 500. Now the survival rate is 75%. Although the number of deaths remains the same, the 5-year survival rate provides a much more favorable picture – a bias that does not affect annual mortality rates (see [Fig. 24.2b](#)). One well-known example is the Mayo Lung Project of the 1970s and 1980s. Smokers were assigned to either a screening group or a control group receiving no screening. Whereas 206 lung tumors were detected in the screening group, only 160 were detected in the control group. However, the overall mortality in both groups was the same. A follow-up in 1999 with patients of both groups who were still alive and had no positive diagnosis in 1983 showed that 585 patients of the screening group compared to 500 in the control group had lung cancer. One interpretation of the data is that the screening detected small and indolent tumors that were not lethal and therefore did not need any treatment (Marcus et al. [2006](#)).

In summary, an increase in 5-year survival rates can be observed under three conditions: First, due to lead-time bias, the tumor is detected earlier, but patients still die at the same age as without screening. Second, due to overdiagnosis, more tumors are detected, but among them are indolent ones – the number of deaths is not affected. Third, screening allows for earlier detection and better treatment – in this case the screening is indeed beneficial. Mortality rates also capture the latter effect but do not fall into the traps of lead-time and overdiagnosis bias. As mentioned above, the correlation between changes in 5-year survival rates and changes in mortality rates is zero. Furthermore, a comparison of survival and mortality rates for 20 tumors between 1950–1954 and 1989–1995 showed an absolute increase in 5-year survival rates of between 3% and 50% over 5 years, whereas changes in mortality rates ranged from –80% to 259% (Welch et al. [2000](#)). As mentioned above, those changes were completely uncorrelated.

The influence on treatment evaluations of 5-year survival rates in comparison to mortality rates was shown by Wegwarth et al. ([2011](#)). They presented physicians with either a 5-year survival rate only, annual disease-specific mortality only, or a combination of the two formats with or without incidence rates, and all the numbers were based on the same, real data. When only 5-year survival rates were presented, 66% of the physicians recommended screening; 78% were convinced of the screening's efficacy and showed the highest overestimation of the screening's benefit. In contrast, when confronted with mortality rates, only 8% gave a recommendation and only 5% considered the screening to be efficient. The two combined versions produced results in between these values. This study illustrates the influence of the format used to describe screening effects on measures of risk reduction as well as behavioral measures. Only annual mortality rates convey a transparent and unbiased picture of actual changes in mortality that could be the result from screening. As the 5-year survival rate is a highly specific medical concept, it is not surprising that patients would be unaware of its misleading potential, but that even doctors are not aware of these problems is worrying.

Lessons learned: Five-year survival rates do not allow us to adequately evaluate health interventions, particularly screenings. In contrast, annual mortality should be used to illustrate effects.

## Graphical Representations

A promising alternative way to present numerical estimates is with graphs. As the saying goes, a picture is worth a thousand words. In the eighteenth century, William Playfair was the first to use bar charts and pie charts to illustrate economic and political data. Later, at the beginning of the twentieth century, the philosopher and economist Otto Neurath proposed symbols to display statistical information. Since then, different formats have been identified and used to communicate risks. The advantages of graphs are manifold (see Lipkus and Hollands 1999; Ancker et al. 2006; Lipkus 2007; Zikmund-Fisher et al. 2008a, b):

1. *Graphs often attract and maintain attention:* Attention and the expectation of successfully handling quantitative information are important prerequisites for a motivated patient to get involved in personal health decisions.
2. *Graphs foster automatic and intuitive processes:* A transparent and well-designed graph reduces the cognitive effort needed to extract and understand the information. For instance, certain formats do some of the mathematical operations for the observer and consequently facilitate understanding (e.g., part-to-whole relationships; ratio concepts).
3. *Data patterns can be detected:* Some graphs help display data over a longer period of time and show patterns and trends in the long run (e.g., lifetime incidence).
4. *Graphs can help communicate uncertainty:* A main challenge in risk communication is the inclusion of uncertainty parameters. Graphs can facilitate displaying uncertainty transparently.
5. *Graphs can overcome low numeracy:* Statistical illiteracy and innumeracy are widespread phenomena. Especially those low in numeracy tend to misunderstand risk information. Graphs offer an alternative format to help people with low numeracy understand risks and make informed decisions.

Although graphs facilitate the communication of statistical information, a variety of visualization formats can be used to provide the same information – and not all are equally effective. Again it is a question of ecologically structured information. Just like numbers, some graphs have the potential to display information in a biased way and consequently mislead the public. Additionally, understanding graphs requires basic skills to extract the relevant information and read beyond the data given – an ability described as graph literacy.

## The Example of Icon Arrays

One format to visually display risks is icon arrays (pictographs). Icon arrays are graphical visualizations consisting of icons (faces, circles, figures) that represent individuals belonging to a certain group or a group as a whole (see Fig. 24.3).

Fagerlin et al. (2005) tested the impact of pictographs on a hypothetical treatment choice in an angina scenario. Subjects had to choose between two treatments and received anecdotal evidence about success and failure rates of the respective treatments. Anecdotal evidence was either representative of the success rates or not. The treatment with the higher success rate was chosen more often when anecdotal evidence was representative in comparison to when it was not. However, when pictographs were included, the representativeness effect of the anecdotes diminished. By including icon arrays, the influence of narrative evidence can be reduced.

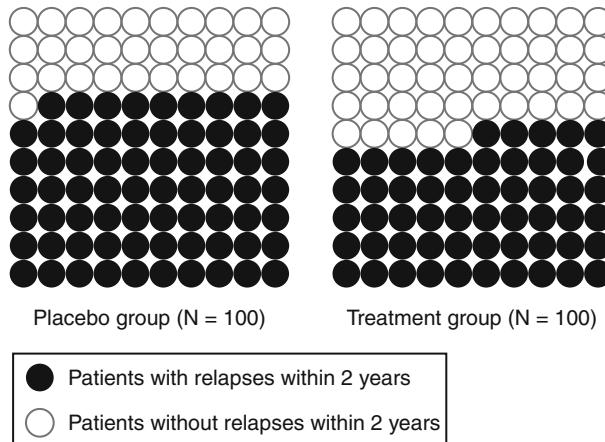

Fig. 24.3

**Icon array: Benefit of interferon therapy for multiple sclerosis patients (modified from Heesen et al. 2008, p. 40).** The treatment aims to reduce multiple sclerosis relapses. Displayed are two groups – a placebo group (*left*) and a treatment group (*right*) – with 100 patients in each. In the placebo group, out of 100 patients 31 patients had no multiple sclerosis relapse within 2 years. In the treatment (interferon therapy) group, 45 had no multiple sclerosis relapse within 2 years. In other words, 14 out of 100 patients benefit from interferon therapy

Icon arrays also help reduce base rate neglect (Garcia-Retamero and Galesic 2009; Garcia-Retamero et al. 2010). Subjects had to compare a treatment group with a control group. When the two groups have equal sample sizes, subjects showed no difficulties in estimating treatment effects. However, the proportion of correct estimates decreased when the groups differed in sample size – the denominator information was often neglected. Icon arrays call attention to the different sample size in the treatment and control group and thereby help to reduce base rate neglect.

It could be argued whether icon arrays facilitate understanding of risk information in addition to transparent numerical formats. But in fact, graphs have an incremental effect on risk perception. In one study, subjects received treatment effects framed as absolute or relative risk reduction with or without icon arrays (Galesic et al. 2009). Icon arrays improved performance for both framing formats. Especially those low in numeracy benefited from the additional visualization.

When Stone et al. (1997) compared a numerical risk reduction format (30–15) with stick figures to understand people's willingness to pay for improved toothpaste versus standard toothpaste, they observed a higher willingness to pay in the graphical condition. They interpreted the result as meaning that graphs led to higher risk avoidance in comparison to numbers. However, while the base rate was presented in the numerical condition, the stick figures did not represent the part–whole relationship. In later experiments (Stone et al. 2003), the stick figures were replaced by charts and stacked bar charts. The inclusion of the part–whole relationship in the graphical formats reversed the original effect: Willingness to pay was lower in the graph conditions than in the numerical conditions. Similarly, Garcia-Retamero and

Galesic (2010) found that bar charts and icon arrays primarily improve risk understanding when the population at risk is included. Pie charts and horizontal bar charts helped people with low numeracy to overcome framing effects.

## Graph Literacy

Despite graphs being more intuitive and facilitating the interpretation of statistical information, their understanding requires basic skills. Galesic and Garcia-Retamero (2011) developed a 13-item scale to measure graph literacy in the medical domain. The scale is meant to differentiate people's ability to read graphical information (e.g., find the correct data), to read between the data (find relationships, e.g., to identify which proportion in a pie chart is larger), and also beyond the data (e.g., inferences and predictions that can be derived from the data). The scale covers different graph formats such as bar graphs, pie charts, line graphs, and icon arrays. The authors validated the scale on probabilistic samples in Germany and the United States and reported correlations between graph literacy and education in Germany (0.29) and the United States (0.54) and between graph literacy and numeracy in Germany (0.47) and the United States (0.55). The majority of people who are low in numeracy are also low in graph literacy and those high in numeracy are usually higher in graph literacy. Primarily those low in numeracy but high in graph literacy benefited from the inclusion of visualizations; those high in numeracy but low in graph literacy had no incremental benefits.

Notwithstanding the advantages of graphs to communicate risks, shortcomings of visual displays cannot be overlooked. People who lack basic graph literacy skills have difficulties extracting and interpreting the relevant information. Up to now, little has been known about how graphical, text, and numerical information interplay. People might shift all their attention to graphs, thereby ignoring any other information relevant to a decision. Additionally, more research is needed to know under what condition a particular visualization format works best. Some graphs are better than others for communicating lifetime prevalence or contrasting different treatment effects. Last but not least, many graphs in newspapers and the scientific literature look fancy but are in fact uninformative or even misleading. Wainer (1984) summarized the 12 most powerful techniques for displaying data badly. In sum, as Lipkus (2007) pointed out, "knowledge of how graphical displays affect risk perceptions is still in its infancy and remains, with few exceptions, a largely atheoretical research area" (p. 702).

Lessons learned: Graphs are a promising tool for improving people's interpretation of risks. However, research about graphs is still in its infancy.

## Uncertainty Communication

The French philosopher Voltaire once said "Doubt is not a pleasant condition, but certainty is absurd." Our world is fundamentally uncertain and yet many people cling to the illusion of certainty. Knight (1921) previously distinguished between risk, which can be computed numerically, and uncertainty, which is immeasurable. A less strict definition of uncertainty allows estimating parameters of uncertainty probabilities, such as standard deviations, confidence intervals, or experts' confidence ratings. A further distinction is made between

uncertainty and variability (Thompson 2002). Variability refers to the fact that different individuals or groups in a population have different risks. This could be due to differences in age, gender, region, or exposure to risk factors. This is different from uncertainty, which refers to imperfect knowledge. Although often ignored, uncertainties play a major role in medical decision making (see, e.g., Politi et al. 2007). First, scientific evidence is limited. Even randomized controlled trials – often regarded as the gold standard in medical research – have limitations due to design principles, sample size, and lack of validity and reliability of measures. Second, risk estimates are based on population data and therefore cannot be applied one-to-one to individuals (see example of individual vs. public health perspective on pap smear screening above). Third, risk estimates are based on past events. Their application to the present and future rests on the assumption that the environment and underlying forces do not change.

### Fear of Disclosing Uncertainty

Uncertainty communication is more the exception than the rule. When in 2009 the World Health Organization proclaimed the H1N1 pandemic, it was assumed that worldwide about two billion people could become infected and between 2 and 7.4 million people could die. This forecast influenced many policy decisions, such as the implementation of H1N1 vaccination programs (Feufel et al. 2010). However, at that point of time, little was known about the actual severity and spread of the virus. In hindsight, this prediction appears exaggerated. Why do experts shrink from disclosing and communicating uncertainty?

First, many experts believe that the public is incapable of understanding uncertainty (Frewer et al. 2003). Communicating uncertainty confuses people who are mainly ambiguity averse and uncertainty intolerant (Epstein 1999). Second, experts might fear losing trust and perceived competence if they reveal that some aspects of an issue are unknown. However, as the H1N1 example illustrates, the opposite can happen: Maintaining an illusion of certainty that in hindsight turns out to be false decreases trust in the expert (Holmes et al. 2009; Feufel et al. 2010). Narrative evidence underlines this conclusion. When the Bank of England started to publish the protocols of their board meetings and transparently reveal related uncertainty in their prognoses about economic growth, the British public rated it as the most trusted institution (Gigerenzer 2007, p. 215).

### How to Communicate Uncertainty

The core question is still how to transparently communicate uncertainty. Ibrekk and Morgan (1987) studied laypeople's understanding of nine different graphical uncertainty representations. Subjects received graphs of weather forecasts about the probability of snow (without any explanations) and the prediction of water depth in a flood (with explanations). As a dependent measure, subjects had to assess the most likely estimate as well as the range. Findings showed that a point estimate including a 95% confidence interval and a Tukey box were easiest to understand. The presence of an explanation led to a slight improvement. Subjects were most sure about their estimates if the point estimate plus confidence interval or a histogram was provided. Cumulative density functions and pie charts seemed improper for communicating risks. This was among the first studies investigating tools to communicate uncertainty to laypeople.

Johnson and Slovic (1995) conducted four studies to understand the influence of uncertainty information. They concluded that people are unfamiliar with uncertainty information and that the recognition of uncertainty caused trouble. However, graphical tools can help communicate uncertainty; the disclosure of uncertainty also signaled honesty for some people but was a sign of incompetence for others. To better understand laypeople's perception of uncertainty, Schapira et al. (2001) formed focus groups and asked women whether an uncertainty statement (in this case a confidence interval) should be included in risk communication. More highly educated women appreciated the inclusion of confidence intervals and interpreted the information as more complete, whereas less educated women reacted with a decrease in trust and the dilution of the actual treatment benefit. Another study investigated effects of doctor's uncertainty disclosure on breast cancer patients (Politi et al. 2010). Although women's breast cancer treatment choice and consistency with expert's opinion was independent of the doctor's disclosure of uncertainty, uncertainty communication reduced decision satisfaction.

With respect to risk perception, it is assumed that increased uncertainty leads to an increase in perceived risks. Put differently, the more uncertain a hazard, the greater the worry that is associated with it, which in turn shifts people's focus to bad outcomes (Einhorn and Hogarth 1985; Viscusi et al. 1991). Yet Kuhn (2000) found that the communication of uncertainty interacts with prior attitude. Subjects were split into two groups defined by high or low environmental concern and received five different scenarios describing environmental hazards. When the risk information was presented as a point estimate, environmental attitudes predicted environmental risk perception. However, the differences between the two groups reduced when an uncertainty statement was included, primarily because those with high environmental concern showed lower perceived risks. A potential explanation is that people with high environmental concern appreciated the uncertainty information (either as a verbal or numerical statement) and perceived the communicator as more honest – similar to the conclusion drawn by Johnson and Slovic (1995). These results are also in line with other proposals, namely, that one way to increase credibility and trust is to present uncertainty instead of maintaining an illusion of certainty (Frewer 1999; van Dijk et al. 2008).

Interestingly, uncertainty communication can improve decisions with respect to a normative criterion (Nadav-Greenberg and Joslyn 2009). Subjects played a road treatment task and had to decide whether to salt roads based on either a point estimate ("It will be 1.7°C tomorrow") or an uncertainty forecast ("It will be 1.7°C tomorrow, but there is an 18% chance that it will freeze"). For every treatment of the road, an amount of \$1,000 had to be paid. However, if the decision maker did not salt the roads and the temperature dropped to freezing, a penalty of \$6,000 had to be paid. According to the expected value, the roads should be treated when the probability of freezing is above 16.7%. Subjects with a deterministic forecast showed a larger deviation from expected value compared to subjects with probabilistic forecasts, resulting in a higher end budget for those who had access to the deterministic forecast *and* probability of a freeze.

In sum, evidence suggests that uncertainty communication is not as prejudicial as often believed. Laypeople understand and even appreciate uncertainty information. There is no evidence that confirms experts' fear of losing trust and perceived credibility when disclosing uncertainty – the opposite effect might be true. However, this is only a tentative conclusion; more research is needed to better understand how uncertainty communication affects and interacts with trust, credibility, and decision-making processes. People have different expectations in different domains that affect their willingness to accept uncertainty – these inter- and

intraindividual differences should be examined to improve risk communication and make uncertainties more salient.

Lessons learned: Uncertainty communication is not bad per se. How it finally affects decision quality, trust, credibility, and satisfaction still requires further examination.

## Further Research

---

Throughout this chapter, we have presented and discussed the current state of research in health risk communication. The research presented here so far has sought to support the idea that transparent risk communication can inform the public and become the basis for shared decision making. In the following, we will discuss what boundaries exist that undermine transparent risk communication and how to overcome them. The following three aspects are at the center of our discussion:

1. Research gaps: Where is further research needed?
2. Political and societal obstacles: Why is risk communication rarely put into practice?
3. Teaching statistical literacy: How can society become statistically literate?

Whereas the first point primarily addresses the research community, the latter two require transferring research into practice and demand the interaction between researchers and policy makers.

### Research Gaps

---

While research in risk communication has already identified multiple formats and alternatives for representing statistical information, there are still many open research questions to be addressed. Here are three potential research fields.

### Individual Differences

It would be interesting to look at the role of interindividual differences in understanding risk communication. People do not only differ with respect to numeracy and graph literacy skills, which have important implications for their understanding of risks. Other frequently discussed factors are age, education, socioeconomic status, intelligence, need for cognition, prior experience, and media competency. Especially the development of patient support technologies, which aim at providing tailored information to individuals, requires knowledge about how individual differences affect information search and decision making, and how to discover these differences. With the help of tailored information, patients can evaluate and select those treatments that fit their personal preferences and needs.

Let us illustrate this with a fictitious example: Imagine three patients who are thinking about participating in colon cancer screening. They have four alternatives: fecal-occult blood test, DNA test, colonoscopy, and sigmoidoscopy. The screening programs differ on various dimensions like how well the test detects early stages of cancer, how often the test errs, how invasive the treatment is, what the side effects are, and how much the test costs. One patient searches for information about all four alternatives on all dimensions. He weights each

question according to his preferences and adds up his evaluations of all treatments. Finally, he selects the one with the highest score. This is called a weighting and adding strategy. However, the second patient follows a different strategy: She thinks that the test should be as good as possible in detecting early stages of cancer. Therefore, she ignores the other questions. If two tests are equally effective, she compares those alternatives on the level of side effects and chooses the one with less severe side effects. Using this heuristic, she might select a different treatment from that chosen by the first patient. A third patient does not search for any information about the treatment and simply asks his doctor for a recommendation. Tailored information needs to be designed to satisfy the consumer's information search and decision strategy. Research about individual differences is still rare but is crucial to understanding the interplay between risk communication and cognitive strategies.

## **Integrating Information Sources**

Another research branch addresses the interaction of different information sources and its effect on health decisions. To learn about health treatments, a patient can consult many different sources: health professionals, friends, patient associations, newspaper reports, and the World Wide Web. Especially the latter provides a new and prominent platform to learn more about health treatments. The Web has both advantages and disadvantages. There are almost no limits on what information patients can search for, and information is often up to date. However, at the same time, patients have to evaluate this information and judge the credibility and trustworthiness of various sources, which is particularly important as even short exposure to misinforming Web sites can have a lasting influence on people's risk perception (Betsch et al. 2010). Patients must decide to what extent they can, for instance, trust information from the pharmaceutical industry or how objective the information is on vaccine-critical Web sites. Evidence and opinions on the Web are often conflicting and might confuse rather than educate the consumer. Again, patients run the risk of being misinformed and misled if they rely on doubtful evidence. Research can help us understand people's Web information search behavior (e.g., Hargittai et al. 2010) and how people identify reliable sources. Also, research has started to identify the relevant skills required to use the Internet successfully (Hargittai 2005, 2009), which could lead to the development of interventions to improve those skills in the future.

In addition, the Web has had a direct impact on the doctor–patient relationship (e.g., Diaz et al. 2002; McMullan 2006). Patients are not “naïve” and uninformed any more but have prior attitudes and expectations when meeting their doctors. On the one hand, the doctor–patient interaction benefits from informed patients. Patients and doctors have a more balanced relationship and need less time since the patient is already informed. On the other hand, doctors might have difficulties disabusing patients of potentially false beliefs and expectations acquired through the Internet. The pros and cons of using the Internet to inform patients and increase expertise in laypeople still needs further research.

## **Implementing Theories of Risk Communication**

Another issue that researchers have to address that relates to the intersection between research and practice is the lack of theoretical frameworks in the field of risk communication, and in

decision aids in particular. Durand et al. (2008) evaluated 50 decision support technologies with respect to their theoretical frameworks. Only 17 were explicitly based on a theoretical framework, mainly expected-utility theory. The lack of theories and their application in the design of decision aids, as well as in the evaluation process, leads to insufficient and ad hoc constructed decision aids. Therefore, researchers need (1) to formulate and test theories on which decision support technologies can be based, (2) to make these theories available to designers of decision support technologies, and (3) to evaluate the implementation of the theories in the decision support technologies.

## Obstacles to Implementing Risk Communication

---

Investigating and identifying transparent risk communication formats is one requirement to improve risk communication in society. However, the second step is to transfer research into practice. As the lack of theories in designing decision support technologies shows, there is a long way to go from theory to practice.

Policy makers still communicate relative instead of absolute risk reductions, pharmaceutical industries promote their interests with misleading statistics, and health professionals themselves have difficulties with numbers. Why is this still the case? An answer is found in the seven sins identified by Gigerenzer and Gray (2011), which is already mentioned in the ➤ [Introduction](#). Three of these sins directly address the issue of transparent risk communication, and were part of this chapter: biased reporting in medical journals, pamphlets, and the media. We also alluded to the lack of statistical literacy in health professionals and will discuss consequences and challenges in the next section. We have also already described another sin: defensive decision making. Doctors often do not prescribe those treatments that seem best but are guided by the desire to minimize potential legal consequences. Finally, biased funding refers to the pharmaceutical industry often sponsoring research trials. Consequently, researchers are not free in the research topics they select, the study design, data analysis, and data interpretation since industrial interests need to be considered. One might argue that researchers have to disclose conflicts of interests. However, this is not always the case. Weinfurt et al. (2008) found that consistent disclosure of financial interests was the exception in the biomedical literature and asked editors and authors to take responsibility.

One movement that has tried to eliminate industrial interests in research trials was launched by *JAMA*, the *Journal of the American Medical Association*. The editors launched a requirement for independent statistical analysis of industry-driven research in 2005. In contrast to other medical journals, *JAMA* published fewer RCTs and also fewer industry-driven RCTs (Wager et al. 2010). Further advances have been made by the introduction of standards and guidelines for reporting observational research (i.e., STROBE statement 2007; CONSORT statement 2009). Simple checklists help authors and editors evaluate research reports and assure complete and unbiased reporting. Such guidelines and standards should not be restricted to scientific journals but should also be set for media health coverage and health advertisements.

Media analyses and advertisement content analyses have repeatedly shown that the media rarely communicate numbers, and when they do, they use biased formats. Yet the mass media have the power to shape health decisions (Grilli et al. 2009) and thereby intentionally or

unintentionally misinform and mislead the public. Health promotion campaigns from the pharmaceutical industry primarily follow financial interests and persuade rather than inform. For instance, in the United States in 2008 the pharmaceutical industry ranked second (behind the automotive industry) in dollars spent on advertising (Nielsen 2009).

An alternative approach to advertising is the use of so-called facts boxes (Schwartz et al. 2007). Facts boxes summarize the current state of evidence about drugs or other treatments in a way that laypeople can easily understand. They cover basic information and provide numbers in transparent formats by contrasting treatment and placebo groups and hence serve an educational purpose. ↗ *Figure 24.1* represents a facts box with basic information about mammography screening based on current scientific evidence.

## Teaching Statistical Literacy

---

Many people in our society are statistically illiterate and innumerate. This phenomenon applies not only to laypeople, but also to experts. A way out of this dilemma is to promote education in statistical thinking on at least three levels: Statistics should be taught in schools, and statistics training should be offered to health professionals and (science) journalists.

### Statistical Teaching in Schools

Statistical thinking is hardly taught at schools. Mathematics curricula do not include teaching statistical concepts; instead, the focus is on the mathematics of certainty, such as algebra, geometry, and trigonometry. In contrast to a widespread belief that children cannot deal with statistics, children at the elementary school level are already capable of understanding fundamental concepts of statistical thinking, such as natural frequencies and icon arrays (Zhu and Gigerenzer 2006). Hands-on approaches to problem solving, such as with tinker cubes, lego-like units, allow even first graders to learn about conditional frequencies through play (Kurz-Milcke and Martignon 2007; Kurz-Milcke et al. 2008). Despite attempts to include statistics in school curricula, there are four constraints that undermine successful and sustainable implementation. First, the first contact with statistics occurs too late in schools. Second, many textbooks use confusing representation formats. Third, statistics are often taught in a pallid way by abstract and unrealistic examples. Fourth, teachers themselves are often not as familiar with these concepts as they ought to be. A rethinking in mathematical teaching is pivotal for future statistically literate generations.

### Statistics Training Education for Health Professionals

The second step addresses education of health professionals. Doctors directly interact with patients and therefore require the skills not only to understand statistics, but also to transparently communicate them. As far back as 1937 an editorial in the Lancet called attention to the strong link between medicine and statistics and the lack of fundamental abilities of doctors to deal with statistical information (“Mathematics and Medicine” 1937). It stated that the use

(or abuse) of statistics “tends to induce a strong emotional reaction in non-mathematical minds.” It complained that for “most of us figures impinge on an educational blind spot,” which “is a misfortune, because simple statistical methods concern us far more closely than many of the things that we are forced to learn in the 6 long years of the medical curriculum.” What has changed since then? Doctors still have trouble calculating positive predictive values and are prone to framing effects (e.g., 5-year survival rates vs. mortality rates, or relative vs. absolute risk reduction). Health professionals need to be trained in statistics. This will teach them how to identify biased reporting and how to translate statistical information into transparent formats.

### Statistics Education for (Science) Journalists

The third target population is journalists. As previously mentioned, the mass media play an important role in educating the public. However, journalists might just reproduce biased reporting that has its origin in the medical literature. Therefore, educating scientists and making them aware of these biases will help them see through embellishments and obfuscations to translate risk information into comprehensive formats. They may also put public pressure on those who practice biased reporting.

## Conclusion

---

Risk communication is a requirement for an informed public to be able to adequately deal with risks and uncertainties. On the one hand, experts and laypeople have difficulties in dealing with statistical information. On the other hand, the problem is less in people’s minds and more in a health environment that puts little effort into presenting risks in an unbiased way. Biased reporting encompasses the omission of important information as well as the use of nontransparent communication formats. Informed and shared decision making will remain an illusion unless transparent risk communication formats are consistently applied.

We believe that statistically literate patients improve health decisions on an individual as well as on a public health level. Throughout this chapter, we proposed ways to design risk communication to educate and inform patients, instead of persuading them. These points should be kept in mind (see  [Table 24.3](#)):

- Absolute risk changes are preferred over relative risk changes.
- Natural frequencies facilitate Bayesian reasoning in comparison to conditional probabilities.
- Annual mortality rates are less misleading and less biased than 5-year survival rates.
- Graphs can help overcome innumeracy.
- Disclosing uncertainty can help overcome the illusion of certainty.

People are able to make personal decisions that reflect their preferences and needs when they have sufficient information on which to base their decisions. There are two fundamental “adjustment screws”: the consequent application of transparent communication formats and the implementation of education programs on different societal levels. Last but not least,

**Table 24.3**

**Nontransparent versus transparent communication of risks: Four examples of how risks can be communicated to mislead and misinform the public and their transparent counterparts**

How to communicate risks nontransparently	How to communicate risks transparently
<p><i>Relative risks</i> “The new generation of the contraceptive pill increases the risk of thrombosis by 100%.”</p>	<p><i>Absolute risks</i> “The new generation of the contraceptive pill increases the risk of thrombosis from 1 in 7,000 to 2 in 7,000.”</p>
<p><i>Conditional probabilities</i>            – The probability of breast cancer is 1% for a woman at age 40 who participates in routine screening (this is the prevalence or base rate)            – If a woman has breast cancer, the probability is 90% that she will get a positive mammography (this is the sensitivity or hit rate)            – If a woman does not have breast cancer, the probability is 9% that she will also get a positive mammography (this is the false-positive rate)            What is the probability that a woman at age 40 who had a positive mammogram actually has breast cancer?  <math>P(H D) = \frac{0.9 \cdot 0.01}{0.9 \cdot 0.01 + 0.09 \cdot 0.99} = 0.092</math> </p>	<p><i>Natural frequencies</i>            – Ten out of 1,000 women at age 40 who participate in mammography screening have breast cancer (prevalence or base rate)            – Of these 10 women, 9 have a positive mammogram (sensitivity or hit rate)            – Out of the 990 women who do not have breast cancer, about 89 will have a positive mammogram nonetheless (false-positive rate)            Now imagine a representative sample of 1,000 women age 40 who participate in breast cancer screening. How many of these women with a positive test result actually have breast cancer?  <math>P(H D) = \frac{9}{9+89} = 9.2</math> </p>
<p><i>Five-year survival rate</i> “The 5-year survival rate for people diagnosed with prostate cancer is 98% in the USA vs. 71% in Britain.”</p>	<p><i>Annual mortality rate</i> “There are 26 prostate cancer deaths per 100,000 American men versus 27 per 100,000 men in Britain.”</p>
<p><i>Single-event probability</i> “If you take Prozac, the probability that you will experience sexual problems is 30–50% (or: 30 to 50 chances out of 100).”</p>	<p><i>Frequency statement</i> “Out of every 10 of my patients who take Prozac, 3–5 experience a sexual problem.”</p>

lessons learned in health risk communication can be adapted to other domains as well. Transparency and statistical literacy help people evaluate financial, environmental, and technological risks, and enable society to competently meet future challenges.

**Abstract:** Risk perception is important in policy making. Most research on risk perception has been carried out with nonexperts and members of the public at large, but there are some interesting exceptions, notably the study of experts. Very large differences in risk perception usually appear between experts and nonexperts, but they seem to be partly related to responsibility and social validation and not only to knowledge. Models of risk perception have usually been based on Cultural Theory or the Psychometric Model, but they have had only limited success in accounting for perceived risk. The chapter discusses factors which can improve on the explanatory power of risk perception models, such as Interfering with Nature, Risk Sensitivity, and Risk Target (self or others). Emotions and values have also been investigated. Emotions do play an important role in risk perception, but values have so far not been found to be important. “Affect” is an unclear term since it can refer both to emotions and attitudes. Trust has been another focus of research on risk perception. Trust has almost always been conceived as social trust, i.e., trust in people or organizations. Trust in this sense has a limited influence on risk perception. Epistemic trust, i.e., trust in the science behind risk assessments and risk management, is possibly more important than social trust; at any rate, both types of trust should be considered. Finally, new risks appear all the time, and they require new concepts if we are to understand how people perceive and react to them.

## Introduction

---

The field of policy making with regard to risk issues is difficult to navigate because members of the public often have strong views which differ dramatically from those of experts and administrators, captains of industry, and politicians. Risk issues are often very contentious, and parties tend to have distorted views of each others’ beliefs and values (Sjöberg 1980). In a study of nuclear-waste risk perception (Sjöberg et al. 2000b), it was found that experts and members of the public made systematic errors in estimating each others’ level of perceived risk for a number of risk aspects, see [Figs. 25.1](#) and [25.2](#). Experts made lower risk estimates than the public thought they did. Members of the public made higher risk estimates than the experts thought they did. Hence, the gap between experts and the public was wider than either party believed it to be.

In a democracy, there is a need to understand people’s attitudes and to accommodate policies with those attitudes. Research on risk perception and related attitudes is an important part of this work. Scientific risk estimates are of course important in policy making, but risk perceptions cannot be ignored (Sjöberg 2001b, c). For an excellent review of risk perception research, see Breakwell (2007).

## Received Models of Risk Perception

---

The two best-known models of risk perception are the Psychometric Model (Fischhoff et al. 1978) and Cultural Theory (Douglas and Wildavsky 1982). They have both had a historically important influence on the field, but current work throws doubt on their validity. I summarized my critical analysis of these two models in Sjöberg (2002b), while another paper (Sjöberg 1997) is devoted particularly to Cultural Theory. “Heuristics and biases” (Tversky and Kahneman 1974; Sjöberg 1979) have also played an important role in discussions of risk perception, particularly the availability heuristic (Tversky and Kahneman 1973).

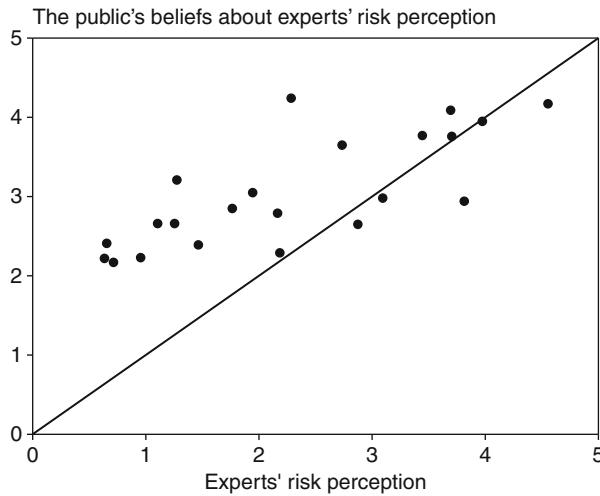

Fig. 25.1

Risk aspects of nuclear waste: experts' risk perceptions and the public's beliefs about the experts' perceptions. Scales refer to size of perceived risk, where 0 = no risk and 5 = a large risk

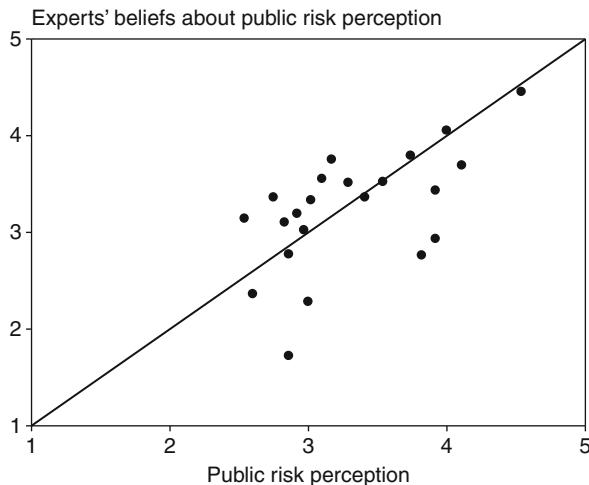

Fig. 25.2

Risk aspects of nuclear waste: the public's risk perceptions and experts' beliefs about the public's perceptions. Scales refer to size of perceived risk, where 0 = no risk and 5 = a large risk

The "heuristics and biases" approach to risk perception stresses availability as a major factor driving perceived risk (Combs and Slovic 1979; McCombs and Gilbert 1986). Information which is more easily brought to mind, more dramatic and striking, etc., is said to be evoke stronger perceptions of risk. Although this principle sounds reasonable, it has not been generally supported by data. In an experimental study, we showed dramatic films about a fire and a nuclear power plant accident and found no tendency toward increased risk perception related to the

contents of the films (Sjöberg and Engelberg 2010). Reasons for perceived risk may be due to the semantics of the concepts instead. For example, “nuclear waste” is a combination of two negatively loaded and threatening concepts, and it is no coincidence that opponents to siting projects make it even more negative by using such terms “atomic garbage.” Industry seems, on the other hand, to prefer the term “spent nuclear fuel.” Brehmer found that people judged road crossings which looked dangerous as risky, even if they had not been exposed to any information about accidents having taken place there (Brehmer 1987).

The basic thrust of the criticism of the Psychometric Model and Cultural Theory is that both models are empirically weak when it comes to accounting for perceived risk of technologies. Scales of Cultural Theory dimensions were suggested first by Wildavsky and Dake (Wildavsky and Dake 1990), and that publication suggested that they may be powerful explanatory concepts. However, these results have not been possible to replicate. Correlations between Cultural-Theory scales and perceived risk are typically around 0.05–0.10. This is a very low level of explanatory power. It can be argued that even low correlations may describe relationships of practical value in interventions and experimental designs, but that is a largely irrelevant argument in the present context, where the scales are used in order to test the validity of a theory. Later attempts at operationalizing the concepts of Cultural Theory have not resulted in stronger relationships than the original Wildavsky–Dake scales, see, e.g., Silva et al. (2007). Cultural theory has been found to be useful in work which is more qualitatively oriented, however (West et al. 2010).

Value dimensions in general have been found to be weak explanatory concepts of perceived risk. Other examples than Cultural Theory-scales are the value scales devised by Schwartz (Schwartz 1992), and scales measuring the personality constructs in Jung’s theory of psychological types (Myers et al. 2003). An attempt was made to find relations between Schwartz-type value scales and risk perception of nuclear waste, but no strong relationships were found (Sjöberg 2008b).

A discussion of “distal” explanatory concepts was given by Sjöberg (2003c). The word distal refers to the case when the explanatory factors are semantically divergent from the concept of perceived risk. It is very hard to find strong results with such factors. On the other hand, proximal variables, the opposite of distal variables, should not necessarily be rejected as trivial explanatory concepts. I will return to this issue when I discuss attitude and “affect” later in this chapter.

Interesting, and stronger, results were found with scales measuring “New Age” beliefs (Sjöberg and af Wåhlberg 2002). People who espouse such beliefs tend to be skeptical toward technology. Even stronger relationships have been found with political preferences, measured as party preferences in a multiparty democracy such as Sweden (Sjöberg 2008b). It is likely that values do partly explain party preferences but apparently not values of the kind measured by existing methods to measure value systems, such as the system by Schwartz (Schwartz et al. 2001). Of course, constructs other than values could also be important for political preferences.

The Psychometric Model is another story. It has a high level of explanatory power for *average* ratings of hazards. This is a case of a general principle: averages tend to correlate more strongly than raw data, a phenomenon sometimes referred to as the ecological fallacy (Robinson 1950). However, for *individual* data, the model has only a moderate level of explanatory power, even if it fares better than Cultural Theory. It may, in some cases, explain about 20% of the variance of perceived risk. The most powerful dimension of the Psychometric Model is “dread” (Gardner and Gould 1989).

In spite of occasional successes at the 20% level, the model frequently fails to achieve a better result than Cultural Theory for individual data. Its credibility probably depends of two factors:

1. Data analysis based on averages more or less guarantees high correlations, but it is sometimes not understood that this does not mean that the model explains the risk perception of individuals.
2. The basic dimensions, New risk and Dread, seem to match widespread commonsense notions about lay people's risk perception. There was a particularly powerful demonstration in the basic 1978 paper by Fischhoff et al. which appeared to show that opposition to nuclear power was based on ignorance and emotions.

## Beyond the Psychometric Model

---

As pointed out in the previous section, the traditional models of risk perception explain only a minor part of the variance. In the present section, I briefly review work on other constructs which have led to considerably stronger models. The aim of the work has been to find a model which is as fully explanatory as possible. If a considerable share of the variance of perceived risk is left unexplained, there could be aspects and phenomena which are important but simply not covered at all. The result is likely to be bias in the regression parameters estimated, see e.g., Pedhazur's discussion of specification errors in regression models (Pedhazur 1982, pp. 225–230).

For example, in practical risk perception survey work, which has developed to become a minor "industry," more or less exclusive concern with traditional dimensions of Cultural Theory and the Psychometric Model may have led investigators, and their customers, astray since they have worked with only weak constructs which typically leave about 80% or more of the variance of perceived risk unexplained. It could also be the case that different and more powerful constructs override the effects of the traditional dimensions. For a review of this approach, see Sjöberg (2000b). There are many examples of the low explanatory power of risk perception models, see, e.g., Huang et al. (2010). Eurobarometer work on risk perception of genetically modified food reached only about 30% explained variance (Gaskell et al. 2004); twice as much could be achieved with a less traditional design, see Sjöberg (2008c).

The first successful construct to be mentioned here is that of *risk sensitivity*, see Sjöberg (2004a). People tend to use a risk rating scale in systematically different ways. Some rate all or most hazards very high on the scale, others do the opposite. If all hazard items are treated as part of an attitude scale or as a personality trait, it is always found that they correlate highly and a high alpha value is found. Averaging all items yields a measure of risk sensitivity. It is an interesting topic to inquire into the factors that lead some people to deny or reject all or most hazards as dangerous, while some (usually fewer) do the opposite, see Sjöberg (2006a). The overall risk sensitivity index typically is a very powerful explanatory factor for the risk perceived in any given hazard. Of course, the risk sensitivity index must be adjusted when relating it to any given hazard. The rating of that hazard must be deleted from the index in order to avoid an artifactual relationship.

A second important construct is that of *interfering or tampering with nature*, see Sjöberg (2000c), a third is that of *morality*, see Sjöberg and Winroth (1986). Many people

believe that it is dangerous to interfere with nature, and some also believe that it is morally wrong to do so, possibly because they have religious convictions about nature being created by God. These are powerful factors in perceived risk and attitude toward technologies such as genetically modified food. But they are important also in less obvious cases, such as nuclear technology or nanotechnology (Vandermoere et al. 2010).

Interfering with nature is different from involvement in the environment for two reasons. First, interfering with nature is more widely applicable than involvement with the environment. Second, concern about interference is a quite specific issue and not general, as is the case is with involvement.

What is nature? That is a tricky question. Drottz-Sjöberg and Sjöberg (2009) reported that people will agree that “illness” is part of nature, while the HIV virus is not, in their view. Of course, everything is nature in one sense of the word. To reach a more specific definition, one needs to think hard. It suffices here to point out that people are worried about interference with nature, and that such worries account for a sizable share of the variance of perceived risk.

Nuclear power is at the present becoming more acceptable in many countries. Why? One often mentioned possibility is that the level of perceived risk has decreased, another is connected with benefits. In particular, people may consider that nuclear power is irreplaceable, in the sense that the alternatives are either too costly (solar power, wind) or environmentally unfriendly (fossil fuels). As a more general argument, I show in Sjöberg (2002c) that a technology which was seen as irreplaceable was more readily acceptable, and that this factor contributed strongly beyond perceived risk.

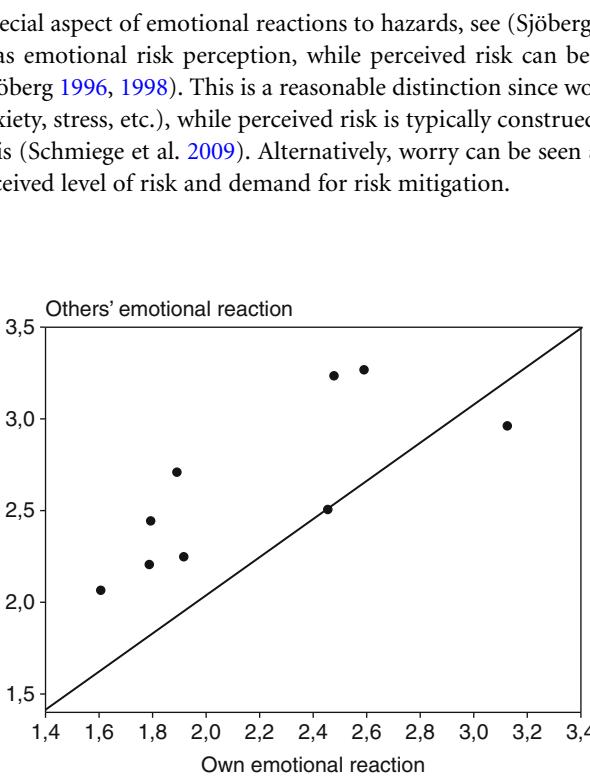

A methodological perspective is brought in by Sjöberg (2003b). In much risk perception work, people were asked to judge “risk” without any further specification. However, it is easy to demonstrate that people make a clear distinction between risk as pertaining to them, personal risk, and risk to others, general risk. The difference has been found to be related to perceived control (Harris and Middleton 1994). People apparently believe that they can control risks, at least some risks, and that others are not willing or able to do so. This is true in particular of lifestyle risks such as smoking or drinking alcohol. When the risk target is not specified, people judge general risks.

Policy implications are different for general and personal risks. Personal risks are important for policy attitudes with regard to environmental and technology risks.

## Affect and Emotion

“Affect” is an ambiguous word (Sjöberg 2006b). It can refer to emotions or values, or both. Emotions are not implicated in studies, where affect is operationalized as value or attitude. It has indeed been found that attitude is a powerful explanatory factor in risk perception; see Sjöberg (1992). The attitude referred to here is that of an object or a construct which is seen as driving the hazard. For example, a nuclear accident is caused by nuclear power. Hence, the perceived risk of a nuclear accident is likely to be found to be explained, to a rather large extent, by the attitude to nuclear power. One could of course question the causal direction here. However, Sjöberg (1992) presents results which support the interpretation that attitude is causally prior to perceived risk.

Emotions are discussed in Sjöberg (2007a). If people are asked to judge their personal emotional reactions to a hazard, it is found that emotions are powerful explanatory concepts of perceived risk. A whole range of emotions (Sherry-Brennan et al. 2010), including fear and anger, are important (Lerner et al. 2003). Positive emotions also enter the picture. Some people react positively to such a concept as nuclear power, finding it interesting or beneficial. The problem with the emotional component in the Psychometric Model (“dread”) is that it is rated for others, not for the respondent him- or herself, and that the model does not include a range of emotions, only one.

It can also be noted that people rate the negative emotions of others as stronger than their own. We tend to believe that others are “emotional” and “irrational,” and that they are more negative toward technology than we are. There is an interesting connection with disaster planning here. “Panic” is expected by many planners, who certainly do not think that they are likely to have such reactions themselves (Wester-Herber, *in press*). Quarantelli showed long ago that this is a myth (Quarantelli 1954), and modern work on risk perception supports his argument.  Figure 25.3 is a scatter plot comparing the strength of anticipated emotional reactions between individuals and others. The x-axis is labeled "Own emotional reaction" and ranges from 1,4 to 3,4. The y-axis is labeled "Others' emotional reaction" and ranges from 1,5 to 3,5. A diagonal line represents the identity line (y=x). Eight data points are plotted, showing that others' emotional reactions are generally stronger than one's own emotional reactions. The data points are approximately at (1.6, 2.1), (1.8, 2.2), (1.8, 2.4), (1.9, 2.7), (2.5, 3.2), (2.5, 3.2), (2.5, 3.3), and (3.2, 2.9).

Worry is a special aspect of emotional reactions to hazards, see (Sjöberg 1998). Worry has been construed as emotional risk perception, while perceived risk can be seen as cognitive (Rundmo and Sjöberg 1996, 1998). This is a reasonable distinction since worry has emotional components (anxiety, stress, etc.), while perceived risk is typically construed as a judgment of how large a risk is (Schmiege et al. 2009). Alternatively, worry can be seen as a driving factor both behind perceived level of risk and demand for risk mitigation.

 Fig. 25.3

Anticipated emotional reactions: own reactions and those of others. Scales refer to strength of anticipated emotional reaction. This figure has been published previously as Fig. 4 in Sjöberg (2007a)

## Trust and Antagonism

Trust has been shown to be an important factor in risk perception (Slovic et al. 1991). It is natural to assume that low trust should be related to a high level of perceived risk. However, the relationship is only moderately strong (Sjöberg and Wester-Herber 2008). The reason appears to be that trust has been too narrowly conceived. Researchers have been mostly interested in social trust, i.e., trust in people and organizations, not in *epistemic* trust or trust in the quality of the knowledge that people and organizations base their risk assessments on.

Drott-Sjöberg found that epistemic trust was frequently mentioned by her respondents in interviews about a nuclear-waste siting project (Drott-Sjöberg 1996, 1998). Sjöberg (2001a) found that epistemic trust was more important than social trust. Effects of social trust on risk perception seemed to be mediated by epistemic trust (Sjöberg 2008a).

Sjöberg (2008a) introduces another concept, namely, *antagonism*; see also Sjöberg and Wester-Herber (2008). Competence is a factor which has been traditionally implicated as important in social trust (Peters et al. 1997). However, perceived competence in an enemy is not reassuring but the opposite. Active enemies have not been traditionally studied in risk perception research; terrorism is a case in point, see Sjöberg (2005). Antagonism is a rather frequently evoked construct among some members of the public, and it contributes to risk perception beyond social and epistemic trust. The relationship between trust and perceived antagonistic interest is illustrated in Fig. 25.4.

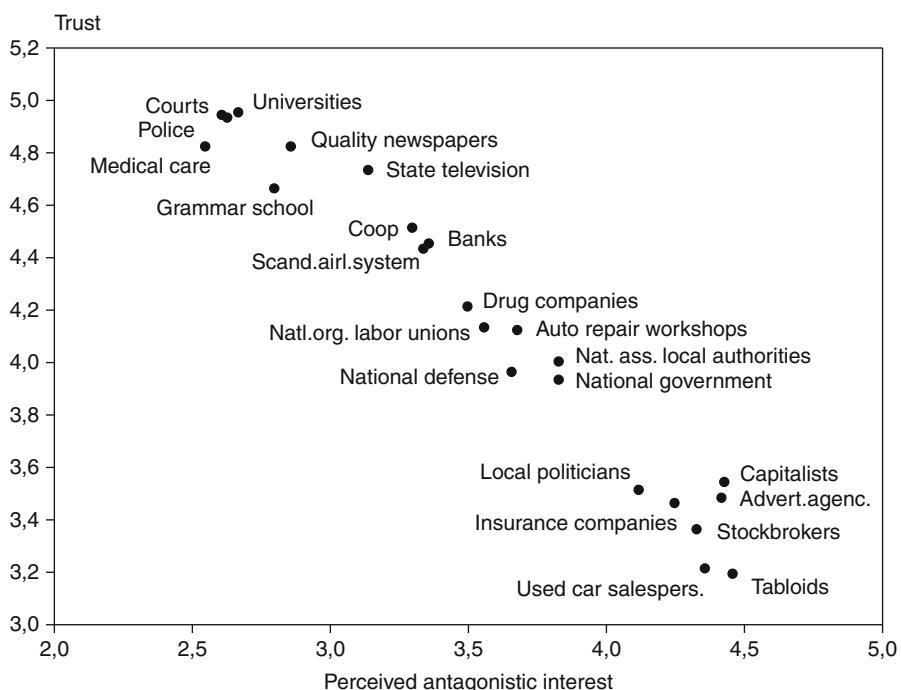

Fig. 25.4

Trust and perceived antagonistic interest of different actors. This figure has been published previously as Fig. 1 in Sjöberg (2008a)

## Risk and Policy

---

One of my earliest papers on risk was an analysis of the conflict between experts and the public about nuclear power (Sjöberg 1980). In the heated debates of the time – and they are not less heated now – both parties were unwilling to listen to each other, and both parties suspected each other of hidden agendas. In the time since then, there have been some notable successes of risk communication, e.g., by the Swedish corporation, SKB, which is working on siting a repository for spent nuclear fuel. This is a notoriously difficult social and political problem in many, perhaps most, countries with nuclear power programs. Only Sweden and Finland have so far been able to proceed to the final stage of the siting process (Sjöberg 2004b, 2008b). The clues to success appear to be:

- Decreased concern over nuclear risks
- Increased emphasis on benefits of nuclear power and worry over climate change
- Information campaigns in the local area
- Open decision making and willingness to let people take part in the process
- An area where many people work in the nuclear industry

Siting issues of this kind are contentious and must be so (Sjöberg 2001b, c). There is no final answer to the size of the “real” risk, and complete unanimity can only be achieved in a totalitarian society, as was the case in Eastern Europe before the fall of the Berlin Wall and the dissolution of the Soviet Union (Sjöberg et al. 2000a). In (Sjöberg 2006a) I tell the story of an impossible “Utopia,” where everybody agrees that risks are large or, more typically, that they are negligible. There are great risks with risk denial. Society tends to regulate risks after the fact, once disasters have happened, rather than plan in order to avoid them. Another paper is about neglected risks and how we can, hopefully, learn from history in order to be more prudent in the future (Sjöberg 2007b). The Precautionary Principle is a dominating policy principle in the European Union. Sjöberg (2009) studied attitudes toward this principle. It was found to be yet another factor contributing to risk perception, probably increasingly important in the future and not only in the EU. Attitudes towards the Precautionary Principle could also be influenced by perceived risk.

The trials and tribulation of risk perception have often been evoked as a way of explaining obvious “irrationalities” of risk policy. One such a case of irrationality has to do with the allocation of economic resources for risk mitigation, see (Sjöberg 1999b). Data from Sweden (Ramsberg and Sjöberg 1997) and other countries (Morral 1986; Tengs et al. 1995) have shown that there are tremendous differences between different hazards and sectors of society with regard to how much society is willing to pay for “saving a life.” In a separate study, we found that people do accept a certain level of variability in allocated resources, but far from what is actually the case (Ramsberg and Sjöberg 1998).

How important is “risk” for policy decisions? For example, do people demand more risk mitigation if the probability of an accident or other type of negative event is higher? It would seem that such must be the case. However, here as so often in risk perception research, things are not what they seem to be (Sjöberg 2003d). People’s judgments of demand for risk mitigation are mostly related to consequences, not to probabilities. And probabilities are almost the same as perceived risks. Two papers (Sjöberg 1999a, 2000a) demonstrate this thesis empirically. Hence, although “risk” is an ambiguous term with components of both probability and consequences, it is interpreted, in natural language discourse, mainly as probability.

This principle can also be demonstrated with a simple-thought experiment: Which risk is largest – to catch a severe cold or to be contaminated with the HIV virus? Most people say “to get a cold.” But which risk should one be most careful to be protected from? Most people say “the HIV virus.” Hence, risk and demand for protection are separated, and demand for protection is governed by the severity of the consequences.

Experts play a central role in risk debates and decision making. There have been studies of experts claiming that they have a qualitatively different approach to risk perception than the public (Slovic et al. 1979). They were said to make risk perception judgments unaffected by the dimensions of the Psychometric Model and to make judgments close to the “true risks.” However, this claim was based on a very small data set and on experts of doubtful competence (Rowe and Wright 2001). I showed that experts had similar risk perception dynamics to those of the public (Sjöberg 2002a). Further data confirming this conclusion is found in Sjöberg and Drottz-Sjöberg (2008a) and Sjöberg (2008c). The latter paper suggests that the original claim of “objective” risk judgments by experts could be due to two factors: they made judgments of “risk” without a specified target, giving general risk judgments rather than personal ones, and their judgments were correlated with “dread” and “new risk” – factors that have a weak explanatory power in accounting for perceived risk (Gardner and Gould 1989). It should be noted that risk due to hazardous technologies are typically related to general risk, while lifestyle risks are related to personal risk (Sjöberg 2003b).

Slovic, Fischhoff, and Lichtenstein (Slovic et al. 1979) found that both experts and lay people made, on the average, reasonably accurate judgments of annual fatalities due to a number of different hazards. Experts’ mean judgments showed a stronger correlation with technical estimates of fatalities, but both sets of data show similar trends in this respect. These results are interesting and reflect what has been called “The wisdom of crowds” by Surowiecki (Surowiecki 2004). However, when the instruction was to rate “risk” rather than the annual number of fatalities the groups diverged strongly, and it was clear that other factors than technical risks entered the judgments made by nonexperts. The effect of such “other factors” can be construed as effects of consequences of accidents rather than probabilities of technical risk estimates.

Risk judgments are typically low when experts judge risks within their area of responsibility, but otherwise they are comparable to risk judgments made by the public. See  Fig. 25.5 which shows large differences between experts and the public, but only for cases where experts have responsibility for risk management.

It is doubtful that the low risk judgments made by experts are mainly based on superior knowledge. It is more likely that they are also the consequence of two factors: self selection and social validation. People seldom enter a profession which they see as dangerous and full of risks to themselves and others (Drottz-Sjöberg and Sjöberg 1991). And once they have been accepted in a professional environment, they are surrounded by others who reinforce their initially low risk perceptions, driving them even lower.

“Stakeholders” constitute a similar case, see Sjöberg (2003a). People, who are actively involved, for or against a contentious risk topic such as a siting of dangerous waste, tend to have views quite different from those of the public at large. For this reason, it is dangerous for decision and policy makers to listen merely to the “stakeholders” who are not representative. “The silent majority” will make its voice heard once it gets a chance to do so, as for example in a local referendum.

Politicians’ risk attitudes and perception have seldom been studied. Sjöberg and Drottz-Sjöberg (2008b) describe an investigation of a large group of Swedish politicians who were

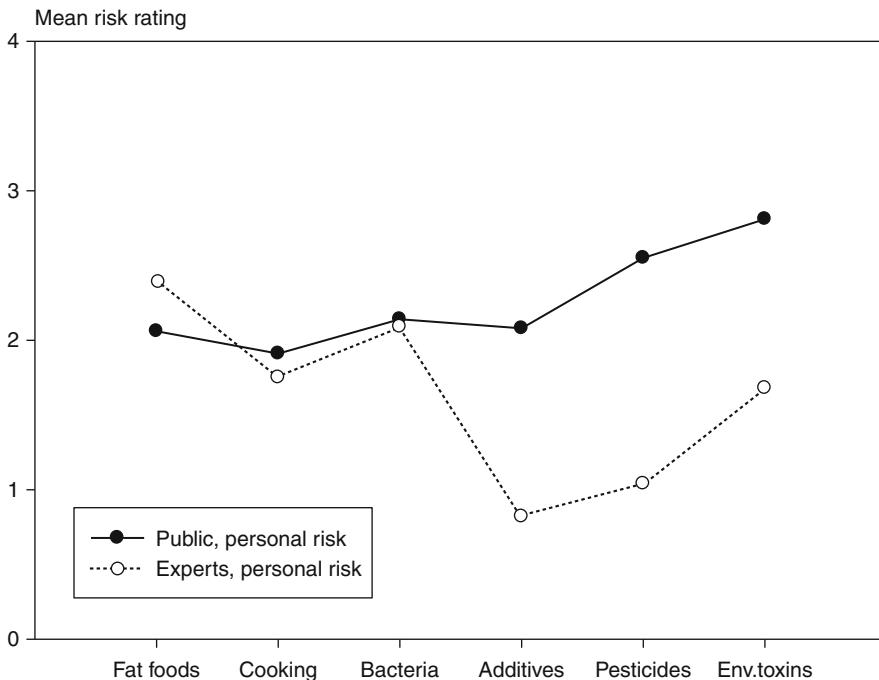

Fig. 25.5

Personal risk ratings, experts, and the public. Y-axis scale refers to size of perceived risk, where 0 = no risk and 5 = a large risk

active in local municipality boards. The major conclusion from this study is that politicians were quite similar to the public in their risk attitudes and perceptions. This was so in spite of the fact that they were older than the average citizen and had a higher level of education. A large proportion of them were men, and men otherwise tend to have lower risk perceptions than women (Davidson and Freudenburg 1996).

## Two Applications

Sjöberg (2008c) and (2005) are reports of risk perception studies of genetically modified food and terrorism, respectively. The first application study shows how the concepts (risk sensitivity, interference with nature, attitude to a hazardous technology, and the distinction between personal and general risks) discussed in the present chapter lead to more powerful models of perceived risk than the traditional ones. It also shows that GM food is a technology which is very little liked by the public in Sweden, similar to what is the case in the EU as a whole and different from the USA. The topic of GM food, and gene technology more generally, is becoming increasingly important. Risk and benefit both play a role, and perhaps benefits are more important than risks for the views of the public. Experts tended to have strongly divergent views as compared to the public. Basic tenets of the experts, such as GM food being in principle no different from food from traditional plant or animal breeding, were simply not believed by the public.

The second application study was about terrorism. There are several new aspects which are brought up by a study of the perceived risk of terrorism (Lee et al. 2010). One is antagonism. Another is general suspiciousness, a personality variable. A third is that of conceptions about the functioning of the terrorists, whether they are rational or not. The study made it very clear that any new major hazard will require its own analysis and new concepts – another important reason why the traditional models of risk perception are insufficient.

## Further Research

---

The differences in risk perception among various groups need more descriptive research and theoretical explanations. Only scientific and technical experts have been investigated to any great extent, while politicians, journalists, and various practitioners such as medical doctors have been little investigated. Yet, all those groups play important roles in societal risk management.

The role of values for risk perception is not well understood. It has been very difficult to find ways of measuring values which show them to be important factors in risk perception. This may be because they in fact are not as important as many people believe them to be, or it may be because our measurement instruments are not good enough, or simply that we do not yet measure the most directly relevant values. Religious values have been little investigated in relation to risk perception.

There has been little work on the life-span development of risk perception from childhood to old age. There are many topics of interest here, such as when gender differences in risk perception tend to appear (Sjöberg and Torell 1993).

Risk perception work originated with the concerns of elites (managers, experts, politicians) over what they saw as irrational worries of the public. Such worries constituted, in the view of many, obstacles to the “rational” exploitation of technologies and natural resources. However, one could turn the question in the opposite direction: why are some people very *unconcerned* about risks? Neglect of risks has sometimes led to disasters. “Whistle-blowers” can make a very useful societal contribution, but they often have to take great personal risks when they do so.

There are many important problems connected with how various groups conceive of each other, such as experts and nonexperts, politicians, and their constituencies.

New technology introduces new risks, and risk perception researchers should be in the forefront of research. Terrorism is one example, nanotechnology another. New concepts are needed. Society faces new and important risks, and the social and psychological factors they bring on to the stage call for evermore research in the fascinating field of risk perception.

## Conclusions

---

A number of principles can be derived from the work reviewed in the present chapter:

1. Personal and general risks differ as to level and, structure; they tend to have different correlates.
2. Models of risk perception need to be extended beyond the Psychometric Model and Cultural Theory. A number of important additional dimensions are mentioned in the chapter (risk sensitivity, interference with nature, attitude to a hazardous technology, and

- the distinction between personal and general risks). The level of explained variance of perceived risk can be enhanced to some 60–70% (Sjöberg 2004a).
3. Trust is important for understanding perceived risk, both social and epistemic. The latter type of trust tends to be the most important one. Perceived antagonistic interest is another important dimension of the general trust concept.
  4. Probabilities and consequences are both important for understanding risk related attitudes, but severity of consequences is more important than probabilities.
  5. Experts tend to have a different risk perspective from that of the public. They rate risks as lower, but only in cases where they have direct responsibility for risk management.
  6. Specific hazards require an analysis in their own right. General risk dimensions are insufficient to catch all the unique aspects brought in by new hazards.

**Abstract:** This chapter provides an overview of key conceptualizations of and evidence for the role of feelings in perceived risk. Influence from feelings in judgment and decision making was first recognized nearly three decades ago. More recent work has developed models that generalize the mechanisms by which feelings operate. Feelings may play multiple roles in judgment and decision processes, including providing information, enabling rapid information processing, directing attention to relevant aspects of the problem, facilitating abstract thought and communication, and helping people to determine social meaning and to act morally. Feelings may be anticipated or experienced immediately and either integral (attached) to mental representations of the decision problem or incidental (unrelated), arising from moods or metacognitive processes. A rich repertoire of psychological concepts related to risk, such as appraisal and memory, can be used to help explain the mechanisms by which affect and analysis might combine in judgment and decision making. Phenomena such as psychophysical numbing, probability neglect, scope insensitivity, and the misattribution of incidental affect all provide empirical support, albeit fragmented, for the important influence of feelings. Future research needs to utilize multiple dependent variables and methodological approaches to provide convergent evidence for and development of more sophisticated descriptive and predictive models. An additional direction for future research is to develop tools that help risk communicators and risk managers to address complex, multidimensional risk problems.

## Introduction

---

The study of the role of feelings in risk judgments began with a focus on regret and disappointment theories within an economic framework (Bell 1982; Loomes and Sugden 1982) and experimental manipulations of mood (Johnson and Tversky 1983; Isen and Geva 1987). Nearly three decades later, researchers have amassed considerable evidence recognizing the importance of feelings in shaping risk perceptions. Numerous approaches have been used to capture and explicate feelings-based processes in a wide variety of domains. Research has moved on from establishing that feelings play a role, to developing models that generalize the mechanisms by which risk perceptions are influenced (Pham 2007; Slovic 2010). This chapter provides an overview of key conceptualizations of and evidence for the role of feelings in risk judgments. An intentionally wide-ranging use of the term “feelings” is employed to include studies of affect, emotion, and mood, reflecting the diverse theories and methods that comprise this field of research.

## Conceptualizations

---

### Dual-Process Theories: Recognizing Reliance on Feelings

---

Neoclassical economics asserts that individuals, over time and in aggregate, process risk information only in a way that maximizes expected utility (von Neumann and Morgenstern 1947). From this perspective, judgments are based on a utilitarian balancing of risks and benefits and feelings are only a byproduct of the cognitive process. That is, emotions such as fear, dread, anger, hope, or relief are experienced *after* the risk-benefit calculation is complete.

More recently, dual-process theories have conceptualized perceptions of and responses to risk as typically reflecting two, interacting, information-processing systems (Damasio 1994; Epstein 1994; Sloman 1996; Kahneman 2003; Bechara and Damasio 2005). The “analytic” system reflects the slow, deliberative analysis we apply to assessing risk and making decisions about how to manage hazards. The “experiential system” reflects fast, intuitive, affective reactions to danger. “Affective reactions” refer to a person’s positive or negative feelings about specific objects, ideas, images, or other target stimuli. Feelings may also reflect emotions (intense, short-lived states of arousal accompanied by expressive behaviors, specific action tendencies, and conscious experiences, usually with a specific cause,Forgas 1992) and moods (feelings with low intensity, lasting a few minutes or several weeks, often without specific cause, Isen 1997). From the dual-process perspective, feelings that arise from or amidst the experiential mode of thinking are influential *during* judgment and decision-making processes (Schwarz and Clore 1988).

Reliance on feelings in the process of evaluating risk has been termed “the affect heuristic” (Finucane et al. 2000a). Feelings provide potentially useful inputs to judgments and decisions, especially when knowledge about the events being considered is not easily remembered or expressed (Damasio 1994). Many theorists have also given feelings a direct and primary role in motivating and regulating behavior (Mowrer 1960; Zajonc 1980; Damasio 1994; Isen 1997; Kahneman 2003; Pham 2007). Positive feelings act like a beacon of incentive, motivating people to act to reproduce those feelings, whereas negative feelings motivate actions to avoid those feelings.

Since recognizing the importance of feelings, scholars have attempted to clarify the nature and timing of their influence on risk perceptions. Distinguishing the impact of specific emotional states is of concern because the desirability of the impact may be a function of the intensity, valence, and appraisal content of the emotion. For instance, Lerner and Keltner (2001) have shown that fearful people express pessimistic risk estimates and risk-averse choices, whereas angry people express optimistic risk estimates and risk-seeking choices. Similarly, the importance of anticipated regret and disappointment has been demonstrated by Zeelenberg et al. (2000) and Connolly and Butler (2006). The timing of feelings is also critical. In analyses of the time course of decisions, Loewenstein and Lerner (2003) distinguish between anticipated emotions (beliefs about one’s future emotional states that might ensue after particular outcomes) and immediate emotions (experienced when making a decision, thereby exerting an influence on the choice process). (For similar distinctions see Kahneman 2000.) Loewenstein and Lerner further identified two types of immediate emotions, namely, integral emotions (caused by the decision problem itself, such as feelings about a target stimulus or available options) and incidental emotions (caused by factors unrelated to the decision problem at hand, such as mood or cognitive fluency); see also Bodenhausen (1993) and Pham (2007). Empirical demonstrations of the influence of integral and incidental feelings on a wide variety of judgments and decisions are reviewed below.

In sum, early models of judgment and decision making emphasized cognitive aspects of information processing and viewed feelings only as a byproduct of the cognitive process. More recent models, however, give feelings a direct and primary role in motivating and regulating behavior in response to risk. Feelings may be anticipated or immediate and either integral to the decision problem or incidental, arising from moods or metacognitive processes. Identifying the role of feelings and how they interact with cognitive processes is the current focus of scientific inquiry for many researchers.

## Functional Frameworks: Identifying the Roles of Feelings

---

In recent work, Peters (2006) proposed a framework to capture four roles that feelings play in judgment and decision processes. The first role is to provide information about the target being evaluated. Based on prior experiences relevant to choice options (integral affect) or the result of less relevant and ephemeral states (incidental affect), feelings act as information to guide the judgment or decision process (Slovic et al. 2002). The second role is as a spotlight. The extent or type of feelings (e.g., weak vs. strong or anger vs. fear) focuses the decision maker's attention on certain kinds of information, making it more accessible for further processing. Third, feelings may operate as a motivator of information processing and behavior, influencing approach-avoidance tendencies (Frijda et al. 1989; Zeelenberg et al. 2008). Incidental mood states may also motivate people to act in a way that maintains a positive mood (Isen 2000). A fourth role is to serve as a common currency in judgments and decisions, allowing people to compare disparate events and complex arguments on a common underlying dimension (Cabanac 1992). Integrating good and bad feelings is easier than trying to integrate multiple incommensurate values and disparate logical reasons. A similar functional framework has been proposed by Pfister and Böhm (2008), who emphasize the role of feelings in providing information, directing attention to relevant aspects of the problem, and enabling rapid information processing.

An additional function of feelings, according to Pfister and Böhm (2008), is to generate commitment to implementing decisions, thus helping people to act morally, even against their short-term self-interest. Roeser (2006; 2009; 2010) also highlights the importance of emotions in providing moral knowledge about risks and that emotions are needed to correct immoral emotions. Kahan (2008) describes emotion as providing "a perceptive faculty uniquely suited to discerning what stance toward risk best coheres with a person's values." In his cultural evaluator theory, Kahan regards emotion as entering into risk judgments as a way of helping people to evaluate the social meaning of a particular activity against a background of cultural norms and to express the values that define their identities. When people draw on their feelings to judge risk, they form an attitude about what it would mean for their cultural worldviews for society to agree that the risk is dangerous and worthy of regulation. Kahan distinguishes the role of feelings not as a heuristic but as unique in enabling a person to identify a stance that is "expressly rational" for someone with commitment to particular worldviews. Consistent with his theory, Kahan et al. (2007) found that the impact of affect relative to other influences (such as gender, race, or ideology) was significantly larger among people who knew a modest or substantial amount about nanotechnology. This contrasts with the heuristic perspective in which affect is expected to play a larger role when someone lacks sufficient information to form a coherent judgment.

Finally, feelings may help to facilitate abstract thought and communication (Finucane and Houpis 2006). Feelings help people to think abstractly because they link abstract concepts (e.g., good, bad) to the physical or sensory world. Without such links, judgments are slower and less accurate. One subtle demonstration of the link between affect and analytic thought is research showing that positive words are evaluated faster and more accurately when presented in white font, whereas negative words are evaluated faster and more accurately when presented in black font, despite the brightness manipulation being orthogonal to the valence of the words (Meier and Robinson 2004). Similarly, Meier and Robinson (2004) showed that people assign "goodness" to objects high in visual space and "badness" to objects low in visual space. Linking abstract concepts to physical or sensory experiences helps the analytic system to interpret the meaning of stimuli so that they can be incorporated in cognitive calculus.

In sum, several roles of feelings in judgments and decisions about risk have been identified. Additional roles may be articulated as diverse disciplines apply their perspectives. Which role dominates in any particular judgment or decision is likely to be a function of multiple factors (e.g., task demands, time pressure, preferred decision style, social norms).

## Clarifying the Relationship Between Feelings-Based and Cognitive Processes

---

Despite recognition that feelings-based and cognitive processes represent interdependent systems in decision making (Damasio 1994; Epstein 1994; Sloman 1996; Kahneman 2003; Bechara and Damasio 2005), theory and research to date have struggled to convey the exact nature of the relationship. The cognitive origins of behavioral decision theory may have encouraged people to assume that the domain of feelings is qualitatively different and functionally separate from the domain of cognition. Such distinction is reflected in the dichotomies often portrayed in this field, such as irrational emotions disturbing rational cognitions, intuitive feelings dominating deliberate thinking, and hot affect overwhelming cold logic (Pfister and Böhm 2008). However, overlapping commonalities in the systems have been noted also. For instance, the processing of experiences may be involved in both affective and analytic approaches. Johnson and Lakoff (2002; Lakoff and Johnson 1999) point out that even our most abstract thinking (mathematics, for example) is based on our “embodied” experiences. They describe how the locus of experience, meaning, and thought is the ongoing series of physical interactions with our changing environment. Our embodied acts and experiences are an important part of our conceptual system and in making sense of what we experience.

Clarifying the mechanisms by which feelings and cognitions are related and integrated in human judgment and decision making is a critical next step in understanding perceived risk. Finucane and Houpis (2006) recommend expanding and linking the risk-as-analysis and risk-as-feelings approaches by adopting a “risk-as-value” model. This model emphasizes that responses to risk result from a combination of analysis and affect that motivates individuals and groups to achieve a particular way of life. Derived from dual-process theories, the risk-as-value model implies that differences in perceived risk may arise from differences in the analytic or affective evaluation of a risk or the way these evaluations are combined. As research moves from simply describing variance to predicting it, having multiple potential loci for such variation with different substantive interpretations will be useful. The risk-as-value model does not posit a specific rule for combining affective and analytic evaluations, although traditional information integration rules (adding, averaging, multiplying) may be applicable in some contexts. When the implications of both affective and analytic evaluations are congruent, the processes may be more likely to combine additively. However, incongruence may result in greater emphasis on analytic or affective processing, depending on an array of task, decision-maker, or context variables (e.g., analysis may be increased if it is viewed as more reliable, but may be attenuated under time pressure).

The relationship between affective and analytic processes may be more fully explained by drawing on the rich repertoire of empirically tested concepts related to the psychology of risk, such as appraisal and memory. Lerner and Keltner’s (2000) appraisal-tendency theory suggests that emotions arise from but also elicit specific cognitive appraisals. For instance, fear

arises from and evokes appraisals of uncertainty and situational control, whereas anger is associated with appraisals of certainty and individual control (Lerner and Keltner 2001). Lerner et al. (2003) showed that anger evokes more optimistic beliefs about risks such as terrorism, whereas fear evokes greater pessimism about risks. Weber and Johnson's (2006) preferences-as-memory framework highlights how risk judgments are made by retrieving relevant (cognitive and affective) knowledge from memory. Framing normatively equivalent information positively or negatively (e.g., 90% lives saved vs. 10% lives lost) influences preferences because the different descriptions prime different representations in memory (predominantly positively or negatively valenced). Also drawing on modern concepts of memory representation, retrieval, and processing, Reyna and colleagues (Reyna and Brainerd 1995; Reyna et al. 2003) have proposed a dual-process model called fuzzy-trace theory (FTT). FTT posits that people form two kinds of mental representations. The first, verbatim representations, are detailed and quantitative. The second, gist representations, provide only a fuzzy trace of experience in memory. People tend to rely primarily on gist, which captures the meaning of experience, including the emotional meaning. FTT differs from other dual-process models by placing intuition at the highest level of development, viewing fuzzy intuitive processes as more advanced than precise analytic processes (Reyna 2004).

In sum, the mechanisms by which feelings and cognitions are combined in judgment and decision making need to be clarified. Studies from a wide range of disciplines, including cognitive and social psychology, emotion and motivation, economics, decision research, and neuroscience, need to be integrated to develop models that explicitly specify possible causal constructs or variables that influence reactions to risk, allow for individual and group differences in these variables or in the relationships between them, and generalize across risk domains and contexts. Such model-based research can broaden our understanding of risk perceptions specifically and of basic psychological phenomena more generally.

## **Empirical Support**

---

This section briefly reviews empirical support for the role of feelings in risk judgments and decisions. Although the empirical literature seems fragmented and sometimes inconsistent, evidence for the influence of emotion, affect, and mood is compelling.

### **Integral Feelings as a Proxy for Value**

---

Early evidence of the role of feelings in risk perceptions came from studies showing that “dread” was the major driver of public acceptance of risk in a wide range of contexts, including environmental hazards such as pesticides, coal burning (pollution), and radiation exposure from nuclear power plants (Fischhoff et al. 1978). This observation led to many studies looking at how risk judgments are influenced by feelings that are integral (attached) to mental representations of hazardous activities, technologies, or events (Loewenstein et al. 2001; Slovic et al. 2002). In the first paper published on the affect heuristic, Finucane et al. (2000a) demonstrated that providing information about benefit (e.g., of nuclear power) changed perceptions of risk and vice versa. They also showed that whereas risk and benefit (e.g., of natural gas, chemical fertilizers) tend to be positively correlated across hazards in the world,

they are negatively correlated in people's judgments. Moreover, this inverse relationship between perceived risks and benefits increased greatly under time pressure, a situation in which opportunity for analytic deliberation was reduced. Although subconscious cognitive processes cannot be ruled out entirely, these results support the notion that in the process of judging risk, people may rely on feelings as a source of information about whether or not they are at risk and how they should respond.

Underpinning processes such as the affect heuristic are images, to which positive or negative feelings become attached through learning and experience. Images include perceptual representations (pictures, sounds, smells) and symbolic representations (words, numbers, symbols) (Damasio 1999). In an influential series of studies using the Iowa Gambling Task, Damasio, Bechara, and colleagues (Bechara et al. 1994; Damasio 1994; Bechara et al. 1997) proposed that in normal individuals, emotional responses evoked by objects are stored with memory representations (images) as somatic markers of these objects' value (for challenges to the original interpretation, however, see Maia and McClelland 2004; Fellows and Farah 2005). Other research suggests that more vivid, emotionally gripping images of harm are more salient than emotionally sterile images, making those risks more likely to be noticed, recalled, and responded to (Hendrickx et al. 1989; Sunstein 2007). One explanation for this vividness effect may be that initial affective responses to an object seem to trigger a confirmatory search for information that supports the initial feelings (Pham et al. 2001; Yeung and Wyer 2004), possibly increasing the subjective coherence of judgments based on affect (Pham 2004). Another explanation may relate to the inherently strong drive properties of integral feelings, which motivate behavior and redirect action if necessary (Frijda 1988).

A simple method for studying the relationship between affect, imagery, and perceived risk is called affective image analysis, a structured form of word association and content analysis (Slovic et al. 1991; Benthin et al. 1995; Finucane et al. 2000b; Jenkins-Smith 2001; Satterfield et al. 2001). This method allows researchers to examine the distribution of different (sometimes conflicting) meanings of risk across people and to identify and explain those images that carry a strongly positive or negative emotional charge. For instance, Finucane et al. (2000) asked study participants to free associate to the phrase "blood transfusions." Associations included "HIV/AIDS," "hemophilia," "gift giving" and "life saving." Participants were then asked to rate each of their associations on a scale from bad (-3) to good (+3); these ratings were correlated with a number of other measures, such as acceptability of having a transfusion and sensitivity to stigmatization in other risk settings. Affective image analysis was also used in a US national survey by Leiserowitz (2006), who found that holistic negative affect and image affect were significant predictors of global warming risk perceptions, explaining 32% of the variance. Holistic negative affect was also predictive of support for national policies to address global warming, but less predictive than worldviews and values. A content analysis of affective imagery associated with "global warming" revealed that the phrase evoked negative connotations for almost all respondents, but that the most dominant images referred to impacts that were psychological or geographically distant, generic increases in temperature, or a different environmental problem.

In sum, integral affective responses are feelings elicited by real, perceived, or imagined images of the object of judgment or decision. These feelings are predictive of a variety of behavioral responses to risk. Evaluation and choice processes are more likely to be influenced by vivid, emotionally gripping images than pallid representations, possibly because strong feelings trigger a confirmatory information search or strong drive states.

## Psychophysical Numbing

---

Considerable evidence suggests that affective responses follow the same psychophysical function that characterizes our sensitivity to a range of perceptual stimuli (e.g., brightness, loudness). In short, people's ability to detect changes in a physical stimulus decreases as the magnitude of the stimulus increases. Known as Weber's law, the just-noticeable change in a stimulus is a function of a fixed percentage of the stimulus. That is, to notice a change, only a small amount needs to be added to a small stimulus, but a large amount needs to be added to a large stimulus (Stevens 1975). Our cognitive and perceptual systems are designed to detect small rather than large changes in our environment. Fetherstonhaugh et al. (1997) demonstrated this same phenomenon of psychophysical numbing (i.e., diminished sensitivity) in the realm of feelings by evaluating people's willingness to fund alternative life-saving medical treatments. Study participants were asked to indicate the number of lives a hypothetical medical research institute would have to save to merit a \$10 million grant. Nearly two-thirds of participants raised their minimum benefit requirements to warrant funding when the at-risk population was larger. A median value of 9,000 lives needed to be saved when 15,000 were at risk, compared with a median of 100,000 lives when 290,000 were at risk. In other words, 9,000 in the smaller population seemed more valuable than saving ten times as many lives in the larger population. Psychophysical numbing or proportional reasoning effects have been demonstrated also in other studies (Baron 1997; Friedrich et al. 1999).

In striving to explain when feelings are most influential in judgments about saving human lives, several researchers have explored the "identifiable victim effect" (Jenni and Loewenstein 1997; Kogut and Ritov 2005; Small and Loewenstein 2005). For instance, Small et al. (2007) asked participants to indicate how much they would donate to a charity after being shown either statistical information about the problems of starvation in Africa ("statistical victims") or a photograph of a little girl in Africa and a brief description of the starvation challenges she faces ("identifiable victim"). Results showed that the mean donation (\$2.83) for the identifiable victim was more than twice the mean donation (\$1.17) for the statistical victim, as might be expected given the affectively engaging nature of the photograph of the identifiable victim. Most interestingly, however, when participants were shown both statistical and identifiable information simultaneously, the mean donation was \$1.43. When jointly evaluating statistics and an individual victim, the reason for donating seems to become less compelling, possibly because the statistics diminish reliance on affective reactions during decision making. Small et al. also measured feelings of sympathy toward the cause (the identified or statistical victims). The correlation between these feelings and donations was strongest when people faced the identifiable victim.

In a follow-up study by Small et al. (2007), participants were either primed to feel ("Describe your feelings when you hear the word 'baby'") or to deliberate ("If an object travels at five feet per minute, how many feet will it travel in 360 s?"). Relative to the feelings prime, priming deliberative thinking reduced donations to the identifiable victim. There was no discernable difference of the two primes on donations to statistical victims, as would be expected because of the difficulty in generating feelings for such victims. Similarly, Hsee and Rottenstreich (2004) demonstrated that priming analytic evaluation led to more scope sensitivity and affective evaluation led to more scope insensitivity when participants were asked how much they would be willing to donate to help save endangered pandas. In their study, the number of pandas was represented in an affect-poor manner (i.e., as large dots) or an affect-rich manner (i.e., with a cute picture). The dots were related to a fair degree of scope sensitivity

(mean donations were greater for four pandas than one), whereas pictures were related to scope insensitivity (mean donations for four versus one panda were almost identical). This scope insensitivity violates logical rationality, suggesting that inherent biases in the affective system can lead to faulty judgments and decisions.

In sum, the affective system seems designed to be most sensitive to small changes at the cost of making us less able to respond appropriately to larger changes further away from zero. Consequently, we may fail to respond logically to humanitarian and environmental crises.

## Nonintuitive Consequences

---

Integral affect may lead decision makers astray in several other ways. One example is the phenomenon of “probability neglect” – the failure of people to adjust their decisions about the acceptability of risks to changes in information about their probability. Loewenstein et al. (2001) observed that responses to uncertain situations appear to have an all-or-none characteristic, sensitive to the possibility of strong negative or positive consequences and insensitive to their probability. That is, strong feelings tend to focus people on outcomes rather than probabilities. Rottenstreich and Hsee (2001) demonstrated that while people were willing to pay more to avoid a high than a low probability of losing \$20, they were not willing to pay more to avoid a high than a low probability of receiving an electric shock (a prospect rich in negative affect). Another example comes from Denes-Raj and Epstein’s (1994) jellybeans experiment. When given a chance to draw a winning red bean either from a small bowl containing a single red bean and nine white beans (10% chance of winning) or from a larger bowl containing nine red beans and 91 white beans (9% chance of winning), people tend to choose to draw from the larger bowl, even though the probability of winning is greater with the small bowl. The more abstract notion of probability (the distribution of beans in a random draw process) is less influential than the affective response people have to the concrete representations of objects (seeing multiple red beans). One interpretation of these results is that integral affect provides a largely categorical approach to assessing value. That is, objects are categorized in terms of their significance for well-being, regardless of their probability or magnitude.

The emerging field of neuroeconomics provides convergent evidence for the nonintuitive consequences of integral affect (Trepel et al. 2005). Using methods such as functional magnetic resonance imaging, researchers have examined brain activity in areas known to process affective information. For instance, examining the neurobiological substrates of dread, Berns et al. (2006) showed that when people are confronted with the prospect of an impending electric shock, regions of the pain matrix (a cluster of brain regions activated during a pain experience) are activated. This finding suggests that people not only dislike experiencing unpleasant outcomes, they also dislike waiting for them. Contrary to tenets of economic theory, people seem to derive pain (and pleasure) directly from information, rather than from any material outcome that the information might lead to. Anticipating future outcomes in this way can have a major impact on intertemporal choices (decisions that involve costs and benefits that extend over time). While an economic account of intertemporal choice predicts that people generally want to expedite pleasant outcomes and delay unpleasant ones (Loewenstein 1987), an affective account predicts that people may prefer to defer pleasant outcomes when waiting is pleasant or to expedite unpleasant outcomes when waiting is frustrating or produces dread.

Another nonintuitive feature of feelings-based judgments is that they tend to be more relativistic or reference-dependent than are reason-based judgments. That is, affective responses are often not based on the object or outcome in isolation, but in relation to other objects or outcomes (Mellers 2000). Winning \$10 in a gamble will elicit greater pleasure if the alternative outcome is losing \$5 rather than only \$1. This finding is also consistent with work on the evaluability principle. Hsee (1996) asked people to assume they were music majors looking for a used music dictionary. Participants were shown two dictionaries and asked how much they would be willing to pay for each. Dictionary A had 10,000 entries and was like new, whereas dictionary B had 20,000 entries but also had a torn cover. In a joint-evaluation condition, willingness to pay was higher for B, presumably because of its greater number of entries. However, when one group of participants evaluated only A and another group evaluated only B, the mean willingness to pay was much higher for A, presumably because without a direct comparison, the number of entries was hard to evaluate whereas the defects attribute was easy to translate into a precise good/bad response. Wilson and Arvai (2006) have extended this work to show that in some contexts, enhanced evaluability may not be sufficient to deflect attention away from the affective impressions of the choice pair and toward other decision-relevant risk information, a behavior they call affect-based value neglect.

In sum, strong feelings can lead people to ignore probabilities and magnitudes, possibly because in some situations integral affect can provide only a categorical and reference-dependent approach to valuation. Risk theory and practice will benefit from further explorations of the conditions under which feelings influence attention to and use of different types of information.

## Misattribution of Incidental Feelings

---

In addition to studies focusing on integral feelings, a large number of studies have shown that affective states unrelated to the judgment target (incidental feelings) may influence judgments and decisions (Schwarz and Clore 1983; Isen 1997). An early study by Johnson and Tversky (1983) demonstrated that experimental manipulation of mood (induced by a brief newspaper report on a tragic event such as a tornado or flood) produced a pervasive increase in frequency estimates for many undesirable events, regardless of the similarity between the report and the estimated risk. More recently, Västfjäll et al. (2008) showed that eliciting negative affect in people by asking them to think about a recent major natural disaster (the 2004 tsunami) influenced judgments when the affect was considered relevant (e.g., the perceived risk of traveling to areas affected by the disaster), but also when it was not relevant (e.g., developing gum problems).

In a classic study, Schwarz and Clore (1983) demonstrated that people reported higher levels of life satisfaction when they were in a good mood as the result of being surveyed on a sunny day than people who were in a bad mood as a result of being surveyed on a rainy day. People incorrectly attributed their incidental moods as a reflection of how they felt about their personal lives. In general, the misattribution of incidental feelings to attentional objects tends to distort beliefs in an assimilative fashion. However, research suggests that the influence of incidental affect is not stable nor unchangeable. Rather, it is a constructive process in which the decision maker needs to determine whether their feelings are a reliable and relevant source of information (Pham et al. 2001; Clore and Huntsinger 2007). For instance, Schwartz and Clore

were able to reduce the influence of mood on participants' judgments of well-being with a simple reminder about the cause of their moods (e.g., sunny vs. cloudy weather), presumably triggering people to question the diagnostic value of the affective reaction for the judgment. Importantly, the manipulation changed the diagnostic value of the affective reaction, not the affective reaction itself (Schwarz 2004). Västfjäll et al. (2008) also demonstrated that manipulating the ease with which examples of disasters come to mind can influence risk estimates. Asking participants who had been reminded of the 2004 tsunami to list few (vs. many) natural disasters led to more pessimistic outlooks (measured via an index averaging judgments of the likelihood of positive and negative events), presumably because listing many natural disasters rendered incidental affect relatively less diagnostic for judgments.

Incidental affective states have been shown also to influence the nature of information processing most likely to occur. Negative mood states generally promote a more analytic form of information processing, whereas positive moods generally promote a less systematic, explorative form of processing. From an evolutionary perspective, negative moods may highlight a discrepancy between a current and desired state, signaling a need to analyze the environment carefully (Higgins 1987). Positive moods, on the other hand, may encourage variety seeking in order to build future resources (Fredrickson 1998). Empirical findings are not entirely consistent, however. Both positive and negative moods have been related to increased and decreased systematic processing (Isen and Geva 1987; Mackie and Worth 1989; Schwarz 1990; Baron et al. 1992; Gleicher and Petty 1992; Wegener and Petty 1994; Isen 1997).

In sum, incidental feelings may influence risk judgments and decisions. The diagnostic value of the feelings depends on the context. Fortunately, people can be primed to examine the diagnostic value of their feelings. Incidental feelings may also influence the extent to which individuals engage in systematic processing, although the exact nature of this relationship remains unclear.

## Generalizations

---

Several generalizations can be made about the role of feelings in risk judgments. First, feelings in the form of emotions, affect, or mood can have a large impact on how risk information is processed and responded to. The multiple ways in which feelings influence risk judgments and decisions likely relate to several functions of feelings: providing information, focusing attention, motivating behavior, enabling rapid information processing, generating commitment to outcomes to help people act morally, and facilitating abstract thought and communication. Other functions may be identified with more in-depth explorations from diverse disciplinary perspectives on the relationship between feelings and perceived risk.

Feelings that are integral to objects are often interpreted as signals of the value of those objects, motivating people to approach or avoid accordingly. Assessments of value based on integral affect differ from cognitive assessments in that the feelings tend to be more categorical, reference dependent, and sensitive to vivid imagery. Consequently, judgments based on integral feelings may be insensitive to scale (probability or magnitude) and myopic, emphasizing immediate hedonic consequences (positive or negative) over future consequences. The influence of specific characteristics of feelings (e.g., valence, intensity) on judgment processes needs further investigation.

Milder incidental feelings that are unrelated to the judgment target are also influential in judgment processes. In seeking information to inform their judgments, people tend to use whatever is available to them at the time and sometimes misattribute their mood states or metacognitive experiences as a reaction to the target. A variety of interventions can help people discern the diagnostic value of feelings.

## Further Research

---

Since empirical studies are designed in a specific theoretical and methodological context, no single study can fully answer the complex question of how feelings affect risk perceptions. However, to address the fragmented and sometimes inconsistent findings reported to date, future research needs to work to provide converging evidence for the role of feelings in judgment and decision processes. Converging evidence will be obtained by looking at multiple dependent variables and by using multiple methodological approaches to test alternative explanations of results (Weber and Hsee 1999). Though methods and measures for studying affect may be unfamiliar to many risk researchers, a wealth of tools exist in diverse disciplines studying the form and function of feelings. An interdisciplinary effort including physiological, neurological, psychological, sociological, and other approaches can be used to examine the interplay of affective and analytic processes in risk judgments, to yield the fullest understanding of risk reactions.

Future research also needs to explore new (e.g., qualitative) understandings of how affective and analytic processes (and their interactions) are best represented. A growing body of ethicists and social scientists have criticized purely quantitative approaches as ill-equipped to reflect public conceptualizations of the complex, multidimensional, and often nonmonetary qualities of risks being faced (Stern and Dietz 1994; Prior 1998; Satterfield and Slovic 2004; Finucane and Satterfield 2005; Roeser 2010). Likewise, the seemingly categorical, reference-dependent nature of the affective system may require new approaches to fully explicate nonintuitive consequences of feelings on risk judgments.

Another direction for future research is to evaluate the ecological validity of feelings. Adopting a Brunswikian (Brunswik 1952) approach, Pham (2004) suggests examining (a) the correlation between integral feelings elicited by objects and these objects' true criterion value (the ecological validity of feelings) and (b) the correlation between other available proxies of value and the object's criterion value (the ecological validity of alternative bases of evaluation). The ecological validity of incidental feelings could be examined in a similar fashion.

Finally, in a more practical realm, future research needs to help risk communicators and risk managers to determine the most effective tools for presenting and processing risk information. For instance, research will help to make risk estimates more accurate and risk mitigation behaviors more timely if it informs us of how to make abstract probabilities meaningful, reduce the gap between anticipated and experienced affect, facilitate the integration of non-commensurate metrics, or engage ethical assessments. Practitioners from diverse fields such as health care services, food safety, terrorism prevention, environmental resource management, and disaster preparedness would benefit from a systematic translation of the rich body of research into practice. Tools that account for the role of feelings in a way that facilitates efficient yet sound decision making will enhance our ability to successfully regulate risks.

**Abstract:** In constructing warning messages, analytic-cognitive factors have traditionally been stressed: having script and/or images of sufficient size and legibility which show dangerous consequences and communicate how they can be avoided and safety maintained. Emotional, or affective-cognitive, factors have rarely been considered in the design of warnings. Indeed, employing emotional appeals to persuade an audience is widely regarded to be unethical, smacking of manipulation. However, emotional factors have been employed with great effectiveness in advertising and marketing, sometimes to actually weaken legitimate safety concerns. Advertisements for dangerous products routinely ignore risk or if required present warning information in a form that is easily overlooked or disregarded. However, emerging research on decision-making has found that emotion plays a critical role in reaching optimal conclusions. It is now recognized that emotional or affective-cognitive factors can influence judgment processes in many ways. First, there are immediate emotions involved in the decision itself, and the emotions anticipated to flow from the decision. Second, there are emotions intrinsic to the decision that may be evoked by the message itself, and emotions incidental to the decision that nevertheless may influence the outcome. Third, emotion can influence the degree of rationality or mindfulness in the deliberation itself. Effective warnings must command attention, stimulate memory, and evoke emotion, as well as communicate consequences and safe behavior. In addition, to construct effective warnings, one must recognize the emotions that people are likely to experience in dangerous situations, and help them to understand those feelings and desires in a context of mindfully managing risk.

## Introduction

---

Emotional appeals have historically been viewed as morally inferior to rational presentations of objective risk information. Emotional appeals are often regarded as manipulative and unethical, because they intentionally target processes that may be outside an individual's awareness in an attempt to produce a desired behavior (See Buck and Davis 2010). Emotional appeals have been strongly criticized as diminishing the “manipulee’s” abilities to make free and rational choices (Beauchamp 1988). Threat-based emotional appeals in particular have been described as explicitly using “the force of fear to try to manipulate human behavior” (Hastings et al. 2004), and have been denigrated for creating unnecessary consumer anxiety (Benet et al. 1993). These judgments persist even when critics acknowledge that social advertisers have good intentions (Arthur and Quester 2003). As such, officials often feel obligated to present risk information in a fashion that is as objective as possible, presenting only “factual” information about the numerical risks of a behavior, technology, or situation, and the potential benefits – again, framed in terms of change in objective risk – of a preventive behavior. This is intended to allow the public to make an autonomous, but informed, choice (see Buck and Davis 2010 for a detailed discussion). However, we argue that objectively presenting risk information outside of the context of emotion may not be the best, or morally preferred, strategy for two key reasons.

First, and importantly, emotional appeals have long been employed in the advertising field, where they can promote the mindless acceptance of risk (Buck and Davis 2010). For example, the popular advertising technique of *branding* involves using advertisements to encourage the public to associate emotionally charged images and videos with a certain consumer brand name. The intended outcome of this technique is essentially to increase positive emotions associated with the brand, which in turn directly and positively impacts purchase behavior

(e.g., Greifender et al. 2007; Pritchard and Morgan 1998). For example, through Nike's "Just Do It" campaign, consumers learn to associate with the Nike brand affectively laden images of fit, strong, and attractive elite athletes engaging in action-packed sporting activities, and the associated feelings of accomplishment, pride, and body satisfaction.

The consequences of these types of advertisements to the public may not be dramatic, beyond an increase in consumer spending on Nike products. However, emotional appeals in the media are not always so seemingly innocuous. In televised drug advertisements, the presentation of required information about significant side effects is often presented with images of health and happiness accompanied by soothing music, this emotional content directly contrasting with the information about risk presented often with rapid verbalization. Moreover, many advertising campaigns for tobacco and alcohol products promote unhealthy smoking or drinking behavior by linking their brands to affectively laden images associated with being fun-loving, popular, young, and loved. These types of advertisements have been utilized, with much success, by the tobacco and alcohol industry for decades, and they belie the small "warning labels" imposed on tobacco and alcohol products. In another example, fast food campaigns have successfully linked their brands with emotions associated with family and fun, such as loyalty, love, pleasure, and satisfaction. These emotional appeals in advertising are well-documented and quite effective in creating sustained changes in consumer behavior (e.g., Chaudhuri 2006), including increases in consumption of harmful products like cigarettes or unhealthy foods. These emotional appeals divert attention from potentially harmful effects of these behaviors, resulting in the mindless acceptance of risk on the part of consumers (Buck and Davis 2010).

Effective emotional risk messages by the public health field have the potential to counter these harmful emotional appeals from the advertising industry, and there are relevant examples. For example, cigarette packages in Canada and Brazil have been required to include large color photographs illustrating the harmful effects of smoking: preterm birth, impotence, tooth decay, cancer (Buck and Davis 2010). New US Food and Drug Administration regulations will similarly require such images to be introduced in the USA. However, risk communicators often miss the opportunity to make a difference in these behaviors by attempting to counter the advertising industry's emotional appeals with often ineffective appeals to reason. If emotional appeals are more effective than appeals to reason, it begs the question: Is it really more ethical to present objective and rational risk information when emotional appeals can promote behavior that is in the public's best interest? In a related line of reasoning, Thaler and Sustein (2008) argue that the choice environment and public policy affect decision-making at the individual level, and that policy makers have an obligation to structure choices in such a way that it "nudges" individuals toward decisions that are in their own best interest without forcing these choices.

A second reason that objectively presenting risk information may not be the morally preferred strategy is that, although emotional appeals in risk communication have been seen as unethical, it can be argued that all public health and safety appeals are emotional to some degree, since all perceptions and messages contain some affective component (Zajonc 1980). Indeed, Hilton (2008) argues that though the pragmatic view of communication calls for information to be presented in an objective way so that the decision maker may accurately interpret alternatives and make autonomous decisions, our language is structured in such a way that it always has evaluative properties, and even minor variances in sentence structure convey evaluation and emotion. This assertion is supported by examination of the effectiveness of warnings. A meta-analytic review of warnings indicated that, though warnings have a modest effect overall, there is considerable variability, with some

warnings producing behavior that is actually more unsafe than the behavior of the comparison group who does not receive a warning (Cox et al. 1997). Arguably, if individuals were behaving “rationally” and emotions were not aroused by warning messages, these warnings would either have a positive effect on behavior, or would have no effect if other considerations (e.g., pleasure in the risky behavior) trumped the risk information. However, the presence of these unintended boomerang effects of warnings indicates that there are some “irrational,” and perhaps emotional, effects of messages that are intended to be neutral. Thus, we argue that although emotion has been largely overlooked in the design of safety and public health risk messages, emotion is still present in these messages. If risk communicators always convey some emotion in their messages and warnings (Hilton 2008) and create an environment that predisposes certain choices (Thaler and Sustein 2008), is it truly unethical for them not to carefully target the emotional reactions they want to elicit based on empirical evidence in the field of emotion and decision-making?

Because it may be impossible to present information in a disinterested and unemotional manner, and because emotional appeals have the great potential to counter emotional appeals in the advertising industry that mindlessly promote the acceptance of risk, we submit that it is therefore the responsibility of health and safety officials to use emotions effectively to communicate information necessary for individuals to act in their own best interests. Here, we present support for the use of emotional appeals in warnings and risk messages, supporting the assertion that emotional appeals are not only ethical, but also essential in creating effective risk messages. The chapter reviews research concerning emotion and decision-making, and addresses neurobiological determinants of emotion and the implications for judgment and decision-making involving risk. We note the increasing appreciation of the role of emotion in decision-making and persuasion in recent years, after the long period of relative neglect in which rational information processing was emphasized. We conceptualize emotion in terms of affective cognition, and reason in terms of rational cognition, as detailed later in this chapter. The resulting “new look” in decision and persuasion theory has far-reaching implications for both theory and practice in the social and behavioral sciences. It also has the potential to bring academic theory and research more into line with approaches in the private sector, which has long used emotional appeals very effectively to steer decision-making, and indeed as noted at times deliberately to promote mindlessness and unwarranted risk-taking. We close the chapter with recommendations for future directions in emotional risk communication research, as well as recommendations for effective risk communication strategies that appeal to emotions in systematic and empirically driven ways.

## History

---

### Why Emotional Appeals Can Be Effective

---

It is now recognized that emotion, or affective cognition, can influence judgment processes in many ways. First, there are immediate emotions involved in the decision itself. For example, decisions involving risky sexual behavior can be influenced by arousal, excitement, and enthusiasm that may impede feelings of apprehension that might be anticipated were considerations of security and safety more salient. Second, there are emotions intrinsic to the

decision, and emotions incidental to the decision that nevertheless may influence the outcome. Unwise decisions about having risky sex may be greatly facilitated both by an attractive and engaging partner, and by a party atmosphere evoking the very excitement and arousal that motivate the risky behavior. Third, emotion may influence the degree of rationality or mindfulness in the deliberation itself. Here, we provide evidence for the crucial role of emotions in judgment and decision-making.

## Experienced Emotions and Decision-Making

As Damasio and colleagues have argued, emotion plays a critical role in adaptive judgment and decision-making (e.g., Damasio 1994; Bechara et al. 1997). One category of emotion that influences decision-making is “experienced emotion,” which can be both affective cognitions that are relevant to the decision (anticipatory emotions) and affective cognitions that are not directly relevant to the decision but influence it nonetheless (incidental emotions; Han et al. 2007; Loewenstein and Lerner 2003; Loewenstein et al. 2001). Anticipatory emotions are actually experienced at the time of the decision in response to cognitive representations of potential outcomes, and have been shown to influence behavior (Bagozzi et al. 1998). For example, when thinking about an upcoming vacation, one may actually *feel* excitement or contentment, rather than simply cognitively anticipating that these emotions may occur during the vacation in the future. Similarly, when thinking about being diagnosed with cancer, one may actually *feel* worry, dread, or anxiety, rather than simply cognitively anticipating that these emotions may occur during a hypothetical future diagnosis.

Incidental emotions may also be experienced at the time of the decision, but be unrelated to the decision; these also have a demonstrated relationship with behavioral decisions (e.g., Grunberg and Straub 1992; Harle and Sanfey 2007; Lerner and Keltner 2001; Lerner et al. 2004). For example, one may feel sad after watching a depressing movie, and though that sadness has no relationship to a decision about whether to purchase a product or engage in a particular health or safety-related behavior, it may influence that decision nonetheless. Though experienced emotions, both anticipatory and incidental, can be fleeting, their influence on decision-making can endure long after the emotional experience has ceased, perhaps because of the need to behavioral consistency (Andrande and Ariely 2009).

Additionally, anticipated emotions play a role in decision-making. These refer to cognitive conceptualizations of anticipated future emotions. Though anticipated emotions are not experienced at the time of the decision, they can contribute to the information that influences experienced anticipatory emotions, and can also contribute to decision-making at the cognitive level (Loewenstein and Lerner 2003; Loewenstein et al. 2001). For example, thinking about failing an examination in the future may conjure a cognitive judgment that the failure would be accompanied by disappointment; this anticipated emotion may then trigger actual experienced feelings of disappointment, or anticipatory disappointment. The cognitions of anticipated disappointment may be informed by past experience with failing a test. Similarly, imagining that one has been diagnosed with advanced cancer may conjure a cognitive judgment of anticipated regret of not being screened for cancer sooner; this anticipated regret may or may not trigger actual experienced emotions. In this way, past emotions may be used as a heuristic decision-making tool that informs perceptions of anticipated emotions, and indirectly, anticipatory emotions.

## Interactions of Emotion and Reason in Decision-Making

The influence of emotion on judgment and decision-making is important because, as discussed in the next section, affective cognitive reactions are often more rapid than rational cognitive reactions (e.g., LeDoux 1996; Zajonc 1980). These affective cognitive reactions can differ from rational cognitive reactions in a variety of complex ways (e.g., Ness and Klaas 1994; Lipkus et al. 2005; Loewenstein et al. 2001). These divergences are often resolved when the emotional reactions exert a dominant influence on judgment (e.g., Berridge and Aldridge 2008; Lawton et al. 2009; Norton et al. 2005). Additionally, rational cognitive and affective cognitive reactions can interact and influence each other in a variety of ways (Finucane et al. 2003), such as when anticipated emotions influence anticipatory emotions, as described above. Importantly, rational cognitive conceptualizations do not always influence affective reactions as might be expected. For example, affective reactions to risky consequences are largely unaffected by changes in the probability of those consequences, particularly when the consequences are affectively laden (e.g., Rottenstreich and Hsee 2001).

Recent research has demonstrated that emotion and cognition interact in important and interesting ways, influencing behavior in a manner that is not always anticipated. For example, preliminary longitudinal research has demonstrated that, among individuals who worry about cancer, risk perceptions actually have a *negative* relationship with cancer-preventive behaviors such as quitting smoking (e.g., Klein et al. 2009). Additionally, emotion can interact with framing of risk messages to affect behavioral outcomes. For example, enthusiasm and anger may temper the relationship between framing risk information in terms of gains and risk-aversion, whereas distress may increase this relationship (Druckman and McDermott 2008). That is, among individuals experiencing either enthusiasm or anger, gain-framed messages elicited less risk aversion, whereas among individuals experiencing distress, gain-framed messages elicited more risk aversion. These effects held for both naturally experienced and experimentally induced emotion.

Experienced emotions, both anticipatory and incidental, have important influences on the processing of risk information and on decisions made under risky circumstances. For example, fear tends to promote risk aversion, while anger and happiness tend to promote risk-seeking behavior (e.g., Fischhoff et al. 2005; Johnson and Tversky 1983; Lerner and Keltner 2001; Raghunathan and Pham 1999). It has been argued that individual differences in risk-taking preferences are influenced by tendencies of those individuals' emotional reactions to risky options (Hsee and Weber 1997), which is interesting in light of the fact that there are reliable individual differences in reliance on experiential thinking and affective reactivity (Gasper and Clore 1998; Peters and Slovic 2000). Recent research indicates that risk information may be processed through more affective-cognitive, as opposed to analytic-cognitive, pathways (e.g., Loewenstein et al. 2001; Slovic et al. 2004; Weinstein 1989; Weinstein et al. 2007). Further, affective variables such as feeling of dread may influence public acceptance of risk (e.g., Alhakami and Slovic 1994; Fischhoff et al. 1978; Slovic 1987), or may infuse risk information with meaning (Slovic et al. 2004).

Additionally, emotions affect the way that any information is processed and recalled. For example, positive moods facilitate more heuristic thinking, whereas certain negative moods, such as sadness, facilitate more systematic thinking (e.g., Bless 2000; Clore et al. 2002; Fiedler 2000). Individuals also attend more carefully to mood-congruent information,

and are more likely to recall such information when they are in a mood-congruent state (Bower 1991). This highlights the potential for affect to direct individuals' attention to different risk-related information (Diefenbach et al. 2008), orient individuals in the presence of information (Finucane et al. 2003), and act as a perceptual lens for interpreting situations (Lerner et al. 2003).

In light of the evidence presented above, it follows that risk messages should address affective reactions directly, rather than simply attempting to intervene on cognitive reactions.

## Current Research

---

### Affective Versus Rational Modes of Cognition

---

One of the most widely accepted aspects of the new look in emotion and decision-making is the notion that reason and emotion involve different kinds of cognitive processing, or different sorts of knowledge of events. These differences can be approached in two ways: first in terms of levels of cognitive processing from initial perception/appraisal to higher-order understanding, attribution, and perspective-taking; and second in terms of holistic-syncretic versus sequential-analytic styles of cognitive processing. In both cases, the cognitive process in question can be related to specifiable and observable or potentially observable brain mechanisms. Levels of cognitive processing can be related to levels in the hierarchy of neurochemical systems in the brain that respond to events, and styles of cognitive processing can be related to right- versus left-sided mechanisms in the brain.

### Levels of Cognitive Processing in Judgment

*Initial appraisal.* The process whereby the personal relevance of an event is apprehended for good or ill has been termed *appraisal*. Magda Arnold (1960a, b) saw appraisal to be instinctive and immediate: "even before we can identify something we may like or dislike it... There seems to be an appraisal of the sensation itself, before the object is identified and appraised" (1960b, p. 36). She suggested that appraisal is based upon a multilevel *estimative system*, the most fundamental of which she termed the *subcortical estimative system*. Arnold's conceptualization of appraisal accords well with recent evidence on emotional factors in decision-making. However, although her notion has been highly influential and adopted in a general way, most came to see appraisal as a relatively complex higher-order cognitive process.

*Analytic-cognitive appraisal.* Appraisal was defined by Richard S. Lazarus as *the evaluation of the harmful or beneficial significance of some event*. He and his colleagues demonstrated that the apparent harmfulness or stressfulness of the same stimulus event may be manipulated by manipulating appraisal. Spiesman et al. (1964) showed that a gruesome film depicting an apparently painful circumcision-like ritual in an aboriginal tribe caused strong physiological arousal. However, arousal was lessened by sound tracks which promoted *intellectualization* (describing the scene dispassionately and technically from an anthropological point of view) or *denial* (telling subjects that the ritual, while painful at points, was part of a happy celebration on the occasion of coming into manhood). Moreover, Lazarus and Alfert (1964) demonstrated

that the stress could be cognitively “short-circuited” by giving the denial information beforehand: This condition produced significantly less physiological arousal in viewers than the denial commentary accompanying the film.

In this model, events are first evaluated by a cognitive process termed *primary appraisal*. Information about the circumcision ritual being actually a joyful occasion presumably altered the primary appraisal of subjects to the film. If positive or negative emotions are aroused, coping strategies are selected to deal with the event in a cognitive process termed *secondary appraisal*. Some coping strategies are *emotion-focused*, attempting to reduce distressing emotion or increase positive emotion sometimes by defense mechanisms such as denial and intellectualization. Other coping strategies are *problem-focused*, doing something actively to change the situation for the better.

A major point of contention relating to Lazarus’ analysis is whether appraisal can be instinctive and intuitive, as Arnold (1960) argued, or requires more complex cognitive processing. Lazarus was explicit that cognition is both necessary and sufficient for the occurrence of emotion: “*sufficient* means that thoughts are capable of producing emotions; *necessary* means that emotions cannot occur without some kind of thought” (1991b, p. 353. Italics in the original). However, a classic debate with Robert Zajonc provided evidence that emotions can signal goal relevance, rather than the reverse.

*The Zajonc–Lazarus debate.* Studies by Robert Zajonc and colleagues suggested that an individual could respond preferentially to stimuli without knowing what they were. Using ambiguous stimuli like nonsense syllables and oriental ideograms, they showed that mere exposure to these stimuli produced liking. Persons expressed more liking the more that they were exposed to the stimuli, even though they could not consciously recognize them as being more familiar (Kunst-Wilson and Zajonc 1980; Wilson 1979). On this and other evidence, Zajonc suggested that affect occurs prior to, and independently of, cognition (Zajonc 1980, 1984). This ignited a classic debate with Lazarus (1982a, b).

Examining the arguments advanced by Zajonc and Lazarus reveals that their disagreement rests upon what each defines as “cognition.” Lazarus acknowledged that the comprehension that one’s well-being was at stake could be a “primitive evaluative perception” that may be “global and spherical.” In contrast, Zajonc required that cognition involve some kind of transformation of sensory input – some kind of “mental work” – and he complained that “Lazarus has broadened the definition of cognitive appraisal to include even the most primitive forms of sensory excitation” (1984, p. 117). Thus, Zajonc and Lazarus agreed that some sort of sensory information is required for emotion, but they disagree about what would constitute “cognition.”

*The LeDoux findings.* Joseph LeDoux and his colleagues demonstrated that there is direct sensory input to the amygdala and that this input is necessary for the learning of conditioned fear responses (LeDoux 1994). The amygdalae play a crucial role in responding to emotional events and storing emotional memories, as demonstrated by the Kluver-Bucy syndrome, which appeared when the amygdalae were removed bilaterally in monkeys (Kluver and Bucy 1939). Affected animals lost emotional responding even to innately feared stimuli such as snakes and fire; the animal mouthed even distasteful and painful stimuli such as dirt, feces, rocks, and burning matches.

The classical auditory and visual pathways proceed from the cochlea to the auditory neocortex, and retina to the visual neocortex, respectively. LeDoux and colleagues discovered pathways in the auditory and visual systems that diverge and proceed directly to the amygdalae (LeDoux et al. 1984). Therefore, the amygdalae have their own subcortical sensory inputs.

These inputs appear to constitute evolutionarily primitive early warning systems that trigger fast responses to threatening stimuli essential in the quick “assignment of affective significance to sensory events” (LeDoux 1993, p. 110). LeDoux termed this fast but relatively undifferentiated response to events the “low road” to cognition. The amygdala inputs are several synapses shorter than those of the classical sensory systems and therefore offer “a temporal processing advantage at the expense of perceptual completeness” (p. 112). Microseconds after the initial sensory input is received, more completely processed input enters the amygdalae from the neocortex and other centers associated with higher-order cognition, so that we are able to consciously “know” what caused the emotional reaction: This slower but more differentiated process LeDoux termed the “high road” to cognition.

LeDoux’s research speaks to the fundamental issue of the nature of the brain’s initial response to events. It appears that low road emotional responding precedes and can guide high-road cognition. Moreover, stimulation, lesions, and chemical manipulations (e.g., by drugs) of the central nervous system can lead to apparently complete emotional experiences and goal-directed behavior with no high-level cognitive “reason” for the state. This is the case despite the fact that the responder may recognize that the feelings are inappropriate and be striving unsuccessfully to control them.

The LeDoux studies had an important influence on the Zajonc–Lazarus debate, for they demonstrated that the subcortical amygdalae receive basic information about sensory events before the neocortex. In response, Lazarus (1991a) accepted that there are in fact two levels of cognitive processing: one direct and immediate, the other involving information processing. Lazarus acknowledged what he termed an “automatic mode of meaning generation” (1991a, p. 155). He suggested that there are two sorts of appraisal: one rapid, “automatic, involuntary, and unconscious”; the other “time-consuming, deliberate, volitional, and conscious” (Lazarus 1991a, p. 188).

*Appraisal and the frontal cortex.* The notion that there are multiple levels of cognition can be related directly to different processing and memory systems in the brain, and indeed it accords well with Magda Arnold’s (1960a, b) notion of multilevel “estimative systems.” LeDoux (1994) and Panksepp (1994) distinguished levels of cognition based upon brain mechanisms: “cortico-cognitive” processes are based on the neocortex and hippocampus, and “emotional” processing involves the amygdalae.

A neocortical region involved in the processing of the incentive value of events that receives strong inputs from the amygdalae is the orbitofrontal cortex (OFC), in the front of the brain immediately above the eyes. It has long been known that damage to the prefrontal cortex (PFC) in general and the OFC in particular produces serious deficits in decision-making, emotional processing, and social skills, which may be attributable to an overall insensitivity to future consequences. Damasio and colleagues have suggested that the key to the impairment in patients with OFC damage is their inability to generate normal somatic responses to emotionally charged events. Damasio’s (1994) Somatic Marker Hypothesis states that the positive or negative incentive values associated with appraisal and decision-making are stored as somatic markers in the ventromedial prefrontal cortex (VMPFC), which includes the OFC. Activation of these markers produces bodily feelings that in turn contribute to decision-making. On the other hand, Rolls (1999) suggested that requiring involvement of peripheral somatic processes is unnecessary, and that brain activity in the OFC and amygdalae, and brain structures connected with them, is related to felt emotion directly. Others suggest that the influence of emotion extends beyond valence, or positive–negative reactions, and that specific

emotions – happiness, security, fear, anger, guilt, sex, love, pride, pity, nurturance, resentment, and others – can have specific effects upon judgment and decision-making. We shall return to this issue later in the chapter.

## **Brain Lateralization and Style of Cognitive Processing in Judgment**

Multiple levels of knowledge and decision-making, from basic sensory awareness to higher-order rational cognitive processing, are clearly related to a hierarchy of neurochemical systems objectively visible in brain anatomy. Another concrete aspect of brain anatomy with implications for decision-making is cerebral lateralization. The left and right hemispheres of the brain are different in many respects – in embryological origin, in microstructure, and in gross anatomy – and these differences have functional implications. Most obviously, the left hemisphere (LH) is associated with language in the vast majority of human beings. The functions of the right hemisphere (RH) are less well understood but are the subject of intensive current research.

Lateralization of function appears in vertebrates including fish, reptiles, birds, and mammals (Denenberg 1981, 1984). Species with eyes placed laterally tend to scan for predators with the left eye, indicating RH involvement; while conspecific vocalizations tend to be processed in the LH (Des Roches et al. 2008). In most humans, language is processed in the LH, with Broca's area in the anterior LH associated with language expression and Wernicke's area in the posterior LH associated with language comprehension. Indeed, the human brain is more lateralized than most other vertebrate brains because the size of the corpus callosum, which connects the left and right neocortices, increases greatly during evolution, while the size of the anterior commissure, which connects left and right paleocortical and subcortical regions, does not. For this reason, many paleocortical and subcortical regions of the human brain are more directly connected with the ipsilateral neocortex than they are with corresponding paleocortical and subcortical regions on the other side (Ross 1992).

*Holistic-syncretic versus sequential-analytic styles of cognitive processing.* Tucker (1981) summarized evidence that the LH and RH are associated with different styles of conceptualization. The RH is characterized by an ability to holistically integrate and synthesize analog information from a variety of sources into a form of nonverbal conceptualization termed *syncretic cognition*. In syncretic cognition, sensory, affective, and cognitive elements are fused into a global construct. Syncretic ideation is particularly suited to picking up the affective meaning of complexes of nonverbal information provided by facial expression and gesture, vocal prosody and tone, and body movement and posture. In contrast, the LH is associated with *analytic cognition*, which is characterized by linear and sequential cognitive operations that can logically and rationally differentiate and articulate concepts. Language provides a prime example of analytic cognition. The global, holistic, and nonverbal knowledge of the RH is compatible with emotional cognition, while the verbal, linear, and sequential knowledge of the LH is compatible with rational cognition.

*Brain lateralization and emotion.* There are two major theories of the brain lateralization of emotion. The right hemisphere hypothesis states that the RH is specialized for all emotion processing (Borod et al. 1998), while the valence hypothesis holds that the RH is specialized for negative and the LH for positive emotion (Ahern and Schwartz 1979; Bogen 1985; Davidson 1992). A variant of the valence hypothesis was proposed suggesting that the RH is specialized

for avoidance emotions and the LH for approach emotions (Davidson and Irwin 1999). This answered evidence of LH involvement in emotions such as anger, which although considered to be hedonically negative is considered an approach emotion (Harmon-Jones et al. 2010).

Examination of the literature reveals that the right hemisphere hypothesis appears to be correct for emotional *communication*, both expression and recognition aspects (Borod and Koff 1990; Borod et al. 1986; Etcoff 1989; Ross 1981, 1992; Silberman and Weingartner 1986; Strauss 1986). There is much evidence that systems in the anterior and posterior RH are involved in the display and recognition of emotion, respectively. Buck and Van Lear (2002) suggested that these play roles in *spontaneous emotional communication* that are analogous to roles Broca's and Wernicke's areas in the LH play in the expression and comprehension of intentional symbolic messages, notably language.

The valence hypothesis may be more relevant to the question of the brain loci of emotional *experience*. Despite considerable evidence favoring the valence hypothesis, there are data that are difficult to reconcile. For example, although the theory holds that the LH is involved in positively valenced emotion, there is evidence that disgust is represented in the left insula (Calder 2003; Calder et al. 2000; Straube et al. 2010). This may be compatible with the approach-avoidance version of the valence hypothesis as, like anger, disgust albeit hedonically negative has been described as an approach emotion, and indeed a prosocial emotion, as a common response to disgust is to invite others to experience the disgusting object for themselves (Rozin et al. 1993). On the other hand, evidence that orgasm is based in RH mechanisms (Janszky et al. 2002; Holstege et al. 2003) seems difficult for both the valence and approach-avoidance theory accounts. Ross, Homan, and Buck (1994) suggested an alternate to the valence hypothesis that may answer some of the problems of the original conceptualization. This was based upon a study of patients undergoing the Wada test, where a brain hemisphere is temporarily deactivated by sodium amobarbital in preparation for brain surgery. Before the operation, patients were asked to describe a life event they had experienced that gave rise to strong emotion. During the Wada test while the RH was deactivated, they were asked about the same event. After the operation, they again described the event. Although the RH inactivation did not change the factual content of the life event, eight of the ten patients showed evidence of minimizing or denying primary emotions such as fear or anger. In a few cases, the RH inactivation seemed to produce a change in emotion. A man who described himself as "angry and frustrated" at the inability of physicians to diagnose his condition described himself as "sorry for people that they had so much trouble finding out what was wrong" when the RH was inactivated. A woman who said that she was "mad and angry" at being teased for her epilepsy as a child, when the RH was inactivated stated that she was "embarrassed" at the abuse. When the RH functioning was restored, the patients denied being sorry or embarrassed and insisted that they had been angry.

Ross et al. (1994) suggested that the RH inactivation produced changes consistent with a change in *type* of emotion in addition to valence: specifically a change from selfish to prosocial emotion (Buck 2002). This was consistent with an observation by Buck and Duffy (1980) in LH and RH damaged patients in responding to emotionally loaded slides, which suggested that the RH might be associated with the spontaneous expression of emotion, while the LH is associated with learned display rules: expectations about how and when emotions should be expressed. Specifically, most patient groups accentuated positive displays and attenuated negative displays, as would be expected from display rules, while LH-damaged patients did not.

The Ross et al. (1994) results suggested an extension of this: that the RH is associated with basic emotions, both negative and positive (e.g., the right-lateralization of orgasm), while the LH is associated with social emotions, including the voluntary modulation of RH-mediated basic emotions via display rules (pseudospontaneous communication: Buck and Van Lear 2002). Indeed, social emotions may often appear to be positively valenced because display rules often (but not always) encourage the expression of cheerful and positive albeit perfidious displays that are at variance with the “true feelings” of the responder. For example, Davidson and Fox (1982) demonstrated that social smiling is associated with LH activation in human infants, and interpreted this as consistent with the association of the LH with positively valenced emotions. However, another explanation is that the infants’ social smiles reflect prosocial attachment emotions as opposed to “selfish” pleasure. Indeed, stimuli used to elicit positive emotion may often elicit prosocial emotions as well (e.g., pictures of cute children, a baby gorilla). Unfortunately, stimuli used in these studies sometimes are not sufficiently described to judge whether the positive slides are actually prosocial in nature (e.g., Balconi et al. 2009).

Another consideration relevant to the Ross et al. (1994) hypothesis is that the LH is clearly associated with language, so that linguistically learned and structured display rules may be associated with LH responding regardless of the nature of the emotion being controlled. Moreover, language itself is not necessarily unemotional. Human beings derive pleasure when language is used well and frustration when it is misused, and it makes sense that such “linguistic emotions” are associated both with sociality and with LH processing (Buck 1988, 1994). There are known to be significant connections between Wernicke’s area in the LH and underlying limbic system structures, which exist most clearly in human beings (LeDoux 1986) and this could be a mechanism by which emotional factors are involved directly in language.

While relatively few studies have directly evaluated the Buck and Duffy (1980) and Ross et al. (1994) hypothesis, Shamay-Tsoory et al. (2008) found support in two studies. In the first, they tested the ability of patients with lesions in left versus right PFC to recognize photographs of six basic emotions (happy, sad, afraid, angry, surprised, disgusted from Ekman and Friesen 1975) and seven complex social emotions (interested, worried, confident, fantasizing, preoccupied, friendly, suspicious from Baron-Cohen et al. 1997). Shamay-Tsoory et al. found that left PFC-damaged patients were significantly more impaired in recognizing complex social emotions, and right PFC-damaged patients were slightly albeit not significantly more impaired in recognizing basic emotions. In the second study, they showed pictures of eyes posing basic versus complex social emotions to normal persons in left or right visual field presentations. This found the RH to be significantly better at recognizing basic than complex social emotions, and the LH to be slightly more accurate in recognizing complex social emotions than basic emotions. Shamay-Tsoory et al. (2008) concluded, consistent with Ross et al. (1994), that there is a RH advantage in recognizing basic emotions and an LH advantage in recognizing complex social emotions. The findings of Prodan et al. (2001) are also consistent: They showed that upper facial displays which are more likely to reflect basic emotions are processed in the RH, while lower face displays which more likely reflect the moderating effects of display rules are processed in the LH.

Another study relevant to the lateralization of basic versus social emotions was conducted by Gur and colleagues (Gur et al. 1995), who studied resting metabolism in brain areas associated with emotion. Among other things, results indicated that metabolism was left-lateralized in the cingulate gyrus, and right-lateralized in most ventro-medial temporal

lobe regions of the limbic system and their projections in the basal ganglia. As the amygdalae in the temporal-limbic region are associated with self-preservation, while the cingulate is associated with species preservation in MacLean's (1993) analysis, the pattern of greater relative left-sided cingulate metabolism and greater relative right-sided temporal limbic system metabolism accords well with the Ross et al. (1994) suggestion that selfish emotions are right-lateralized and prosocial emotions left-lateralized.

In conclusion, the evidence regarding the nature of the differences between the LH and RH in emotion is suggestive but not definitive, but attention should be paid to the selfish versus prosocial nature of stimuli as well as their valence and approach/avoidance implications. Studies of the lateralization of the amygdalae and PFC may shed further light on this issue.

*Lateralization of the amygdalae.* There is evidence that the amygdalae are asymmetrical, both structurally (Szabo et al. 2001) and functionally (Baas et al. 2004; Phelps et al. 2001; Schneider et al. 1997). We saw that LeDoux and colleagues showed the amygdalae to be necessary in the conditioned fear response. Subsequent research suggested that the right and left amygdalae are differentially involved in fear. Coleman-Mesches and colleagues found that temporary inactivation of the right, but not the left, amygdala by drug microinjection disrupted the retention of passive avoidance responding in rats (Coleman-Mesches and McGaugh 1995a, b, c), and that inactivation of the right but not the left amygdala attenuated the response to a reduction in reward (Coleman-Mesches et al. 1996). Also, lesions to the right amygdala led to larger reductions in fear responses than lesions to the left amygdala (Baker and Kim 2004). In humans, right temporal lobectomies led to lessened ability to recall unpleasant emotional events, while left temporal lobectomies did not (Buchanan et al. 2006). These results suggest that the right amygdala may make a greater contribution than the left to the memory for aversive experience. Also, Smith et al. (2008) described a case of post-traumatic stress disorder (PTSD) in a patient with no left amygdala, and suggested that because PTSD survived in the absence of the left amygdala, the right amygdala normally plays a greater role in its symptoms: fear conditioning, modulating arousal and vigilance, and maintaining memory for emotional context.

The functions of the left amygdala are not well understood but are the subject of much recent interest on the part of researchers. In a meta-analysis, Baas et al. (2004) found that, in studies of emotional processing, the left amygdala is more often activated than the right, and it appears to be activated by positive as well as negative emotion. Hardee et al. (2008) demonstrated that the left more than the right amygdala discriminated between increases in eye white area that signaled fear versus a similar increase in white eye area associated with a lateral shift in gaze direction, suggesting that parallel mechanisms code for emotional face information. This result is consistent with suggestion by Markowitsch (1998) that the left amygdala encodes emotional information with a relatively greater affinity to detailed feature extraction and language, while the right amygdala responds to pictorial or image-related emotional information in a relatively fast, shallow, or gross response. This analysis is consistent with the syncretic cognition-RH versus analytic cognition-LH distinction considered previously (Tucker 1981).

There are suggestions that the left amygdala is involved in the functioning of a "social brain" whose functioning is compromised in Asperger Syndrome (AS), a core feature of which is impaired social and emotional cognition. Fine et al. (2001) reported a case study of a patient with early left amygdala damage who was diagnosed with AS in adulthood. This patient had severe impairment in the ability to represent mental states (theory of mind, or ToM) in line with the AS diagnoses, but showed no indication of executive function impairment, suggesting both a dissociation between ToM and executive functioning, and that the left amygdala may play

a role in the development of circuitry mediating ToM. Ashwin et al. (2007) found that an AS group showed relatively less activation to fearful faces in the left amygdala and left OFC compared to controls. In contrast, left amygdala hyperactivation in response to emotional faces has been found in Borderline Personality Disorder (BPD: Donegan et al. 2003; Koenigsberg et al. 2009). The contrast between the symptoms of AS versus BPD and left amygdala hypoactivation and hyperactivation may therefore be relevant to understanding the unique functions of the left amygdala.

Both AS and BPD are associated with disrupted interpersonal relations, but for markedly different reasons. AS differs from autistic disorder in that there are no clinically significant delays in language, cognitive development, curiosity, or adaptive behavior other than in social interaction. Major AS symptoms include impairment of social interaction and communication, including deficits in the use of nonverbal behaviors to regulate social interaction (e.g., eye-to-eye gaze, facial expression). There is a typical lack of empathy (awareness of others or their needs), a lack of social or emotional reciprocity, and a preference for solitary activities (American Psychiatric Association 1994). In short, AS (and left amygdala hypoactivation) is associated with something of an obliviousness to other persons.

The pattern of social behavior in BPD is in many respects opposite. Major symptoms of BPD include impulsivity and emotional instability which can involve episodes of intense dysphoria, irritability, anxiety, and inappropriate anger that is difficult to control (American Psychiatric Association 1994). The individual may make frantic efforts to avoid real or imagined separation, rejection, or abandonment; which can lead to unstable and intense interpersonal relationships that alternate between extremes of idealization and devaluation. This pattern of dysregulation may result from a kind of social and emotional hypervigilance (Donegan et al. 2003), which speculatively could be related to left amygdala hyperactivation.

*Lateralization of the prefrontal cortex.* We can continue to consider these issues as we turn to neocortical systems closely connected with the amygdala: the right- and left-sided prefrontal neocortex (PFC) and their subregions. We noted the importance of the PFC in decision-making, particularly, the VMPFC and OFC subregions of the PFC. There is evidence that, like the amygdala, the functions of the PFC are lateralized: We have seen that the amygdala is closely connected with the OFC, and that persons with AS showed relatively less activation to fearful faces in both the left amygdala and left OFC (Ashwin et al. 2007).

Shamay-Tsoory et al. (2008) noted that the Buck and Duffy (1980) analysis implies that, to develop display rules, the child has attained explicit theory of mind (ToM) skills to attribute mental states to others. Also, while emotion recognition has been associated with the right PFC, recognition tasks involving ToM skills are associated with the left PFC. From this, Shamay-Tsoory et al. suggested that the right PFC plays a role in mediating basic emotions and the left PFC has a unique role in complex social emotions.

*Sex differences in brain lateralization.* So, does the left amygdala function with the left PFC along a social-emotional obliviousness to hypervigilance dimension, with normal social behavior and emotional communication requiring a moderate level of functioning? Normal women and men are sometimes said to vary along something of a vigilance-to-obliviousness dimension when it comes to social and emotional communication, so it is of interest that there is evidence of sex differences in amygdala and PFC lateralization. Killgore et al. (2000) hypothesized a redistribution of cerebral functions from the amygdala to the PFC from childhood to adolescence, reflecting greater self-control over emotional behavior. They found that, with increasing age, females showed an increase in PFC relative to amygdala activation in the left hemisphere in

response to fearful faces, whereas males did not show a significant age-related change. (Killgore and Yurgelun-Todd 2001) found both sexes to have greater left amygdala activation in response to fearful faces, while happy faces produced greater right than left amygdala activation in males but not females. Moreover, in women, activity in the left, but not right amygdala has been found to predict subsequent memory for emotional stimuli while right amygdala activity predicts emotional memory in men (Cahill et al. 2004). Cahill (2005) suggested that, in processing emotional experiences, women generally use the left and men the right amygdala, which among other things helps women remember details and men the central ideas of events.

In conclusion, there appears to be considerable evidence that the selfish-prosocial hypothesis is a viable alternative to valence and approach/avoidance hypotheses of cerebral lateralization. Neither the valence hypothesis nor the approach-avoidance analysis seems compatible with the observed sex differences, or the evidence that AS and BPD relate respectively to left (but not right) amygdala hypo- and hyperactivation, or the right-lateralization of orgasm. The selfish-prosocial hypothesis is compatible with these observations and also allows them to be placed in a wider context of the neurochemical basis of socio-emotional functioning including basic sex differences that are explainable in terms of evolutionary theory, with women being more empathic and verbal in accord with their greater caregiving role.

## Valence Versus Discrete Emotion Approaches

---

### Valence Approaches

Valence approaches assume that the effects of emotion on decision-making involve a dimension of positivity-negativity, with positive emotions having similar influences on behavior generally opposed to the influences of negative emotions (Elster 1998). One application of the valence approach isForgas's Affect Infusion Model (AIM), which posits that positive or negative affective states or moods have a persistent influence on judgment and decision-making by influencing the kinds of information people attend to, interpret, and recall (Forgas 1995), as well as attitudes, values, and judgments (Forgas 1999) and attributions for behavior (Forgas et al. 1990). For example, research in this line indicates that those in good moods make optimistic judgments, and those in bad moods make pessimistic judgments (e.g., Schwarz and Clore 1983). Also, positive emotions encourage the use of heuristics or mental shortcuts, while negative emotions encourage more complex cognitive processing (Schwarz 2002).

As noted previously, the somatic marker hypothesis also states that decision-making is guided by emotions (Damasio 1994). This hypothesis is supported by the research that demonstrates that patients with neural abnormalities in areas that govern emotions and feelings demonstrate abnormalities in these emotion and feelings, which in turn results in severe impairment of judgment and decision-making (e.g., Bechara et al. 2000, 2001; Bechara 2004). For example, individuals who have damage in the VMPFC, which as we have seen is an area involved in anticipatory emotional responses to decisions, are unable to feel anticipatory negative emotions associated with a risky gambling decision; thus, these individuals are unable to adapt to a decision-making task that requires them to learn to choose from less risky decks during the gambling process (Bechara et al. 1997). Emotions are thus seen as essential tools that aid in "rational" decision-making, and individuals who are unable to feel normal emotions are thus incapable of making good decisions.

## Discrete Emotion Approaches

More recent research has focused on the role of specific emotions in judgment and decision-making. In contrast to valence theorists, these researchers posit that different emotions can have different influences on behavior, regardless of whether they are the same valence. One such theory, the Appraisal Tendency Framework, divides emotions on a series of appraisals, including valence, but also other appraisals such as approach-avoidance (Han et al. 2007; Lerner and Keltner 2000). Research in this line has demonstrated that anger and fear, both negatively valenced emotions, have opposite influences on risk processing, such that anger causes individuals to be risk-seeking, whereas fear causes individuals to be risk-averse (Lerner and Keltner 2001).

*Evolutionary theory:* Another discrete emotion approach to persuasion and decision-making involves evolutionary theory. This approach suggests that affective stimuli can arouse specific emotions which motivate thoughts and actions consistent with the evolutionary functions of the emotion in question (Keltner et al. 2006). The evolutionary approach predicts that the effectiveness of an emotional appeal will depend upon the fit between the particular emotion and the context: A particular emotional appeal may be effective in one context and ineffective or counter-effective in another.

As an example, Griskevicius and colleagues (2009) showed that two emotions with clear evolutionary functions – fear and romantic desire – have different effects when combined with two different persuasive tactics from Cialdini and Goldstein (2004). One tactic used the principle of social proof: that if many others are doing it, it must be good; the second used the principle of scarcity: if it is rare, it must be good. Social proof (#1 product in the country!) was effective following the fear appeal but not the romantic desire appeal, while in contrast the scarcity appeal (limited time offer!) was effective when combined with romantic desire, but backfired when combined with fear. With additional analyses, the results suggested that fear motivated participants to stick together, while romantic desire motivated independence. The authors concluded that discrete emotions serve qualitatively distinct functions that cannot be captured by affective valence alone, and that these functions must be considered in judging the effectiveness of emotional appeals (Griskevicius et al. 2010).

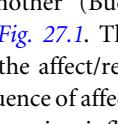

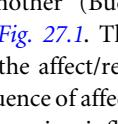

*Affective neuroscience.* A different approach, complementary to evolutionary theory, relates discrete emotions to specific neurochemical systems in the brain (Buck 1999). Paul D. MacLean (1993) was the originator of the Triune Theory of the brain and the limbic system concept, and a pioneer in the study of brain mechanisms of emotion. He suggested that there are three levels of processing systems in the brain: non-cortical (non-layered) *reptilian* systems characteristic of the brains of reptiles, old mammalian systems with 3–5 cortical layers (limbic system) characteristic of primitive mammals, and new mammalian systems with 6 layers (neocortex) characteristic of advanced animals including human beings. In addition, MacLean distinguished two general sorts of emotion at the level of the limbic system: some functioning in the survival of the individual and others functioning in the survival of the species. In his view, more complex species carry the older processing systems, which can influence and even unconsciously set the basic agenda for the newer systems.

Based upon MacLean's analysis, we suggest that there are in human beings *Reptilian* emotions involving “raw” sex and aggression (sex and power) based upon subcortical parts of the brain. Paleocortical (limbic system) areas are associated with more complex

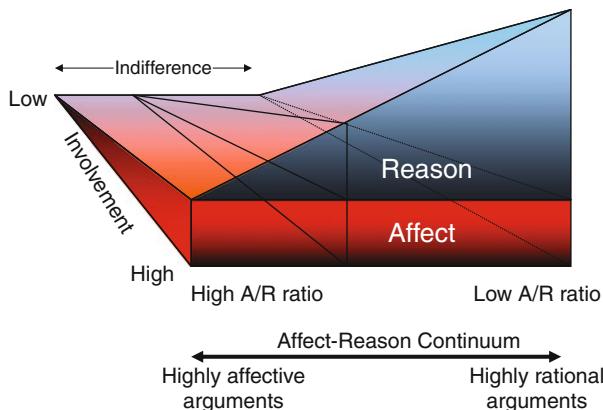

motivational-emotional systems. *Individualist* or selfish emotions involve self-preservation, and can be positive (happiness, satisfaction, security) and negative (anger, fear, sadness, disgust). *Prosocial* emotions involve species preservation, and can be positive (attachment, affiliation, love) and negative (isolation, loneliness, guilt, shame). There are also *Cognitive* emotions involved in the structuring of the cognitive system (curiosity, surprise, interest, boredom: Buck 1999). These specific emotions – reptilian, positive prosocial, negative prosocial, positive individualist, and negative individualist, are assessed by the Communication via Analytic and Syncretic Cognition (CASC) scale, which has been adapted to studies of the role of emotion versus reason in persuasion and social influence (Buck et al. 2004).

*The affect-reason-involvement (ARI) model.* A central assumption of this approach is that persuasion involves an interaction of affective and rational cognition, and this implies that involvement can be both rational and affective. Scales developed to measure involvement commonly include items appearing to assess both rational and affective involvement. For example, the McQuarrie and Munson (1987) revision of the Personal Involvement Inventory (RPI) includes items assessing both “risk” (no risk vs risky; easy to go wrong vs hard to go wrong; hard to pick vs easy to choose) and “hedonism” (appealing vs unappealing; unexciting vs exciting; fun vs not fun).

Chaudhuri and Buck (1995) defined *involvement* after Batra and Ray (1983) as the “depth and quality of cognitive processing” (p. 109), and invoked Tucker’s (1981) notion of syncretic versus analytic cognition to argue for two corresponding types of involvement. The tendency of a medium to encourage deep and high quality analytic processing defines its *rational involvement*, while its tendency to encourage deep and high quality syncretic processing defines its *emotional involvement* (Chaudhuri and Buck 1995; pp. 109–110. Italics in the original). Results of studies rating rational-analytic and affective-syncretic responses to 240 magazine and television advertising messages showed that, with a wide variety of product category and advertising strategy variables controlled, print media produced higher analytic-cognitive responses and electronic media higher syncretic-cognitive responses.

The differentiation of analytic and syncretic cognition blurs the common distinction between emotion and cognition: affect becomes a *type of cognition*, a type of knowledge, as we have seen. More specifically, affect involves syncretic cognition (feelings and desires), and reason involves analytic cognition, as defined previously (Tucker 1981). While affect and reason are often considered to be at ends of a continuum, we consider them to be qualitatively different kinds of systems that interact with one another (Buck 1985, 1988). The relationship between affect and reason is illustrated in  Fig. 27.1. The continuum at the base of  Fig. 27.1 describes the mix of affect and reason: the affect/reason continuum (A/R Continuum). On the extreme left of the continuum, the influence of affect is total: Reason has no influence. As one goes to the right, reason exerts an increasing influence relative to affect, although the influence of affect never falls to zero.

As noted, *involvement* is defined conceptually as the depth and quality of cognitive processing, and both affective and rational involvement are possible. Given this conceptualization, *Level of Involvement (LI)* can be defined operationally as the average of affective and rational involvement: that is:  $LI = (A + R)/2$ . In this way, involvement is defined both conceptually and operationally as a combination of affective and rational cognitive processing: If cognitive processing is measured, involvement is measured by definition. This suggests that one can be “hot, cold, or indifferent” in response to attitude objects and messages: “hot

**Fig. 27.1**

The affect-reason-involvement solid. Reason and affect interact on the face of the figure with reason having no influence on the left (high A/R ratio) and an increasing influence to the right (low A/R ratio). Involvement varies from a maximum on the face of the figure to low involvement (indifference) at the rear. An “ARI slice” is shown at the point where the influence of affect and reason are equal (Modified with kind permission from Fig. 2 in Buck et al. [2004])

processing” is relatively high in affect (high A/R Ratio) and high in involvement; “cold processing” is relatively high in reason (low A/R Ratio) and high in involvement; “indifference” is low in both affect and reason, and low in involvement.

The *ARI Solid* presented in [Fig. 27.1](#) models the relationships between affect, reason, and involvement. This is a three-dimensional figure bounded on one side by the A/R continuum and on the other by a low-high LI dimension. The relative influence of affect and reason at any point on the A/R continuum is represented by an *ARI Slice* in which the relative influence of affect and reason remains constant as involvement varies. The “floor” of the ARI solid is a two-dimensional space with the involvement dimension on the Y-axis and the A/R ratio on the X-axis (Buck et al. 2004). The position of an object (e.g., product or message) as represented by LI and the A/R ratio can be mapped on this surface, producing a Reason-Affect Map (RAM). For example, cars are rated high on both affect and reason: They are therefore in the middle of the A/R continuum and high in LI. Insurance is rated low on both affect and high on reason: It therefore is low on the A/R continuum and moderate in LI. Candy is rated high on affect and low on reason: It is therefore high on the A/R continuum and moderate in LI. Paper products are rated low on both affect and reason: They are therefore in the middle of the A/R continuum and low in LI. Messages – persuasive arguments – can also be rated for affect and reason and placed on the floor of the ARI solid.

*Operationalizing the interaction of discrete affects and reason.* Discrete emotion approaches imply that the measurement of affect can be highly specific, involving for example discrete reptilian, individualist, prosocial, and cognitive emotions. For example, Kowta and Buck (1995) asked college students from India and the USA to assess the rational involvement with buying a number of consumer products using standard questions from the McQuarrie and Munson (1987) Revised Personal Involvement Inventory. The students were also asked

what emotions were associated with buying the same products. For each of five kinds of emotion (curiosity, prosocial, individualist, reptilian sex, reptilian power), A/R ratios were computed for each product. This allowed the computation of Reason-Affect Profiles (RAPs) showing the relative mix of reason and affect across the specific emotions. Illustrative results are presented in Fig. 27.2. For condoms, all emotions save curiosity were rated higher than reason, suggesting relatively high affective and low rational involvement across the board. For greeting cards, only prosocial emotions were rated higher than reason. For both headache medicine and insect repellent, individualist emotions were rated as important, perhaps because the individual was seeking relief from pain or insects. Power was also rated high for the insect repellent, perhaps because the individual was using the product to kill insects. Also, interestingly, there were few differences between Indian and American college students in their ratings.

The results of the Kowta and Buck (1995) study are suggestive, indicating that persons are aware that emotional factors are involved in their decisions and able to report on their influence. The proof of the pudding, as it were, is to attempt such measurement, and to investigate whether a greater understanding of the specific emotions involved in behavior, including risky behavior, can be used to design more successful intervention programs aimed at changing such behaviors.

### Effective Public Health and Safety Appeals

Because emotion plays such a fundamental role in judgment and decision-making, risk communicators should pay attention to the affective content of their warnings and messages,

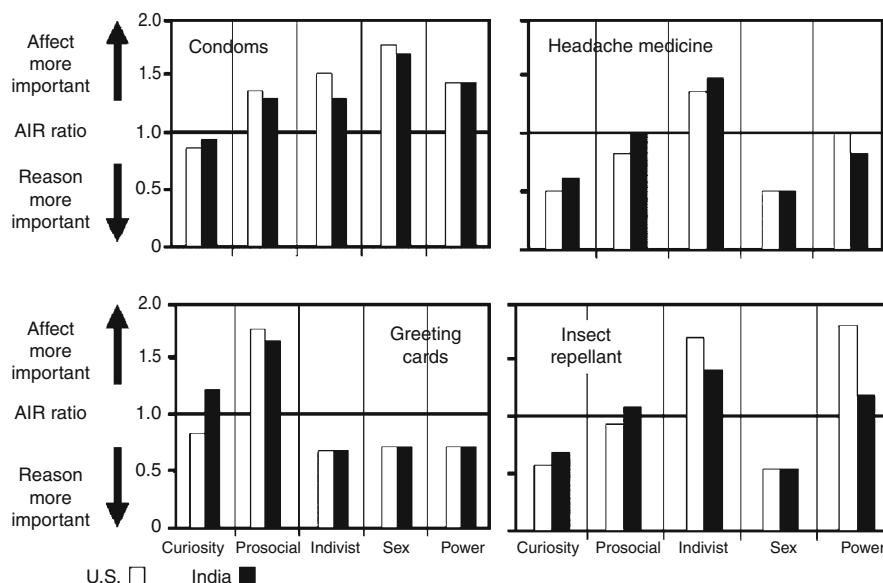

Fig. 27.2

Reason-affect profiles (RAPs) of four consumer products as rated by participants from America and India

and determine under what circumstances individuals are most likely to rely on their emotions to guide their decisions (Finucane 2008; Finucane et al. 2003), and what specific emotions are involved in such reliance. As stated, all communications, including public health and safety appeals, are infused with emotion, since all perceptions and messages contain an affective component (Hilton 2008; Zajonc 1980). Therefore, health and safety officials have an obligation and responsibility to the public to carefully attend to the emotional message they are presenting to the public and to design effective messages with emotion in mind. One of the essential aspects of such an enterprise is to understand the specific emotions involved in the behavior in question. A major example of risky behavior involving emotion is sex.

## **Uncovering Specific Emotional Influences: An Application to Safer Sexual Behavior**

Exploring the role of emotions in specific risky behaviors and their relation to and interaction with social-cognitive constructs may have meaningful implications for designing more effective risk messages. Prior to the design and implementation of emotion-based warnings and risk messages, researchers must first gain a more comprehensive understanding of the dynamics of emotions that are involved in specific risky situations and decisions. For example, if anxiety about a health risk could be reliably linked to adoption of preventive behavior, officials could confidently address anxiety in risk messages with an expectation that these types of appeals would be effective in facilitating appropriate behavior change.

*Emotions in sexual behavior: The SAFECOMM scale.* In an effort to understand the experience and dynamics of emotions involved in potentially risky sexual situations, Buck et al. (2004) developed a version of the CASC scale termed the Safe Sex Communication Scale (SAFECOMM). Participants were asked how “people feel” in a variety of situations including discussing condom use with a potential partner and having sex with and without condoms in situations differing in intimacy (one-night stand, friend, committed relationship). It was expected that condom nonuse would be related to a variety of negative emotions but also some positive emotions involving reptilian sex and power (the “reptilian rewards” hypothesis). Also, it was expected that there would be sex differences in ratings of anger and power, with women relative to men reporting more power but less anger when condoms are used.

Results showed support for the expected pattern of positive and negative prosocial, positive and negative individualistic, and reptilian sex and power emotions; although angry and fearful negative individualistic emotions were distinguished. Main effects indicated that, overall, condom nonuse compared to use was associated with generally higher ratings on negative individualistic and prosocial emotions, and lower ratings of security and confidence.

Negative prosocial emotions (feeling ashamed, embarrassed, and guilty) showed an interesting pattern. When condoms were used, these emotions were at low levels across relationships, but when condoms were not used these emotions were at high levels in one-night stands, decreasing as the relationship became more exclusive. Negative prosocial emotions showed significant interactions between gender and condom use. Women reported higher levels of shame, embarrassment, and guilt relative to men when condoms were not used, and women reported relatively higher levels of shame and embarrassment than did men for less exclusive relationships.

Fearful individualistic emotions (feeling afraid, nervous, and uncomfortable) showed a pattern similar to those of the negative prosocial emotions. Women reported higher overall feelings of nervousness and discomfort, but not of fear. Fear showed a significant interaction between gender and condom use: Women reported less fear than men did when condoms were used, but more when condoms were not used.

Angry individualistic emotions (feeling angry, unsure, insulted, and selfish) showed a pattern generally similar to that of the negative prosocial emotions, with highly significant interactions with relationship exclusivity. When condoms were used, these emotions were at relatively low levels, but when condoms were not used, they showed high levels in one-night stands that decreased as the relationship became more exclusive. Again, there were significant interactions with condom use: Women relative to men reported higher levels of anger, and being unsure and insulted, when condoms were not used. Also, women reported relatively higher levels of anger and being unsure in the less exclusive relationships.

Positive individualistic emotions (feeling secure, confident, and satisfied) generally showed a mirror image of the pattern shown with negative prosocial emotions. Significant main effects indicated that security and confidence were stronger when condoms were used, but the main effect for satisfaction was not significant, and indeed there was a tendency in the opposite direction, due to males' greater reported satisfaction associated with condom nonuse. Significant interactions indicated that, when condoms were used, these emotions were at relatively high levels, but when condoms were not used, they showed low levels in one-night stands that increased as the relationship became more exclusive. Also, positive individualistic emotions showed significant interactions with gender. Relative to men, women reported relatively lower levels of confidence and satisfaction when condoms were not used, and women reported relatively lower levels of security and satisfaction in less exclusive relationships.

Positive prosocial emotions (feeling loving/loved, caring, and intimate) increased as relationships became more exclusive. Interestingly, and importantly, in both sexes condom nonuse was associated with *lower ratings of caring but higher ratings of intimacy*. In the less exclusive relationships, these emotions were at roughly equivalent levels whether condoms were used or not used, but in the long-term relationship these emotions were consistently higher, for both sexes, when condoms were not used. Positive prosocial emotions showed no significant interactions between gender and condom use: Both for females and males, loving, caring, and intimacy tended to be higher in the long-term relationship when condoms were not used. For the less exclusive relationships, women reported relatively lower levels of loving/loved and caring relative to men.

Reptilian erotic emotions increased as relationships became more exclusive; erotic feelings were stronger when condoms were not used, and males reported generally higher erotic feelings. Ratings of erotic feelings showed no significant interactions between gender and condom use or gender and relationship exclusivity. Overall, reptilian power emotions increased slightly as relationships became more exclusive, and feelings of power were marginally stronger when condoms were not used. As expected, power ratings showed a significant interaction between gender and condom use/nonuse: Women indicated relatively greater power when condoms were used and men indicated relatively greater power when condoms were not used. Also as expected, men reported more anger than women when a condom was used and women reported being more angry when a condom was not used.

To summarize, positive emotions were high and negative emotions low when condoms are used; these emotions vary widely with the exclusivity of the relationship when condoms are not used. Also, as expected from the reptilian rewards hypothesis, condom nonuse was associated with higher ratings on reptilian sex and power. Also as expected, when condoms are not used feelings of power are higher for men than women and feelings of anger are higher for women than men. The strong relationships between reported emotions, relationship exclusivity, and condom use/nonuse are consistent with the notion that emotional variables exert important influences on decisions to use or not use condoms. Also, the results demonstrate the intricacy and subtlety of the influence of specific emotions, including reptilian and prosocial emotions not often recognized in many contemporary emotion theories. The complex results concerning positive prosocial emotions – that condom use as opposed to nonuse was seen to be associated positively with caring feelings but negatively with intimacy – was not expected, but on reflection is understandable.

The present authors replicated the Buck et al. (2004) study in a previously unpublished study which examined the hypothesized emotions involved in risky sexual situations, as well as cognitions involved in the same situations, allowing the ARI model to be employed in the analysis. Participants were 337 students from a large Northeastern US University who completed an online and expanded version of the SAFECOMM scale in response to a diverse set of sexual situations (described above). They were asked to rate how “most people would feel” in seven scenarios: discussing condom use with a new sexual partner; and using or not using a condom within sexual relationships of three levels of exclusivity (one-night stand, acquaintance, long-term relationship). The reliabilities of the emotion scales in this study were high ( $\alpha = 0.84\text{--}0.95$ ). Rational processing was operationalized by four questions about whether people think about using condoms (Do most people consider pros and cons of using a condom or not?) and three questions about whether people consider health consequences of using condoms (Do most people think about health consequences of using or not using a condom?) in each of the four situations (discussing, one-night stand, acquaintance, committed relationship). To obtain the A/R score for a given emotion, the emotion rating was divided by the mean of the reason items for each participant in that situation.

Highlights from our findings include the fact that positive prosocial and individualistic emotions increased as relationships become more committed, and negative prosocial and individualistic emotions decreased. Also, there were indications of relationship  $\times$  condom use interactions, such that increasing relationship exclusivity mitigated negative feelings associated with condom nonuse. But, this is not simply a matter of positivity and negativity: Reptilian sexual emotions were rated higher in committed relationships when condoms are NOT used, illustrating again the “reptilian rewards” of not using condoms. Regarding the A/R scores, or emotion *relative to reason*, discussing condom use was relatively the most “rational” of the situations, with reason predominating throughout. The most emotional situation was clearly the committed relationship, with positive prosocial, positive individualistic, reptilian power, and reptilian sex all rated as stronger than reason in that situation. Also, it is noteworthy that reptilian sex was at relatively high levels across the situations.

Together these results provide preliminary evidence for the potential effectiveness of a risk communication strategy that targets positive prosocial and individualistic emotions in the context of committed relationships, and negative prosocial and individualistic emotions in the context of more casual relationships. Additionally, a risk communication strategy that addresses sexual emotions related to condom nonuse may be promising, considering the high

levels of reptilian sex emotions associated with all situations and in particular with situations where condoms are NOT used. Additionally, emotion-based risk communication strategies may prevail over more social or cognitive strategies when addressing actual condom use as opposed to discussing condoms with a new partner, since the A/R scores demonstrate the most “rational” thinking in relation to discussions as opposed to actual sexually charged situations.

## Further Research

---

### Emotion Intervention Strategies: Emotional Education and Emotional Competence

---

One way to address emotions in risk communication is through *emotional education* (Buck 1983, 1985, 1990, 1994). Emotional education is a concept introduced in the Developmental Interactionist (DI) Theory of Emotion, which posits an interaction between reason and emotion that occurs during the course of normal individual development (Buck 1985, 1988, 1999, 2002). DI theory states that individuals learn how to label and understand feelings in childhood by interpreting others' responses to their emotional displays, resulting in naturally occurring emotional education. Basically, emotional education is the process of teaching individuals to correctly (or incorrectly) identify emotions they are experiencing, and what to do when they occur.

Though DI theory posits emotional education as a naturally occurring process, it has also been proposed as means of risk communication and behavior change intervention (e.g., Buck 1985, 1990; McWhirter 1995), and encouraged as a means of supplementing existing risk messages, such as sexual risk reduction interventions (Shaughnessy and Shakesby 1992). According to Buck (1990), though individuals have generalized access to their subjective emotional feelings, they may be unable to consciously identify the cause of the emotion or label the emotion itself. Emotional education in a risk communication strategy may help individuals to identify and label the emotions they experience. When an individual is able to identify experienced emotions confidently and reliably, and can deal with and express them effectively in a way that is appropriate to the situation and in the individual's best interest, this is considered *emotional competence*. Emotional competence is the desired outcome of any emotional education intervention (e.g., Buck 1985, 1990; Buck and Powers 2011; McWhirter 1995).

Research shows that individuals are relatively poor at anticipating how they will feel in a given situation, and how they will react to that emotion in the situation, when they are not emotional at the time of prediction (Finkenauer et al. 2007; Gilbert et al. 1998; Loewenstein 1996). Emotional education may be one way to help individuals to become better at anticipating their emotions, and in developing strategies in advance that might be helpful in dealing with these emotions in ways that facilitate more mindful and therefore safer sexual decision-making. For example, it may be possible to teach individuals to recognize and anticipate positive emotions associated with a healthy or safe behavior, or negative emotions associated with non-adherence to that behavior, and to either increase the experience and the anticipation of these emotions, as well as a strategic response to these emotions that results in the target behavior. If emotional education is successful, it could have a great impact on behavior: as stated above, anticipated and anticipatory emotions have both direct and indirect effects on judgment, decision-making, and behavior (e.g., Loewenstein and Lerner 2003).

In the advertising and marketing field, such an emotional-education approach is quite common. As described earlier, the popular advertising technique of branding involves educating individuals to associate particular affectively laden images with a certain brand, in order to increase emotions associated with the brand and strengthen the link between these emotions and purchase behavior (e.g., Greifender et al. 2007; Pritchard and Morgan 1998). Branding's effects on consumer behavior are well-documented (e.g., Buck and Davis 2010; Chaudhuri 2006).

Though most popular in advertising and marketing, emotional education strategies have been used preliminarily in the risk communication domain as well, though with far less prevalence than in the advertising industry. For example, recent research has directed individuals, through use of role-playing, to "pre-live" emotional consequences of positive and negative genetic testing results when making the decision whether or not to engage in such testing behavior (Diefenbach and Hamrick 2003; Miller et al. 2001). This pre-living of emotion can be seen as a form of emotional education.

One potentially efficacious method of facilitating emotional education and emotional competence is through the use of videos, as people often seek out media for emotional education in everyday life. Videos offer unique access to both the feelings of others as well as a viewer's own feelings by detailing situations in which actors are confronted with emotional stimuli and describe their physical and emotional responses (e.g., Buck 1988; Boyanowsky et al. 1972; Cantor 1982). Movies provide opportunities to consider situations that would provoke various emotional outcomes, as well as examples of others' responses to such situations. For example, Boyanowsky et al. (1972) found that, after a murder took place on campus, attendance at a movie depicting a murder increased, while attendance at a similar film with no murder remained steady, as compared to showings of the same two movies prior to the campus murder. Further, women who lived in the same dorm as the murdered woman were more likely to choose to attend the murder movie than the other movie. This could indicate that individuals may seek out videos in order to facilitate their own emotional education and competence after an emotional event occurs in real life. Thus, media and film are a natural way to facilitate emotional education and emotional competence in risk communication, and can be used in risk messages to affect systematic exposure to different affective-laden situations in a manner that would not otherwise be possible.

Indeed, recent research has demonstrated that videos designed to facilitate emotional education and emotional competence with relation to sexual situations significantly increased condom use when paired with traditional social-cognitive intervention material (Ferrer et al. 2011). The emotional education intervention content was designed to increase individuals' identification and anticipation of specific emotions and to facilitate enactment of response strategies that result in condom use. The design of the intervention drew on results of the SAFECOMM studies described above. The videos addressed sexual situations that occur both inside and outside the context of a committed relationship, and emotions identified by the SAFECOMM studies to be particularly relevant in each context. Positive prosocial and individualistic emotions, such as caring, intimacy, and confidence, were addressed in the context of committed relationships. Also, positive individualistic emotions were targeted in the context of more casual relationships, in addition to targeting negative prosocial and individualistic emotions such as embarrassment, guilt, and detachment. Sexual reptilian emotions were addressed in both relationship contexts, as these were associated with all situations and in particular in situations where condoms were *not* used. All participants

watched videos about both relationship contexts, as relationships among college students can be transient and as such, these individuals may quickly move from a committed to a casual relationship status (or vice versa).

Participants watched the videos designed to highlight these relevant emotions: love and caring for a partner that can be expressed with condom use; confidence and security in a sexual situation as a result of condom use; embarrassment or guilt associated with not using a condom; and eroticism that could be achieved even while using a condom. Discussions followed the videos to reinforce the emotional education. Individuals were randomly assigned, in small groups, to receive (1) the emotional education intervention paired with traditional social-cognitive intervention material, (2) the social-cognitive intervention material only, or (3) no intervention. Compared to the control condition, both the intervention conditions reported increased condom use at 3 months post-intervention. However, at 6 months post-intervention, only the group who had received the emotional education intervention sustained changes in condom use behavior. This study provides preliminary evidence suggesting that emotional appeals to health promotion behavior may be more efficacious in sustaining behavior change than more “rational” appeals alone. Additionally, the intervention was one of few single session interventions demonstrated to increase and sustain condom use, indicating the powerful potential of emotional appeals in effecting desired behavior change. Additional research is necessary to replicate these findings and to demonstrate their efficacy in other health and safety domains; however, these findings provide convincing evidence that such strategies have promise and should be examined further as risk communication strategies that could be used effectively by public health and safety officials.

One essential direction for future research concerns evaluating the effectiveness of emotional appeals in the “real world.” Although such appeals have been demonstrated to change behavior in laboratory and more controlled settings, there is no definitive empirical evidence to demonstrate what types of emotional appeals are most likely to be effected in “the sophisticated and overcrowded clutter of the real-world communications environment” (Hastings et al. 2004). We also know little empirically about the long-term exposure to repeated emotional appeals (Hastings et al. 2004). The marketing and advertising industry has certainly demonstrated that repeated emotional appeals distributed en masse to the public can be utilized effectively (e.g., Chaudhuri 2006). However, publicly available empirical evidence concerning the properties and characteristics of effective (and ineffective) appeals at the mass communication level is sparse. Additional research is necessary to determine what types of emotional appeals are most likely to translate from a controlled environment to the real world.

## Conclusion

In conclusion, the Ferrer et al. (2011) study illustrates the potential of incorporating explicit emotional education appeals in risk messages and interventions. By first understanding the specific emotions that are likely to be encountered in a risky situation, and then by presenting information on how to understand and deal with those emotions, it becomes possible to alert vulnerable persons to anticipate their feelings and desires in ways that promote mindful choice: to appreciate, for example, that sexually transmitted diseases do not “stay in Vegas.” The promotion of mindful choice is clearly beneficial and ethical, even though it may at times

involve manipulating emotion. The full potential of such warning tactics and strategies have yet to be fully tested and evaluated, but they are based upon both the latest research evidence and the compelling and sobering long-term example of success of advertising and marketing.

**Abstract:** Cultural cognition is one of a variety of approaches designed to empirically test the “cultural theory of risk” set forth by Mary Douglas and Aaron Wildavsky. The basic premise of cultural theory is that individuals can be expected to form beliefs about societal dangers that reflect and reinforce their commitments to one or another idealized form of social ordering. Among the features of cultural cognition that make it distinctive among conceptions of cultural theory are its approach to measuring individuals’ cultural worldviews; its empirical investigation of the social psychological mechanisms that connect individuals’ risk perceptions to their cultural worldviews; and its practical goal of enabling self-conscious management of popular risk perceptions in the interest of promoting scientifically sound public policies that are congenial to persons of diverse outlooks.

## Introduction

---

This entry examines two related frameworks for the study of popular risk perceptions: the *cultural theory* of risk, associated with the work of Douglas and Wildavsky (1982); and the *cultural cognition* of risk, a focus of recent work by various researchers including myself. I will present the latter as a conception of the former. The motivation for characterizing cultural cognition as a “conception” of cultural theory is twofold: first, to supply an expositional framework for cultural cognition, the concepts and methods of which were formed to empirically test cultural theory; and second, to emphasize that cultural cognition is only one of a variety of competing approaches for interpreting and testing Douglas and Wildavsky’s influential claims about the nature of risk perception.

Indeed, one premise of this entry is that the answer to the question whether cultural cognition supplies a “correct” understanding of cultural theory, if not entirely unimportant, ultimately has no bearing on whether cultural cognition helps to make sense of individual differences in risk perception. Accordingly, whatever objections one might make to cultural cognition in the name of a particular rendering of Douglas and Wildavsky’s theory does not detract from the explanatory and predictive (and ultimately prescriptive) utility of cultural cognition. Of course, if cultural cognition does a better job than other attempts to operationalize the cultural theory of risk, one might reasonably count this feature of it as a reason to prefer it to other constructs that arguably fit better with some set of theory-derived criteria but that do not, as an empirical matter, conform to the phenomena cultural theory is meant to explain.

There are three features of cultural cognition, I submit, that are distinctive among the various conceptions of cultural theory. One is the way in which cultural cognition *measures* cultural worldviews, which are the primary explanatory variable in the Douglas–Wildavsky account of risk perceptions. Another is the attention that cultural cognition gives to the mechanisms – social and psychological – that explain how culture shapes individuals’ beliefs about risk. And the third is the practical objective of cultural cognition to promote collective management of public perceptions of risk and the effect of policies for mitigating them.

The entry elaborates on these points. Part 2 starts with an overview of cultural theory – a very spare one, which will be filled in over the course of later parts but which suffices to set the exposition in motion. Part 3 will take up the measurement of worldviews, contrasting the methods that I and my collaborators in the Cultural Cognition Project use with those used by other scholars who have tried to test cultural theory empirically. Part 4 addresses the distinctive focus of cultural cognition on psychological mechanisms. I’ll identify how this feature of

cultural cognition does admittedly put it in conflict with an important feature of Douglas and Wildavsky's own view of their theory. But I'll also survey some key empirical findings that cultural cognition has generated by adding psychological mechanisms to cultural theory. Part 5 concludes with an assessment of how cultural cognition can guide research aimed at enabling collective management of the role that culture plays in risk perception, a normative objective that might well strike orthodox cultural theorists as puzzling.

## The Cultural Theory of Risk, in Broad Strokes

Cultural theory asserts that individuals should be expected to form perceptions of risk that reflect and reinforce their commitment to one or another “cultural way of life” (Thompson et al. 1990). The theory uses a scheme that characterizes cultural ways of life and supporting worldviews along two cross-cutting dimensions (Fig. 28.1), which Douglas calls “group” and “grid” (Douglas 1970, 1982). A “weak” group way of life inclines people toward an individualistic worldview, highly “competitive” in nature, in which people are expected to “fend for themselves” without collective assistance or interference (Rayner 1992, p. 87). In a “strong” group way of life, in contrast, people “interact frequently in a wide range of activities” in which they “depend on one another” to achieve their ends. This mode of social organization “promotes values of solidarity rather than the competitiveness of weak group” (Rayner 1992, p. 87).

A “high” grid way of life organizes itself through pervasive and stratified “role differentiation” (Gross and Rayner 1985, p. 6). Goods and offices, duties and entitlements, are all “distributed on the basis of explicit public social classifications such as sex, color,... a bureaucratic office, descent in a senior clan or lineage, or point of progression through an age-grade system” (Gross and Rayner 1985, p. 6). It thus conduces to a “hierarchic” worldview

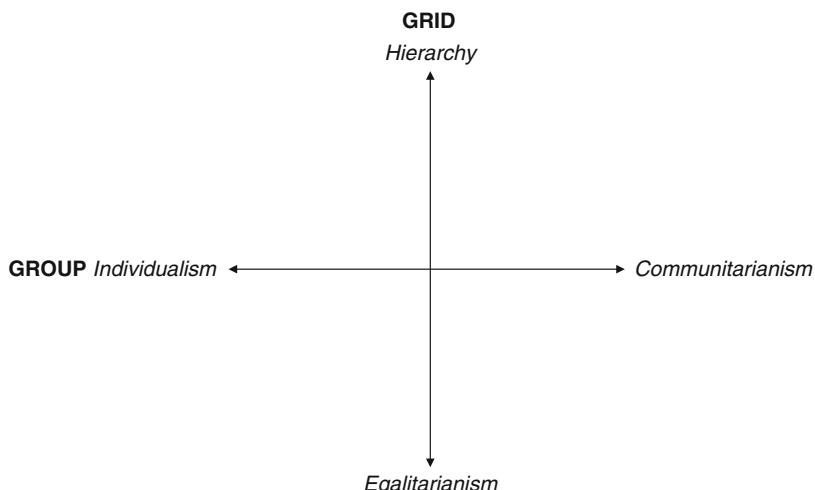

Fig. 28.1

Douglas's “group–grid” scheme. “Group” and “grid” delineate orthogonal dimensions of social organization, or “ways of life,” and supportive values or “worldviews”

that disposes people to “devote a great deal of attention to maintaining” the rank-based “constraints” that underwrite “their own position and interests” (Rayner 1992, p. 87).

Finally, a low grid way of life consists of an “egalitarian state of affairs in which no one is prevented from participation in any social role because he or she is the wrong sex, or is too old, or does not have the right family connections” (Rayner 1992, p. 87). It generates and is supported by a correspondingly egalitarian worldview that emphatically denies that goods and offices, duties and entitlements, should be distributed on the basis of such rankings.

The cultural theory of risk makes two basic claims about the relationship between cultural “ways of life” so defined and risk perceptions. The first is that discrete constellations of perceived risk tend to cohere better with one or another way of life. Forms of conduct understood to inflict collective harm invite restriction, and the people who engage in such behavior censure and blame (Douglas 1992). It thus secures a way of life when its members come to see those who deviate from its norms as exposing the group to risk, in which case “the belief that the innocent are in danger helps to brand the delinquent and to rouse moral fervor against him” (Douglas 1966, p. 134). By the same token, it threatens a way of life, and the authority of those who hold positions of high status within it, to identify its signature forms of behavior as courting collective injury (Douglas and Wildavsky 1982).

The second claim of cultural theory is that individuals gravitate toward perceptions of risk that advance the way of life to which they are committed. “[M]oral concern guides not just response to the risk but the basic faculty of [risk] perception” (Douglas 1985, p. 60). Each way of life and associated worldview “has its own typical risk portfolio,” which “shuts out perception of some dangers and highlights others,” in manners that selectively concentrate censure on activities that subvert its norms and deflect it away from activities integral to sustaining them (Douglas and Wildavsky 1982, pp. 8, 85). Because ways of life dispose their adherents selectively to perceive risks in this fashion, disputes about risk, Douglas and Wildavsky argue, are in essence parts of an “ongoing debate about the ideal society” (Douglas and Wildavsky 1982, p. 36).

The paradigmatic case, for Douglas and Wildavsky, is environmental risk perception. Persons disposed toward the individualistic worldview supportive of a weak group way of life should, on this account, be disposed to react very dismissively to claims of environmental and technological risk because they recognize (how or why exactly is a matter to consider presently) that the crediting of those claims would lead to restrictions on commerce and industry, forms of behavior they like. The same orientation toward environmental risk should be expected for individuals who adhere to the hierarchical worldview, who see assertions of such danger as implicit indictments of the competence and authority of societal elites. Individuals who tend toward the egalitarian and solidaristic worldview characteristic of strong group and low grid, in contrast, dislike commerce and industry, which they see as sources of unjust social disparities, and as symbols of noxious self-seeking. They therefore find it congenital to credit claims that those activities are harmful – a conclusion that does indeed support censure of those who engage in them and restriction of their signature forms of behavior (Wildavsky and Dake 1990; Thompson et al. 1990).

This was the plot of Douglas and Wildavsky’s classic *Risk and Culture: An Essay on the Selection of Technological and Environmental Dangers* (1982). The relationship that Douglas and Wildavsky asserted there between risk perceptions and the various ways of life featured in group-grid has animated nearly two decades’ worth of empirical research aimed at testing the cultural theory of risk.

## Measuring Worldviews

One of central methodological issues in the empirical research inspired by Douglas and Wildavsky's cultural theory is how to measure cultural worldviews. The approach cultural cognition takes toward this task is one of the things that distinguishes it from other conceptions of cultural theory.

### Dake and His Successors

The dominant approach to measuring cultural worldviews can be traced back to Karl Dake, who (along with Wildavsky, his Ph.D. dissertation advisor) published the first empirical studies of culture theory in the early 1990s (Dake 1990, 1991; Wildavsky and Dake 1990). The basis of these studies was a pair of public opinion surveys of residents of San Francisco and Oakland, California. Although the survey instrument was not designed specifically to test cultural theory, Dake was able to use various items from it to construct measures for doing so. Thus, from items relating to respondents' political attitudes, Dake formed separate scales for "Hierarchy," "Egalitarianism," and "Individualism." In subsequent work (Dake 1992), he identified a fourth set of items to represent a "fatalist" worldview, and thereafter identified the four scales with the quadrants demarcated by the intersection of "group" and "grid" (☞ [Fig. 28.2](#)). Among the

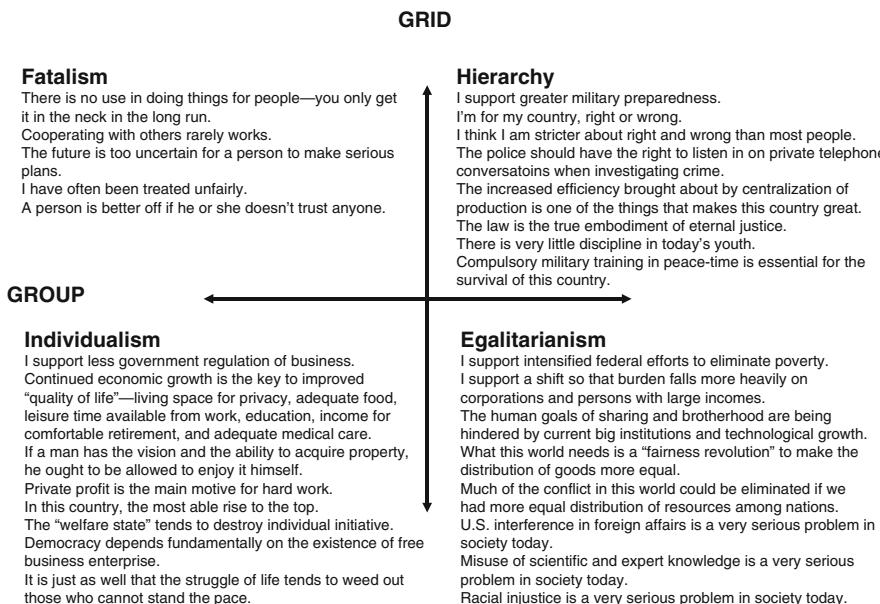

Fig. 28.2

Dake's culture scales. Dake used these items to construct scales for measuring the "worldviews" associated with the group-grid quadrants. The Hierarchy, Egalitarianism, and Individualism scales were used to measure attitudes and analyze risk perceptions in his dissertation (1990) and were the basis of study results published by Dake (1991) and Wildavsky and Dake (1990). The "fatalism" scale was proposed later (Dake 1992)

many studies using Dake's measures or refinements thereof are Ellis and Thompson (1997); O'Connor et al. (1998); Peters and Slovic (1996); Langford et al. (2000); Jenkins-Smith (2001).

Studies based on Dake's measures have encountered two difficulties. The first has to do with the psychometric properties of the various scales. Dake himself did not report any measures of scale reliability. But subsequent researchers have investigated this matter in depth, and they have often found that the separate scales used to measure the respective worldviews perform poorly, failing to display internal validity in tests such as Cronbach's *alpha* (Sjöberg 1998a; Gastil et al. 1995; Marris et al. 1998).

The second problem is conceptual in nature. When one uses separate scales to measure each group–grid worldview, it becomes theoretically possible for a single individual to exhibit multiple, competing orientations – for example, to be simultaneously both a hierarchist and an egalitarian. Indeed, most likely because the items associated with discrete scales do not reflect a high degree of coherence or internal consistency; it's not uncommon for subjects to have high scores on competing scales (Marris et al. 1998). This feature of the Dake scales makes them unsuited for empirically testing cultural theory. Douglas and Wildavsky asserted that individuals attend selectively to risk in patterns that reflect and promote the ways of life to which they subscribe. That claim cannot be cleanly tested with measures that permit individuals to be characterized as subscribing to mutually inconsistent worldviews, for in that case Douglas and Wildavsky's position doesn't yield any determinate predictions about which risks they will credit and which they will dismiss.

## Cultural Cognition

Some researchers, most notably, Hank Jenkins-Smith and his collaborators (Jenkins-Smith and Herron 2009; Silva and Jenkins-Smith 2007; Jenkins-Smith 2001), have made considerable progress in remedying these problems through refinement of Dake's measures. Cultural cognition, however, seeks to avoid them by departing more radically from Dake's strategy for measuring worldviews (► Fig. 28.3).

Cultural cognition uses two continuous attitudinal scales. One, “hierarchy–egalitarianism,” consists of items that determine a person's relative orientation toward high or low “grid” ways of life. The other, “individualism–communitarianism” (we found that readers sometimes were confused by “solidarism,” the term we originally selected to denote the orientation opposed to individualism), consists of items that determine a person's relative orientation toward weak or strong “group” ways of life. In studies performed on general population samples in the USA, these scales have proven highly reliable (e.g., Kahan et al. 2007, 2009, 2010b). They also avoid the logical indeterminacy problem associated with variants of Dake's original measures. When one uses a single scale for group and a single scale for grid, each individual respondent's worldview is identified with a unique point or coordinate in the “culture space” demarcated by the intersection of group and grid (► Fig. 28.4).

More recently, studies using cultural cognition have relied on “short form” versions of the two scales (Kahan et al. 2011). Each short-form scale consists of only six “agree–disagree” items that are “balanced” in attitudinal valance (three items supportive of each end of the two continuous scales). The scales are as reliable as the full-form counterparts. They load appropriately on discrete latent dispositions, generating orthogonal principal components or factors, the scores for which can be used as continuous measures (► Fig. 28.5).

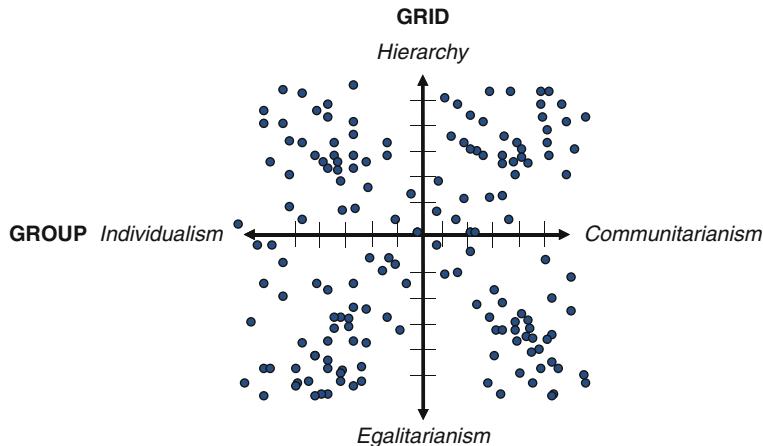

<b>Hierarchy-Egalitarianism</b>		<b>Individualism-Communitarianism</b>	
HCHEATS	It seems like the criminals and welfare cheats get all the breaks, while the average citizen picks up the tab.	IENJOY	People who are successful in business have a right to enjoy their wealth as they see fit.
HEQUAL	We have gone too far in pushing equal rights in this country.	IFIX	If the government spent less time trying to fix everyone's problems, we'd all be a lot better off.
HFEMININ	Society as a whole has become too soft and feminine.	IGOVWAST	Government regulations are almost always a waste of everyone's time and money.
HREVDIS1	Nowadays it seems like there is just as much discrimination against whites as there is against blacks.	IINTRFER	The government interferes far too much in our everyday lives.
HREVDIS2	It seems like blacks, women, homosexuals and other groups don't want equal rights, they want special rights just for them.	IMKT	Free markets—not government programs—are the best way to supply people with the things they need.
HTRADFAM	A lot of problems in our society today come from the decline in the traditional family, where the man works and the woman stays home.	INEEDS	Too many people today expect society to do things for them that they should be doing for themselves.
HWMNRTS	The women's rights movement has gone too far.	INEEDY	It's a mistake to ask society to help every person in need.
EDISCRIM	Discrimination against minorities is still a very serious problem in our society.	IPRIVACY	The government should stop telling people how to live their lives.
EDIVERS	It's old-fashioned and wrong to think that one culture's set of values is better than any other culture's way of seeing the world...	IPROFIT	Private profit is the main motive for hard work.
ERADEQ	We need to dramatically reduce inequalities between the rich and the poor, whites and people of color, and men and women.	IPROTECT	It's not the government's business to try to protect people from themselves.
EROUGH	Parents should encourage young boys to be more sensitive and less "rough and tough."	IRESPON	Society works best when it lets individuals take responsibility for their own lives without telling them what to do.
EWEALTH	Our society would be better off if the distribution of wealth was more equal.	ITRIES	Our government tries to do too many things for too many people. We should just let people take care of themselves.
EXSEXIST	We live in a sexist society that is fundamentally set up to discriminate against women.	CHARM	Sometimes government needs to make laws that keep people from hurting themselves.
		CLIMCHOI	Government should put limits on the choices individuals can make so they don't get in the way of what's good for society.
		CNEEDS	It's society's responsibility to make sure everyone's basic needs are met.
		CPROTECT	The government should do more to advance society's goals, even if that means limiting the freedom and choices of individuals.
		CRELY	People should be able to rely on the government for help when they need it.

Fig. 28.3

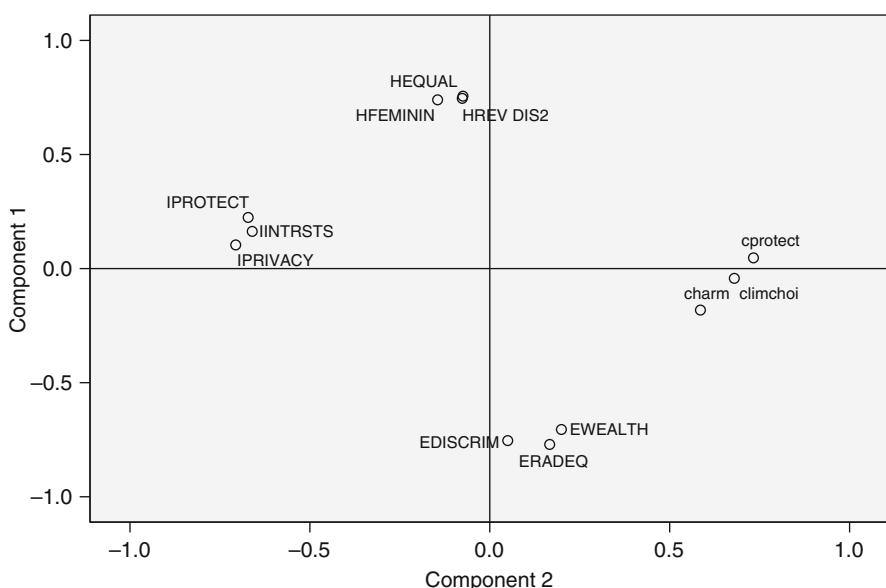

**Cultural cognition scales (“full form”). Study participants indicate the level of their “disagreement” or “agreement” with each item on a four- or six-point Likert response measure. Responses are then aggregated (with appropriate reverse-coding of the “E” and “C” items) to form continuous “Hierarchy-egalitarianism” and “Individualism-communitarianism” worldview scores. When these items are administered to US general population samples, Cronbach’s alpha for each worldview scale consistently exceeds 0.70**

These properties of the scales make them well-suited for testing Douglas and Wildavsky’s theory. If “dangers are culturally selected for recognition” (Douglas 1985, p. 54), then there should be a significant correlation between individuals’ perceptions of risks hypothesized to promote one or another combination of worldviews and the position of individuals’ own worldviews on the “group–grid” map.

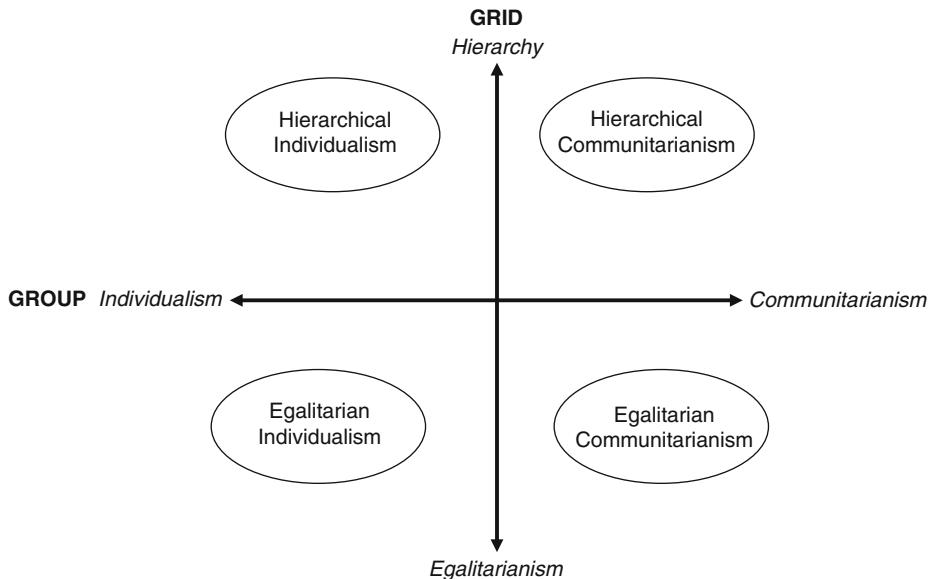

Psychometrically speaking, the scales should be thought of as measures of *latent* or unobserved dispositions, for which the items that make up the scales are simply observable indicators. Because the scales are continuous, they lend themselves readily to correlational analyses (including multivariate regression) in which their influence can be assessed without the loss of statistical power (and the potential bias) associated with splitting a sample into subgroups (Judd 2000).

**Fig. 28.4**

Cultural cognition “map.” The cultural cognition scales can be used to plot the location of any individual on a cultural cognition map (I’d certainly like to say “on a grid” – but you can see how confusing that would become) based on that individual’s scores on the “hierarchy–egalitarianism” and “individualism–communitarianism” scales

**Fig. 28.5**

**Short-form culture scales.** Short forms for Individualism–communitarianism (Cronbach’s  $\alpha = 0.76$ ) and Hierarchy–egalitarianism (Cronbach’s  $\alpha = 0.84$ ), each of which consists of six items loading on orthogonal principal components

**Fig. 28.6**

Cultural cognition “ways of life.” Cultural cognition scales contemplate that combinations of high and low values could have distinctive effects, which admit of measurement through a product interaction term

Cultural theory assigns distinctive effects to the combinations of worldviews supportive of the “ways of life” that inhabit the quadrants of “group-grid.” We designate these four ways of life “hierarchical individualism,” “hierarchical communitarianism,” “egalitarian individualism,” and “egalitarian communitarianism” (● Fig. 28.6), labels we believe are intuitive and appropriately descriptive – albeit different from the diverse array of labels that cultural theorists tend to use (a matter I will return to presently). Even when group and grid are conceptualized as two orthogonal continuous worldview dimensions, the use of an interaction term will make it possible to take account of any unique effects associated with particular combinations of low and high values on the two scales. Added, say, to a multivariate regression, such a term reports the impact of each worldview dimension conditional on a person’s location on the other (see, generally, Aiken et al. 1991). As a result, the effect of a “hierarchical individualist” worldview, say, can have an effect different from (perhaps larger, perhaps smaller than) the one derived by simply adding a low group score and a high grid one.

### But Is It *Cultural Theory*?

However successful it might be in making “cultural worldviews” psychometrically tractable, this approach arguably faces problems of its own related to its fit with cultural theory. I will identify some of these, the elaboration of which also helps to paint a more vivid picture of cultural theory and its intricacies.

## How Many Cultures?

One difficulty has to do with what Thompson et al. (1990) refer to as the “impossibility theorem.” The “impossibility theorem” posits that there are a finite number of viable ways of life – five, according to Thompson et al. (1990), four according to many other cultural theorists – within the space demarcated by group–grid (☞ Fig. 28.7). Because cultural cognition measures treat group and grid as continuous, it might be understood to imply that there can be an infinite number of ways of life formed by congregations of persons around any coordinate in the group–grid map. The impossibility theorem says that’s “impossible” – only five (or maybe just four) ways of life are viable.

To this point – which has been made to us by various cultural theorists – I myself would say the appearance of tension between the cultural cognition scheme and the impossibility theorem might well be illusory. Even if only a limited number of ways of life exist or are “possible,” it doesn’t follow, logically, that every individual must display a worldview that perfectly maps onto these ways of life. A certain measure of heterogeneity among individuals is perfectly consistent with there being aggregations of persons who exert a dominant influence on social structures and affiliated worldviews (Braman et al. 2005). Under either of these conditions, we would expect individuals to form packages of risk perceptions characteristic of their groups in proportion to the strength or degree of attachment to the cultural groups with

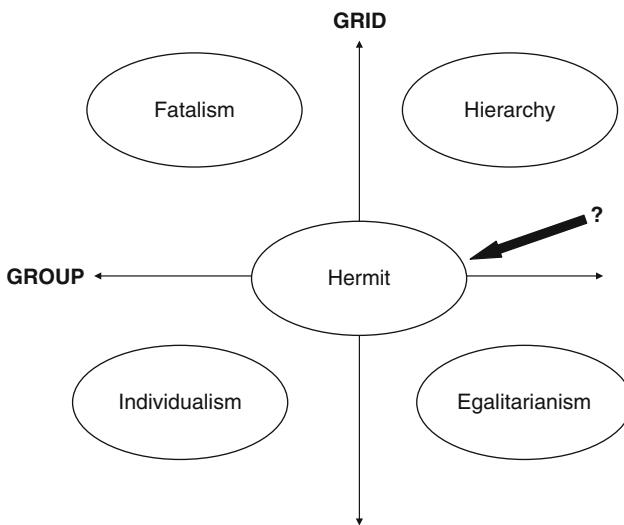

Fig. 28.7

“Impossibility theorem” – only 5 (or maybe only 4). Certain cultural theorists asserts that the number of viable, discrete ways of life (and associated worldviews) within the group–grid scheme is finite, a position known as the “impossibility theorem,” which refers to the impossibility of intermediate ways of life in the interstices of the identified ones. Thompson et al. (1990) posit five such ways of life. The “existence and position on the map” of the “Hermit” are “much disputed,” it is reported, in debates internal to cultural theory (Mamadouh 1999, p. 401)

whom they are most closely affiliated (cf. Manton et al. 1992). That's basically what our measures are designed to show.

But in any case, no one, to my knowledge, has ever purported to empirically test, much less vindicate, the "impossibility theorem," and at least some cultural theorists do indeed take the position (including Mary Douglas at certain points but not at others) that group and grid are inherently spectral in nature and capable of supporting any number of different coherent ways of life within the space demarcated by their intersection (Mamadouh 1999). My collaborators and I take a pragmatic attitude: we are more interested in finding a scheme for measuring cultural worldviews that is internally valid and that has explanatory utility than in finding one that fits a profile dictated by axiomatic, abstract theorizing.

## Where Have All the Fatalists Gone?

Another theory-based objection to the cultural cognition scheme is that it ignores "fatalism." Fatalism is a way of life that Douglas and many other culture theorists associated with weak group, high grid. It is said to generate a worldview that disposes people to accept the diminishment of personal agency and a corresponding perception that steps to abate risk will be futile (Thompson et al. 1990).

The constructs measured by the cultural cognition scales do not imply that weak group, high grid social relations will result in a fatalistic way of life or worldview. Rather, this combination of dispositions will cohere with modes of life in which people, as individualists, are strongly resistant to regulation of affairs by remote, collectivist-minded authorities, but still organize their local institutions in highly regimented, and highly stratified, ways. Think of the iconic American cowboy, the "Marlboro Man": He bridles at outside interference with the operation of his ranch, yet still exerts authority over a small community whose members – from ranch hands, to wives, to sons and daughters – all occupy scripted, hierarchical social roles. He is likely to form a dismissive attitude toward environmental risks (the contribution to global warming associated with his cows' methane emissions, say). However, he might be very concerned that various forms of social deviance could threaten order and generate other bad collective consequences (the residents of Broke Back Mountain, on his view, are destined for calamity). He is no fatalist – he has lots of agency, and he is selectively, not uniformly, risk sensitive.

My own response to this disconnect between the cultural cognition scales and conventional culture theory is a sort of shrug of the shoulders. In truth, I've never gotten the theoretical explanation of why weak group, high grid would generate a "fatalistic" way of life. Indeed, I have a hard time even understanding how fatalism could be a *group way of life*, or why a fatalist stance toward risk could be identified as a worldview as opposed to, say, a personality trait of some kind (possibly one the baleful effects of which could be treated with appropriate pharmaceutical interventions). I think the way of life of the Marlboro Man supplies a more cogent account of what one expects to see with the convergence of hierarchy and individualism. It also happens to generate testable predictions, ones our research confirms, about the distinctive schedule of risk perceptions that people with those worldviews are likely to form. Therefore, I'm inclined to give the infamous "so?" response of Dick Cheney – a Marlboro Man if ever there was one – to the complaint that cultural cognition disregards fatalism.

But I would add to this response that other conceptions of cultural theory also display ambivalence toward fatalism. Dake's original work did not include a fatalism scale, and his analyses reporting the results were confined to assessments of the risk-shaping impact of Hierarchy, Egalitarianism, and Individualism (Wildavsky and Dake 1990; Dake 1990, 1991). In addition, Wildavsky, in his individual writings on how culture influences risk perception and mass political opinion, always left fatalism out of the story too (e.g., Wildavsky 1991), maybe because he was likewise puzzled by it.

## Where Are Cultural Views Located? Institutions Versus Individuals

Yet another conflict between cultural cognition position and at least one understanding of how cultural theory works relates to who should be regarded as the *subject* of cultural worldviews. Cultural cognition theory assumes that cultural worldviews are latent predispositions of individuals (i.e., shared but unobserved orientations that one can measure, with varying degrees of precision, by observable indicators, primarily in the form of professed attitudes). Another view, put forth (at least intermittently) by Stephen Rayner and Michael Thompson, asserts that in fact it is a mistake to see cultural worldviews as fixed or stable features of individuals; rather they are immanent properties of institutions, characterized by one or another mode of social organization, that systematically endow individuals with outlooks conducive to the operation of those institutions during the time (but only then) that individuals happen to occupy roles within them (Rayner 1992).

This picture of how culture shapes risk perceptions is at odds not only with cultural cognition. If it is right, then *any* conception of cultural theory that tries to use individual-level measures of worldviews as an explanatory variable is flawed. Individuals are only temporary receptacles of institution-supporting worldviews that get poured into them as they move from place to place. They will thus "flit like butterflies from context to context, chanting the nature of their arguments as they do so" (Rayner 1992, pp. 107–08).

Some might wonder if such a view could ever generate testable predictions. I think it likely could. All we need (and I don't say this facetiously) is a valid and reliable way for measuring what worldviews "contexts" (nuclear power plants; universities; stock trading floors) of different sorts have. We could then randomly move individuals around from one to one, and see if their risk perceptions – on climate change, say, or on gun possession, or nanotechnology – changed in the ways that cultural theory predicts. (We'd need to randomly manipulate the respondents' locations, rather than just going to those places and polling the people we find at them, for as Rayner notes (1992, p. 107), the view that cultural worldviews belong to individuals predicts that they will self-select into institutions that are congenial to their preferred mode of social ordering.) I seriously doubt that such an experiment would confirm the "social mobility hypothesis," as Rayner dubs it. But I do indeed hope that my doubt spurs him and others to conduct the sort of internally valid test that would be required to settle the issue and that to my knowledge no one has yet attempted.

If they succeed, of course, they might or might not have established a conception of cultural theory, but they will definitely have *demolished* the conception that Douglas and Wildavsky appeared to subscribe to, which was obsessed (for understandable reasons) with political conflict over risk. The egalitarians, individualists, and hierarchs in *Risk and Culture* (1982) were groups of people – not buildings or even "sectors" of some sort of multifaceted

system – who disagreed with each other about the ideal society. The gripping and compelling story Douglas and Wildavsky told about such disagreements would have fallen apart if we imagined that the people who were fighting each other on nuclear power or air pollution were just the ones who at any given moment of the day happened to be at home, at work, at the university, at the salon, etc. Similarly, when we try to make sense of “climate change skeptics” and “climate change believers” today – something even Rayner and Thompson would like to do (e.g., Verweij et al. 2006) – we are trying to understand *people* with relatively stable beliefs, not just temporary receptacles for risk outlooks that get poured into them as they wander from place to place. If we want a theory that explains who believes what and why about politically contested empirical claims about risk, then the “social mobility hypothesis” conception of cultural theory is of no use. Or more accurately, if it can be shown that risk perceptions aren’t persistent but vary in individuals as they move from place to place, we should stop trying to do what cultural cognition and all the other conceptions of cultural theory that reflect what Rayner calls the “stability hypothesis” (which he attributes to Douglas herself) try to do – viz., find explanations for patterns of variance in risk perceptions of different groups of people. Because if the “social mobility” position is right, the explanandum of all such conceptions of cultural theory turns out to be just an (very amazing!) illusion.

But there’s simply no point arguing about which – the “mobility” or “stability” hypothesis – is the “right” view of cultural theory in the abstract. The only version of cultural theory that anyone could have any reason to prefer is the one that actually explains the world we live in. So let the matter be resolved by empirical testing.

## Whose Worldviews? Crosscultural Risk Perception

Another objection to cultural cognition as a conception of cultural theory is that it is parochial. We devised our cultural worldview measures because we wanted to understand variance in perceptions of risk within the US public, and didn’t think that Dake’s measures and variants thereof had psychometric properties necessary to allow us to do that. Accordingly, we developed the measures using US subjects, ones who we interviewed in subjects groups and to whom we administered successive versions of our measures, first in writing and then in phone interviews, over a period of years. It has been pointed out to us, by Mary Douglas herself among others (Douglas 2003), that our measures have a distinctly “American feel,” particularly in relation to their picture of hierarchy, which reflects elements of social stratification (e.g., racial ones) that have played a conspicuous part in animating hierarchic modes of social organization historically in the USA. Some critics of Dake’s measures dismissed them on the ground that if you simply translated them into another language – say, Swedish or Portuguese – they did not furnish reliable measures or predict risk perceptions in the manner that cultural theory says they should (Sjöberg 1998b). I suspect our measures, if subjected to the same test, would also perform poorly, even though they work well for US samples.

But, in my view, that test reflects a very odd expectation of what a successful conception of cultural theory should be able to deliver. Douglas, in a position that was very controversial in its own right, did indeed suggest that the group-grid framework would have an element of universality to it, supplying worldview constructs that could be used to make sense of conflicts over risk across place and time. Let’s grant that she was right (but only for the sake of moving forward; it is a bold claim that merits testing, not an axiom to be dogmatically asserted or

recklessly assumed). It is another matter entirely to say that the *indicators* of the latent dispositions associated with these worldviews must be the same everywhere and forever. Why would we think that when we ask a Hadzabe bushman – or even a Swede or Brazilian – would react the way a contemporary American does to the proposition that “it seems like the criminals and welfare cheats get all the breaks, while the average citizen picks up the tab?” What reason is there to think the two will attach the same *meaning* to this proposition (or that the former will even attach any to it)? If they don’t, then this item won’t be a valid or reliable measure of any sort of latent disposition they happen to share. Because the theory is that differences in a latent characteristic explain variation in risk perception, the way to test the theory is to develop observable indicators that are reliable and valid for that latent characteristic *in* the sample one is studying.

I’d also say that while it’s plausible that the same cultural predispositions toward risk will help to explain variance everywhere, it isn’t necessarily going to be the case that the variance they explain is the same in all places. Douglas teaches that risks grab individual attention and become the currency of blame because of what risk-taking behavior connotes about the authority and legitimacy of contested social orderings: “Each culture must have its notions of dirt and defilement which are contrasted with its notion of the positive structure which must not be negated” (Douglas 1966, p. 160). Those connotations, she recognized full well, will also be a matter of decisive historical contingency. The meanings that made ancient Jews believe that defiance of the commandments of Yahweh would cause him to “strike [them] with consumption, and with fever and with inflammation and with fiery heat and with the sword and with blight and with mildew” (*Deuteronomy* 28:22 (1997); quoted in Douglas 1966, p. 51) were unique to them. If we found today at similar coordinates in the group–grid map a group in the Upper West Side of Manhattan, we would not expect them to attribute floods and fires to the profaning of God – but we *might* expect them to attribute those *very* things to forms of behavior (corporate industrialization and excessive personal consumption) that bear meanings that defy *their* shared commitments. So by the same reasoning, why should hierarchy today dictate the same posture toward the risk of carrying guns in societies of historical experiences as diverse as, say, those of England and the USA? In other words, the validity – and value – of a theory that predicts *that* individuals of opposing predispositions will mobilize themselves into opposing factions over risk doesn’t depend on it being able to say, in a manner oblivious to the historical circumstances of such people, *what* that dispute will be about (Kahan and Braman 2003b).

Recently, social psychology has begun to explore “crosscultural” differences in cognition generally. This line of work focuses on identifying society-level variation, typically between members of “Eastern” (generally, Asian) and “Western” (European) nations. Differences in how members of such societies individuate collective entities (e.g., “schools of fish”) from their individual constituents (“individual fish”) is thought to reflect and reinforce diverse understandings of individual and collective responsibilities and prerogatives (Nisbett 2003). This body of work – which is as fascinating as it is important – is a separate line of inquiry from the one associated with the cultural cognition of risk. It’s possible they might at some point be shown to be connected in some way, although the two seem to reflect different assumptions about the scale of “cultural variation”: whereas the “crosscultural cognition” paradigm envisions that differences in values will manifest themselves at the societal level, the “cultural cognition of risk” focuses on how differences in values result in *intraspacial* conflicts, ones that are likely to be distinctive of conditions that are relatively local in time and space.

## Mechanisms

---

Now I turn to the *mechanisms* of cultural cognition. The idea of “mechanisms of cultural cognition” is meant to be an answer the question *why* individuals are disposed, as Douglas and Wildavsky maintained, to form risk perceptions that cohere with the ways of life they subscribe to.

Douglas and Wildavsky, in separate writings, developed an admittedly *functionalist* answer to this question (Douglas 1986; Thompson et al. 1990). That is, they both took the position that individuals form risk perceptions congenial to their ways of life precisely *because* holding those beliefs about risk cohere with and promote their ways of life. This sort of reasoning – which is associated with classical sociological accounts of ideology – has developed a bad reputation in contemporary social science, which sees it as implausibly attributing agency to collective entities (Boudon 1998). Douglas and Wildavsky were fully aware of this and related objections, and developed ingenious arguments to try to deal with them.

I and the other researchers doing work with cultural cognition take a different tack. The *mechanisms* hypothesis is that worldviews yield risk perceptions through a set of social and psychological processes. The processes are well established; they are the heart of the “*psychometric paradigm*” or psychometric theory of risk pioneered by my collaborator Paul Slovic (2000). What hasn’t been fully recognized until now, our research suggests, is how these social and psychological processes interact with cultural ways of life, generating individual differences in risk perception between people who subscribe to competing worldviews (Kahan et al. 2010a). But importantly, this is not a functionalist account because the social and psychological processes associated with the psychometric paradigm, although different from the ones stressed by rational choice economics, don’t treat the needs of collective entities as the causes of individual behavior but instead derive collective behavior from the interaction of individuals self-consciously pursuing fulfillment of their own ends (Balkin 1998; Elster 1985).

Although this marriage of cultural theory and the psychometric theory of risk wasn’t one that Mary Douglas herself ever sanctioned, she at least recognized such a union as a possible strategy for showing how cultural theory works. She did this in a famous essay, “The Depoliticization of Risk” (1997), which specifically criticized Slovic for failing to explore the interaction of culture and the mechanisms of the psychometric paradigm – a feature of Slovic’s research, she maintained, made it innocent of political conflict over risk. “If we were invited to make a coalition between group-grid theory and psychometrics,” Douglas wrote, “it would be like going to heaven” (Douglas 1997, p. 132). In a sense, cultural cognition, to which Slovic himself has made major contributions, *is* such an invitation. But Douglas, I own, might not have intended to be taken seriously when she made this remark, and few of the scholars who are most interested in her work today have shown any interest in this strategy for exploiting the full richness of her and Wildavsky’s thoughts on risk perception.

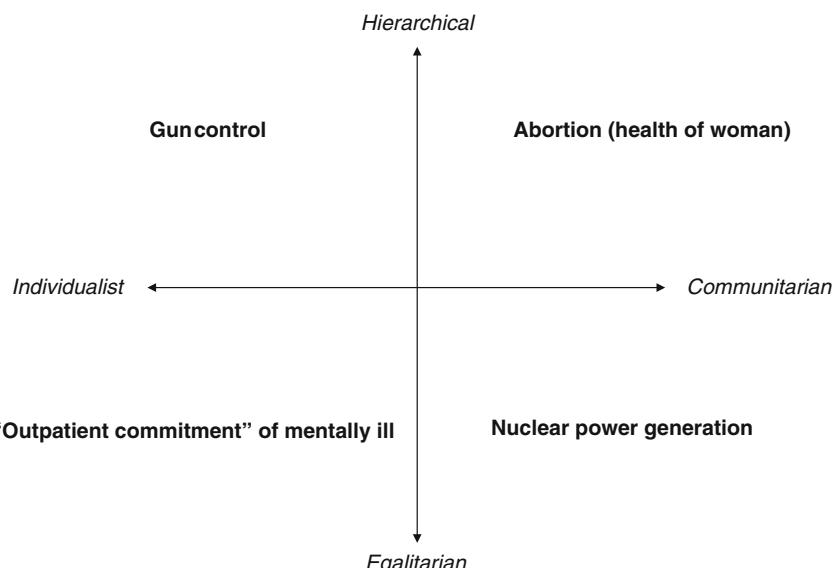

Whether or not viewed as faithful to Douglas’s vision, studies that use psychometric concepts and methods have identified a variety of discrete mechanisms of cultural cognition. The ones I’ll discuss are *identity-protective cognition*; *biased assimilation and group polarization*; *cultural credibility*; *cultural availability*; and *cultural identity affirmation*. I’ll go through them in order, saying something about how each one works in general and then something about studies we’ve done that suggest their influence in connecting cultural worldviews to risk perceptions. This is not an exhaustive list; research is ongoing to investigate additional ones. But these are ones for which there is the best evidence so far.

## Cultural Identity-Protective Cognition

Identity-protective cognition refers to the tendency of people to fit their views to those of others with whom they share some important, self-identifying commitments. Group membership supplies individuals not only with material benefits but a range of important nonmaterial ones, including opportunities to acquire status and self-esteem. Forming beliefs at odds with those held by members of an identity-defining group can thus undermine a person's well-being – either by threatening to drive a wedge between that person and other group members, by interfering with important practices within the group, or by impugning the social competence (and thus the esteem-conferring capacity) of a group generally. Accordingly, individuals are motivated, unconsciously, to conform all manner of attitudes, including factual beliefs, to ones that are dominant within their self-defining reference groups (Cohen 2003; Giner-Sorolla and Chaiken 1997).

The cultural theory of risk holds that groups defined by diverse worldviews can be expected to disagree about risk. Identity-protective cognition furnishes a plausible explanation for why this would be so. One test – of cultural theory generally, and of this particular mechanism for it – would be to determine whether risk perceptions are indeed distributed across groups in patterns that are best explained by the stake individuals have in maintaining the status of, and their status within, groups defined by shared worldviews.

Using our culture scales, we have gathered evidence of such a relationship for a wide variety of risks (Fig. 28.8). Thus, we have been able to show that perceptions of environmental and

**Fig. 28.8**

The distribution of risk perception and cultural identity-protective cognition. Survey evidence establishes that risks associated with the indicated activities are highly correlated with the indicated combination of cultural worldview values even after controlling for other influences. These and like patterns furnish evidence that cultural identity-protective cognition affects the formation of risk perceptions

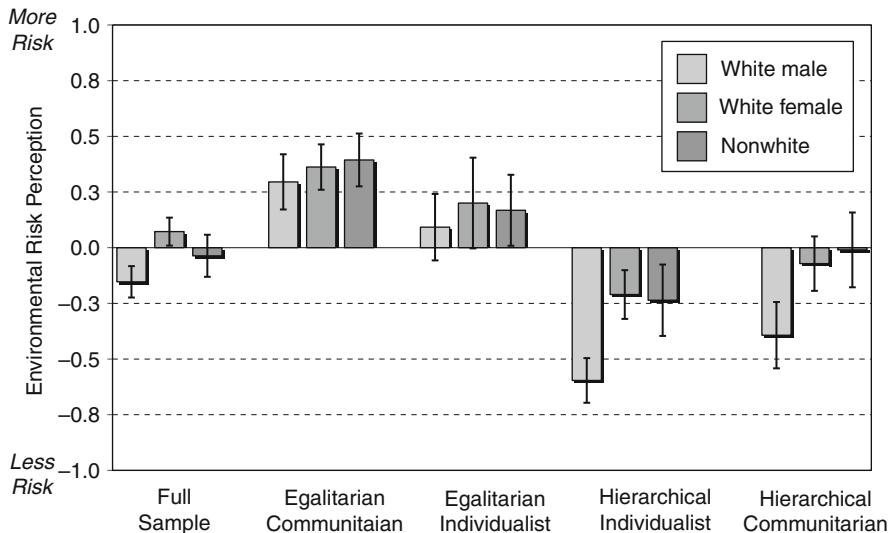

technological risks vary sharply along the lines that Douglas and Wildavsky suggests: that is, as individuals become simultaneously egalitarian and communitarian in their values, they become more concerned, and as they become hierarchical and individualistic less, with climate change, nuclear waste disposal, air pollution, and the like (Kahan et al. 2007). We have also formed and tested our own hypotheses about the distribution of various other risk perceptions that we expected – based largely on ethnographic, historical, and other forms of inquiry – would pit individuals located in one or another quadrant of the group–grid map against those from another. On whether private gun ownership increases or decreases violent crime; on whether abortion impairs the health of women (Kahan et al. 2007); on whether legally compelled submission to medical treatment (including psychotropic drugs) promotes the well-being of mentally ill individuals and the safety of their communities (Kahan et al. 2010a) – in all these cases, we have found that cultural worldviews, as measured with our scales, explained variation better than other individual characteristics, including education, income, personality type, and ideology.

Indeed, the strongest evidence for cultural identity-protective cognition comes from the power of cultural worldviews to explain gender and racial variance in risk perceptions. The “white male effect” refers to the tendency of white males to regard all manner of societal risk as smaller in magnitude and seriousness than do women and minorities (Finucane et al. 2000). We hypothesized (Kahan et al. 2007) that culturally grounded, identity-protective cognition might explain this phenomenon. White males who subscribe to ways of life that feature race and gender differentiation in social roles, our reasoning went, have a special stake in putatively dangerous activities essential to their cultural roles. Accordingly, they should be more powerfully impelled by identity-protective cognition than anyone else to resist the claim that those activities are hazardous for society and should be restricted.

Consider environmental risk perceptions. Hierarchs are disposed to dismiss claims of environmental risks because those claims implicitly cast blame on societal elites. But white male hierarchs, who acquire status within their way of life by occupying positions of authority within industry and the government, have even more of a stake in resisting these risk claims than do hierarchical women, who acquire status mainly by mastering domestic roles, such as mother and homemaker. In addition, *white* hierarchical males are likely to display this effect in the most dramatic fashion because of the correlation between being nonwhite and being an egalitarian.

In a study involving a nationally representative sample of 1,800 US residents, we found strong evidence in support of these hypotheses (Kahan et al. 2007). We found that the race effect in environmental risk perceptions – which persisted even when characteristics such as income, education, and liberal–conservative ideology were controlled for – disappeared once hierarchy and individualism were taken into account. In addition, we found the hypothesized interaction between gender and hierarchy; that is, a disposition toward hierarchy exerted a much stronger effect toward environmental-risk skepticism in men than in women. Indeed, once the extreme risk skepticism of white hierarchical males was taken into account, the gender effect in environmental risk perceptions also disappeared.

We found a similar effect with gun risk perceptions. In the USA, guns enable largely hierarchical roles such as father, protector, and provider, and symbolize hierarchical virtues such as honor and courage. Within hierarchical ways of life, moreover, these are roles and virtues distinctive of men, not women, who again occupy roles that don’t feature gun use. These roles and virtues are also largely associated with being a *white* male, in large part because

**Fig. 28.9**

**Cultural identity-protective cognition and the “white male effect.”** Bars indicate z-score on composite “Environmental risk perception” measure (climate change, air pollution, and nuclear power; Cronbach’s  $\alpha = 0.72$ ). Scores are derived from multivariate regression that included cultural worldview measures, race and gender, and appropriate interaction terms, and controlled for numerous other individual characteristics including education, income, personality type, and political ideology. CIs reflect 0.95 level of confidence. The analysis shows that the sample-wide differential between white males and others is attributable entirely to the extreme risk skepticism of hierarchical white males. The differential is largest among hierarchical individualists. Based on data in Kahan et al. (2007), Table 2, Model 3

of the historical association of guns with maintenance of racial hierarchy in the South. On this account, then, we should expect white hierarchical males to be much more invested in gun possession, and thus to be impelled much more forcefully by identity-protective cognition to resist the claim that guns are dangerous and that gun ownership should be restricted. And this is again exactly what we did find in our national study (● Fig. 28.9).

### Culturally Biased Assimilation of (and Search for) Information and Cultural Polarization

“Biased assimilation and polarization” is a dynamic that characterizes information processing. When individuals are unconsciously motivated to persist in their beliefs, they selectively attend to evidence and arguments, crediting those that reinforce their beliefs and dismissing as noncredible those that contravene them. As a result of this “biased assimilation,” individuals tend to harden in their views when exposed to a portfolio of arguments that variously support and challenge their views. By the same token, when *groups* of individuals who are motivated to persist in opposing beliefs are exposed to balanced information, they don’t converge in their views; as a result of biased assimilation they *polarize* (Lord et al. 1979).

My collaborators and I have hypothesized that identity-protective cognition would unconsciously motivate individuals to assimilate risk information in support of culturally congenial results, and hence drive people with opposing worldviews apart as they consider information (Kahan et al. 2006). If so, *culturally biased assimilation* and polarization could be treated as another mechanism for the sorts of relationships between worldview and risk perception posited by cultural theory.

One study we did to test this possibility focused on nanotechnology risks (Kahan et al. 2009). Nanotechnology involves the creation and manipulation of extremely small materials, on the scale of atoms or molecules, which behave in ways very different from larger versions of the same materials. It's a novel science: about 80% of the American public say they have either never heard of it, or have heard only a little. We did an experiment in which we compared the nanotechnology risk perceptions of subjects to whom we supplied balanced information risk-benefit information to subjects to whom we supplied no information.

The results (Fig. 28.10) confirmed our hypothesis. In the no-information condition, individuals of opposing cultural worldviews held relatively uniform risk perceptions. That's not surprising, since the vast majority of them had never heard of nanotechnology. In the information condition, however, hierarchs and egalitarians, and individualists and communitarians, all formed opposing views. In other words, individuals holding these worldviews attended to the balanced information on nanotechnology in a selective fashion that reinforced their cultural predispositions toward environmental and technological risks generally. As a result, they polarized.

This result thus uses an established mechanism of social psychology – biased assimilation – to ground culturally grounded individual differences in risk perception. But in a reciprocal fashion, it also contributes something a bit back to general understandings of that very mechanism.

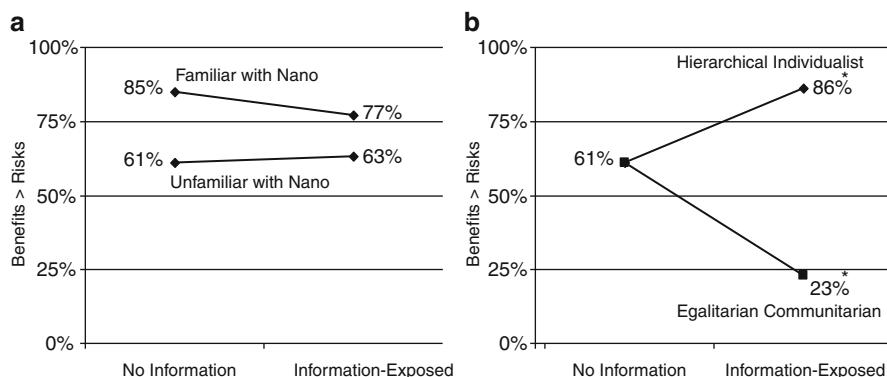

Fig. 28.10

**Biased assimilation/polarization of nanotechnology information.**  $N = 1,850$ . Results derived from statistical simulation based on multivariate logistic regression involving worldviews, information exposure, and prior familiarity with nanotechnology. \* denotes difference between conditions significant at  $p < 0.05$ . Panel (a) shows reactions of subjects to balanced information conditional on prior familiarity and controlling for cultural worldviews. Panel (b) shows reactions of subjects to balanced information conditional on cultural worldviews and controlling for prior familiarity (Kahan et al. 2009)

Conventionally, biased assimilation is determined with reference to individuals' prior beliefs. For example, people who disagree about whether the death penalty deters murder will, when shown studies that reach opposing conclusions, grow even more divided (Lord et al. 1979)

But in our study, individuals, by and large, *had* no priors; most of them said they had not heard anything or anything of significance about nanotechnology before the study. They attended to information, then, in a biased manner supportive of a *predisposition* toward risk. This is a refinement and extension of the biased assimilation/polarization concept. It also attests to the utility of cultural cognition as a *predictive* tool that might be used to anticipate and even, as I will discuss presently, *manage* how diverse persons will react to information about an emerging technology.

Because some of our subjects had in fact learned something about nanotechnology even before the study, we also compared how individuals reacted to information conditional on the level of their prior familiarity. Previous public opinion studies had consistently shown that although relatively few people are aware of nanotechnology, those who are have an extremely positive view of its benefits relative to its risks. This finding has prompted some to infer that as word of nanotechnology spreads, members of the public generally will form positive impressions of this novel science. This is, obviously, a hypothesis at odds with our own.

We found no support for it. It was the case that individuals in our "no information" condition who reported knowing more about nanotechnology had a more favorable view than

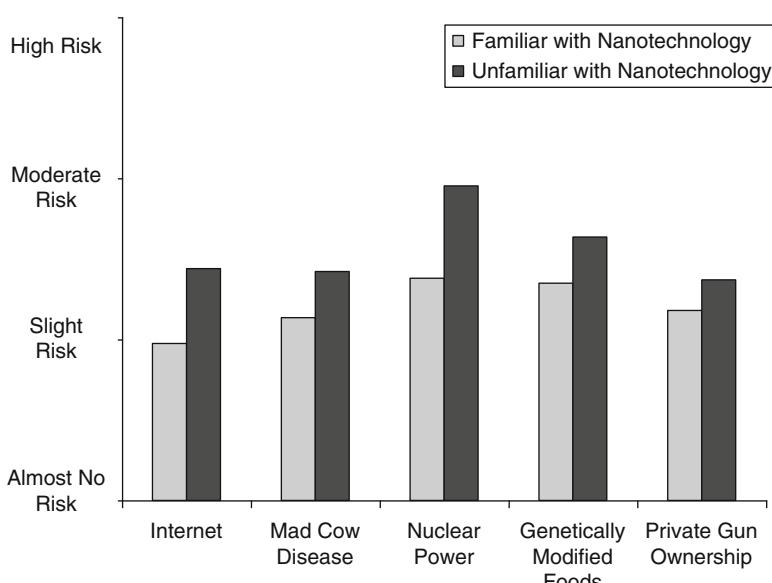

Fig. 28.11

Other risk perceptions among subjects familiar and unfamiliar with nanotechnology.  $n = 1,820$  to  $1,830$ . Risk variables are 4-pt measures of "risk to people in American Society" posed by indicated risk. Differences between group means all significant at  $p \leq 0.01$  (Kahan et al. 2009)

those who reporting knowing nothing or only a little. But when exposed to information, subjects of the latter description did not react in a uniformly positive way; again, they reacted positively or negatively conditional to their cultural worldviews (☞ Fig. 28.10).

We also found out something else interesting about the individuals who claimed they knew a lot or a substantial amount about nanotechnology: they weren't (on average) afraid of anything. They rated the risks of nuclear power as low. They didn't worry about "mad cow disease" or genetically modified foods. They saw owning a gun as low risk too. And so on (☞ Fig. 28.11).

What to make of this? Should the National Rifle Association or the Nuclear Power Chamber of Commerce flood the streams of public communication with information about nanotechnology? Obviously not. This is the signature of spurious correlation: information about nanotechnology is not causing individuals to see guns, the Internet, genetically modified foods, nuclear power, and so forth as safe; some third influence is causing people *both* to form the view that these risks are low *and* to become interested enough in nanotechnology to learn about it before others do.

Why, then, should we not suspect the relationship between familiarity with nanotechnology, on the one hand, and a positive view of its risks and benefits, on the other, as spurious too? Indeed, we'd shown in our experiment that information exposure *doesn't* cause individuals to

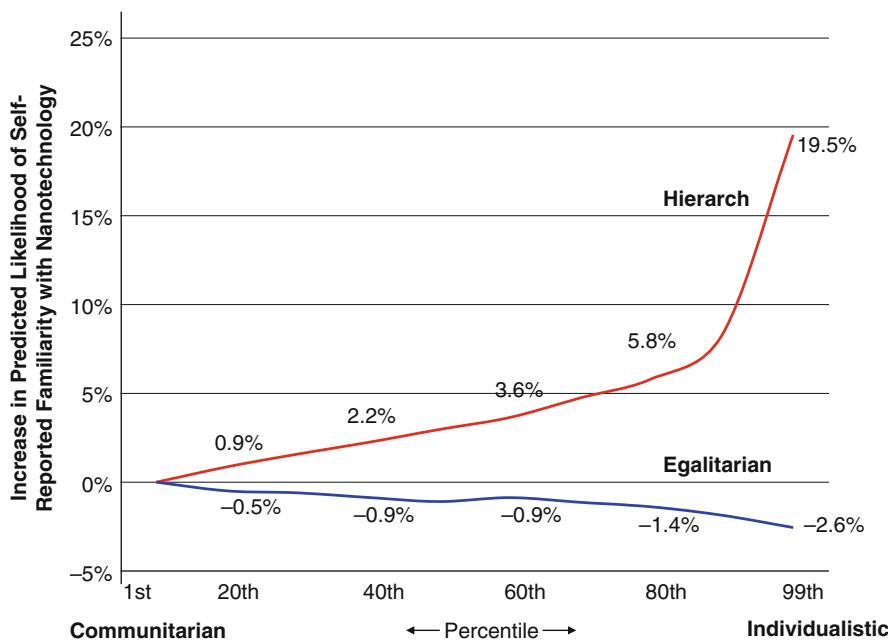

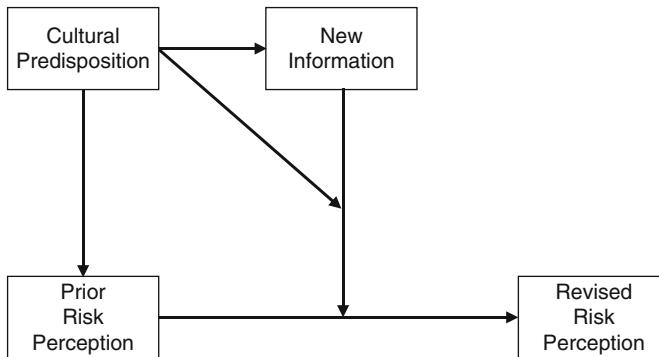

Fig. 28.12

**Predicting familiarity with nanotechnology.**  $N = 1,800$ . Derived from simulation based on multivariate logistic regression with race, sex, gender, education, income, political ideology, and cultural worldview predictors. Interaction between hierarchy and individualism is significant at  $p < 0.05$  (Kahan et al. 2009)

**Fig. 28.13**

**Biased assimilation and search.** Experiment results show that same cultural predisposition responsible for beliefs about environmental risk influence both the search and the effect given to new information

form a positive view. So we tried to see if we could identify a third influence that both causes individuals to learn more about nanotechnology and to see it as low risk.

It shouldn't be hard at this point to guess what we found. The influence that predicts familiarity with nanotechnology is an individual's cultural worldview (☞ Fig. 28.12). The more individualistic a person is, the more likely he or she is to claim to know about nanotechnology, conditional on that person being simultaneously hierarchical in his outlooks – the combination of values that the experiment shows does indeed predispose individuals to become more disposed to form a positive view of nanotechnology when they learn about it.

In this study, then, we have the core of a psychometric theory of how culture influences risk perception. Individuals bear cultural predisposition toward risk – a tendency (founded on identity-protective cognition) to view some risk claims more congenial than others on the basis of latent characteristics indicated by values they share with others. This predisposition not only endows culturally diverse individuals with opposing “prior” beliefs about risk. It also decisively regulates their experience with information about the truth or falsity of those beliefs. People with opposing predispositions seek out support for their competing views through opposingly biased forms of information search. What's more, they construe or assimilate information, whatever its provenance, in opposing ways that reinforce the risk perceptions they are predisposed to form. As a result, individuals end up in a state of cultural conflict – not over values, but over *facts* – that the mere accumulation of empirical data cannot be expected readily to dispel (☞ Fig. 28.13).

## Cultural Availability

The “availability effect” describes a typical distortion that occurs when individuals assess a risk (Kahneman and Tversky 1982). If instances of some fact or contingency relevant to the risk are highly salient, individuals are more likely to notice, assign significance to, and remember them. When they are required to consider the incidence of such a contingency thereafter, the ease

with which those instances can be recalled will induce individuals to overestimate their occurrence. The ready availability of mishaps such as the Chernobyl nuclear accident, the 9/11 attack, and the Columbine school shooting massacre, for example, are thought to explain why members of the public tend to overestimate the risks of nuclear power generation, of terrorist attacks, of accidental handgun shootings, and the like, particularly in relation to less dramatic hazards – swimming pool drowning, say, or climate change.

There is a fairly obvious mystery associated with the availability effect, however: what gives one or another contingency the salience necessary to trigger the effect? The seemingly obvious answer – the vivid or horrific consequences that attend it – in fact begs multiple questions. If people viewed the accidental drowning deaths of children as being as horrific as accidental shooting deaths, then presumably they would notice (or have their attention drawn by the media to) the former more often; they would thereafter more readily recall instances of such mishaps; and as a result they would revise upward their estimation of the incidence of them relative to accidental shootings – which are in fact much rarer.

Disproportionate media coverage of various types of accidents is a common but manifestly unsatisfying explanation of the greater “availability” of them in the public mind. The media’s incentive to disproportionately cover one type of accident is itself a market-driven reflection of the public demand for news relating to that type of accident (e.g., accidental child shootings) as opposed to another, even more frequent type (accidental drownings). What is the source of that demand?

Moreover, if horrifically vivid consequences or disproportionate media coverage are what trigger availability, why do people systematically *disagree* about nuclear power plants, domestic terrorist incidents, and climate change, all of which are attended by signature images of calamity? Indeed, people disagree about the incidence of risk-relevant facts even after attending to images they *agree* are compelling and horrific: in the wake of a school shooting massacre, some people revise upward their estimate of the risks associated with permitting private citizens to own guns, while others revise upward their estimate of the risks associated with *prohibiting* law-abiding citizens from carrying guns to defend themselves. So what determines why people attach differential *significance* to salient, readily available instances of some contingency?

One possibility, I and my collaborators have conjectured, is culture (Kahan and Braman 2003a). If people are more likely to notice risk-related contingencies congenial to their cultural predispositions, to assign them significance consistent with their cultural predispositions, and recall instances of them when doing so is supportive of their cultural predispositions, then the availability effect will generate systematic individual differences among culturally diverse individuals. That would make *cultural availability* another mechanism of cultural cognition.

We examined this mechanism in a study of public perceptions of scientific expert consensus (Kahan et al. 2011). Public dispute about the extent, causes, and likely consequences of climate change often is cited as proof that substantial segments of the population are willing to buck “scientific consensus” on risk issues. But what’s the evidence that those who are skeptical of climate change believe their view is contrary to “scientific consensus?” Why not consider the possibility that such persons are conforming their impressions of what most scientists believe to their own cultural predispositions on climate change? And why not investigate whether the same is true of those who *do* perceive climate change to be a serious risk? A “cultural availability effect” would predict exactly this sort of division: If people are more likely to notice, to assign significance to, and to recall the expression of an expert opinion when it is congenial to their cultural predispositions, then they will form diametrically opposed estimates of what most

scientists believe – and not just on climate change, but on a variety of other risk issues that admit of scientific investigation but that are nonetheless culturally charged.

Our study generated two sorts of evidence suggestive of a cultural availability effect on scientific consensus. The first came from an experiment to see whether cultural predispositions affect whether someone is likely to take note of an expert's opinion. In the experiment, we asked each subject to imagine a friend was trying to make up his or her mind on the existence and effects of climate change, on the safety of nuclear power, or on the impact on crime of allowing

Geologic Isolation of Nuclear Wastes		
High Risk (not safe)	<p><b>"Using deep geologic isolation to dispose of radioactive wastes from nuclear power plants would put human health and the environment at risk.</b> The concept seems simple: contain the wastes in underground bedrock isolated from humans and the biosphere. The problem in practice is that there is no way to assure that the geologic conditions relied upon to contain the wastes won't change over time. Nor is there any way to assure the human materials used to transport wastes to the site, or to contain them inside of the isolation facilities, won't break down, releasing radioactivity into the environment.... These are the sorts of lessons one learns from the complex problems that have plagued safety engineering for the space shuttle, but here the costs of failure are simply too high.</p>	 <p>Oliver Roberts</p> <p><b>Position:</b> Professor of Nuclear Engineering, University of California, Berkeley</p> <p><b>Education:</b> Ph.D., Princeton University</p> <p><b>Memberships:</b></p> <ul style="list-style-type: none"> <li>• American Association of Physics</li> <li>• National Academy of Sciences</li> </ul>
Low Risk (safe)	<p><b>"Radioactive wastes from nuclear power plants can be disposed of without danger to the public or the environment through deep geologic isolation.</b> In this method, radioactive wastes are stored deep underground in bedrock, and isolated from the biosphere for many thousands of years. Natural bedrock isolation has safely contained the radioactive products generated by spontaneous nuclear fission reactions in Oklo, Africa, for some 2 billion years. Man made geologic isolation facilities reinforce this level of protection through the use of sealed containers made of materials known to resist corrosion and decay. This design philosophy, known as 'defense in depth,' makes long-term disposal safe, effective, and economically feasible."</p>	 <p>Oliver Roberts</p> <p><b>Position:</b> Professor of Nuclear Engineering, University of California, Berkeley</p> <p><b>Education:</b> Ph.D., Princeton University</p> <p><b>Memberships:</b></p> <ul style="list-style-type: none"> <li>• American Association of Physics</li> <li>• National Academy of Sciences</li> </ul>

Fig. 28.14

Is this an expert? In an experiment, subjects were substantially more likely to count a university professor as an "expert" when he was depicted as taking a position consistent with their own cultural predispositions on a risk issue than when he was depicted as taking a position inconsistent with the subjects' predispositions (Kahan et al. 2011)

private citizens to carry concealed handguns. The friend, we advised, was planning to buy a book to study up on the subject, but before doing so wanted the subject's advice on whether the book's author was a "knowledgeable and trustworthy expert." Subjects were shown the authors' *curriculum vitae* CV, which indicated that the author had received a Ph.D. from one elite university, was on the faculty of another, and was a member of the National Academy of Sciences. The experimental manipulation involved what the author had *written*: for each topic – climate change, nuclear power, and concealed handguns – subjects were randomly assigned a book excerpt in which the author expressed either the "high risk" or "low risk" position (Fig. 28.14). As we hypothesized, subjects were overwhelmingly more likely to find that the author was a "knowledgeable and trustworthy" expert when the author was depicted as taking a position *consistent* with the subjects' own cultural predisposition than subjects were if the author was assigned the opposing position.

If individuals are more likely to notice or to assign significance to evidence relating to expert opinion when it supports than when it contradicts their own cultural predispositions, then over time we should expect people of opposing cultural outlooks to form opposing impressions of what most experts believe. The second piece of evidence from the study showed exactly that. Polling a large representative sample of US adults, we found that culturally diverse citizens had substantially divergent perceptions of expert consensus on climate change, nuclear waste disposal, and gun control. Indeed, we found that egalitarian communitarians and hierarchical individualists also perceived scientific opinion to be different from the position taken in so-called "expert consensus reports" issued by the US National Academy of Sciences in every instance in which the NAS position differed from the one that matched the subjects' own cultural predispositions. This result seems more consistent with the conclusion that *all* segments of the population are forming culturally biased impressions of what scientists believe than that only one cares about what scientists have to say.

Under these circumstances, the availability effect will interact with cultural worldviews to generate systematic polarization on what experts believe about risk. Asked what "scientific consensus" is on climate change, on nuclear power, or on possession of concealed firearms, individuals will summon to mind all the instances they can recall of experts expressing their views and discover that the overwhelming weight of opinion favors the view consistent with her own cultural predisposition. They'll reach that conclusion, of course, only because of unconscious bias in their sampling: the fit between an expert's position and the one congenial to their cultural predisposition is what *causes* them to take note of that expert's view, to assign significance to it, and thereafter recall it. We all believe that what "most scientists think" about a risk is important. Yet we all tend to overestimate how uniformly scientists believe what we are predisposed to believe is true.

## Cultural Credibility Heuristic

Most people (in fact, all, if one thinks about it) cannot determine for themselves just how large a disputed risk is, whether of environmental catastrophe from global warming, of human illness from consumption of genetically modified foods, of accidental shootings from gun ownership, etc. They must defer to those whom they find credible to tell them which risk claims and supporting evidence to believe and which to disbelieve. The cultural credibility heuristic refers to the hypothesized tendency of individuals to impute the sorts of qualities that make an

expert credible – including knowledge, honesty, and shared interest – to the people whom they perceive as sharing their values.

One study we did that at least makes a start at testing this hypothesis focused on the HPV vaccine. HPV, or the human papillomavirus, is a sexually transmitted disease that is extremely common among young women: it's estimated that as many as 45% of those in their early 20s have been infected by it (testing permits detection only in women). It is also the leading (effectively, the *only*) cause of cervical cancer. The FDA recently approved a vaccine for females. Public health officials recommend that the vaccine be administered by age 12, before girls are likely to become sexually active, because once a female has been exposed to HPV the vaccine won't do any good. Many states in the USA are now considering legislation to require HPV vaccination as a condition of school attendance. These provisions have provoked resistances from groups who argue that vaccination, by furnishing protection against one sort of STD, will increase the incidence of unprotected sex and thus put young girls at risk of other STDs, including HIV. Opponents of mandatory vaccination also cite the risk of unanticipated, harmful side-effects from the vaccine. Numerous state legislatures have defeated legislative proposals for such programs and one state legislature, Texas's, has overridden the creation of a program created by a gubernatorial executive order.

We studied the HPV-vaccine risk perceptions of 1,500 Americans (Kahan et al. 2010b). The sample was divided into three groups. One was supplied no information about the HPV vaccine. Another was furnished balanced information in the form of opposing arguments on whether its benefits outweighed its risks.

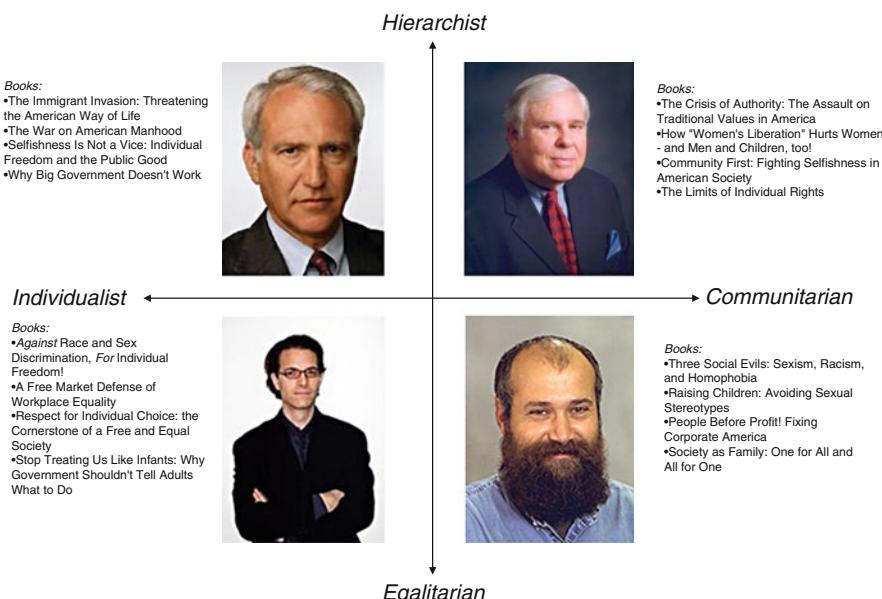

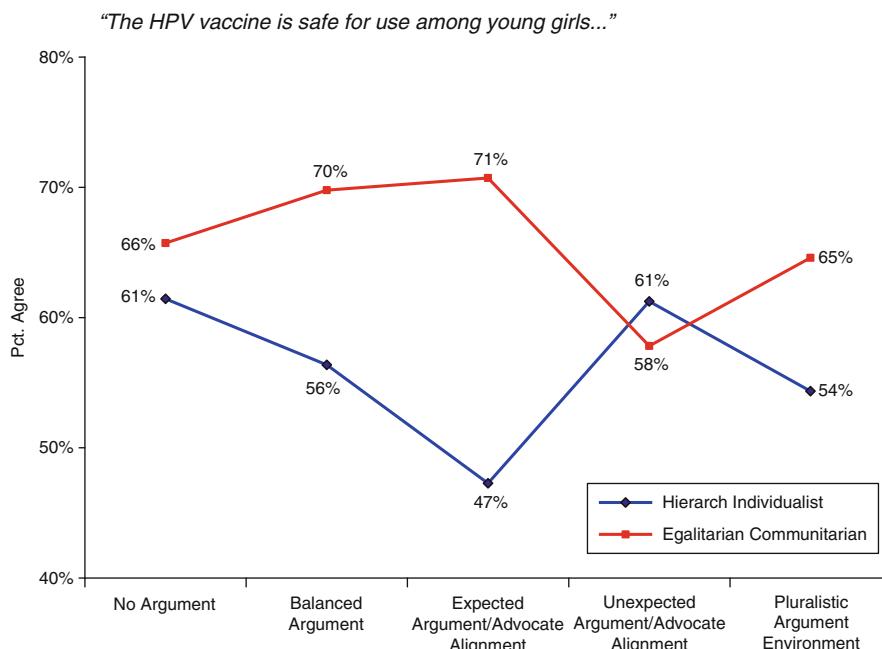

Fig. 28.15

Culturally identifiable advocates. On basis of pretests, fictional "experts" are perceived to have values characteristic of those defined by quadrants demarcated by intersection of group and grid (Kahan et al. 2010a)

The final group was exposed to the same arguments, which in this treatment were attributed to fictional, culturally identifiable experts, who were described as being on the faculties of major universities. We created the advocates in pretests. We showed one set of pretest subjects pictures of individuals, and asked them to try to guess how the pictured individuals would respond to our culture items. We then asked another group of pretest subjects to guess the fictional experts' cultural values after looking at both pictures and mock publication lists. We ended up with four culturally identifiable policy experts whose perceived cultural values located them in the quadrants defined by the intersection of group and grid (● Fig. 28.15). In the actual experiment, subjects (ones who had not previously participated in the pretests creating the culturally identifiable experts) were asked what they thought about the risks and benefits of the HPV vaccine after reading the opposing arguments, which were randomly matched with two of the four experts.

The results (● Fig. 28.16) suggested the operation of various mechanisms of cultural cognition. In the “no information” condition, there was already a division in the views of hierachal individualists and egalitarian communitarians on whether the vaccine is safe. As we had hypothesized, hierarchs and individualists were motivated to see the risks as large, the former because of their association of the vaccine with premarital sex and the latter because of

■ Fig. 28.16

**Impact of information and advocates on perceptions of HPV-vaccine risk.  $N = 1,500$ .** Gap between hierarchical individualists and egalitarian communitarians is significantly greater ( $p < 0.05$ ) in “Balanced Argument” relative to “No Argument,” and in “Expected Argument/Advocate Alignment” relative to “Balanced Argument,” it is significantly smaller ( $p < 0.05$ ) in both “Unexpected Argument/Advocate Alignment” and “Pluralistic Argument Environment” relative to “Expected Argument/Advocate Alignment”

their opposition to state-sponsored public health measures; whereas egalitarians and communitarians were motivated to see the risks as small, the former because they would see opposition as motivated by hierarchical sexual norms and the latter because they favor state-mandated public health measures. This is an identity-protective cognition effect.

These divisions grew in the “information without advocate” conditions. This is a biased assimilation and polarization effect.

In the “information with advocate” condition, the position of subjects was highly conditional on the congeniality of the experts’ values to the subjects. Where subjects received the argument they were culturally disposed to accept from an expert whose values they shared, and the argument they were culturally predisposed to reject from an expert whose values they opposed – call this the expected alignment condition – polarization grew. But where subjects received the argument they were culturally disposed to reject from the expert whose values they opposed, and the argument they were culturally predisposed to reject from the expert whose values they shared – call this the unexpected alignment condition – there was a significant decrease in polarization. Indeed, individualists and communitarians in this condition swapped places. This is powerful evidence, then, supporting the cultural credibility heuristic.

We also found out something else important. In what might be called the “pluralistic advocacy condition,” subjects observed opposing advocates whose cultural worldviews were equally proximate to or remote from their own. In this condition, polarization was also significantly diminished relative to “expected alignment” condition. In effect, confronted with a policy-advocate alignment that seemed to confound any inference that the issue was one that divided their cultural group and a competing one, individuals of diverse worldviews were less likely to polarize when they evaluated the advocates’ arguments. Presumably, this is a more realistic state of affairs to aspire to than one in which experts and arguments are aligned in a manner radically opposed to what one would expect.

Accordingly, one might identify the creation of a “pluralistic advocacy condition” – one in which risk communicators self-consciously recruit communicators of diverse cultural outlooks and are careful to *avoid* selecting ones whose identities or styles of argumentation infuse an issue with a meaning of competition or conflict between identifiable groups – as one way of *counteracting* cultural cognition. In such an environment, individuals might still disagree about the facts on risks, but they are less likely to do so along strictly cultural lines. Work on cultural cognition, then, helps to explain not only *why* we see cultural polarization on risks; it also suggests “cultural debasing” strategies – science communication techniques that make it more likely that individuals of diverse cultural outlooks will attend to information in an open-minded way.

## Cultural-Identity Affirmation

---

The next mechanism, cultural-identity affirmation, also can be seen as a type of “cultural debasing” strategy. This one is based on self-affirmation, a mechanism which is essentially the mirror image of identity-protective cognition and which has been extensively documented by Geoff Cohen, one of the Cultural Cognition Project members (Cohen et al. 2007, 2000). Identity-protective cognition posits that individuals react dismissively to information that is discordant with their values as a type of identity self-defense mechanism. With self-affirmation, individuals experience a stimulus – perhaps being told they scored high on

a test, or being required to write a short essay on their best attributes – that makes a worthy trait of theirs salient to them. This affirming experience creates a boost in a person's self-worth and self-esteem that essentially buffers the sense of threat he or she would otherwise experience while confronted with information that challenges beliefs dominant within an important reference group. As a result, individuals react in a more open-minded way to potentially identity-threatening information, and often experience a durable change in their prior beliefs.

Cultural-identity affirmation hypothesizes that you can get the same effect when you communicate information about risk in a way that affirms rather than threatens their cultural worldview. We tested this hypothesis in an experiment involving global warming (Cultural Cognition Project 2007). In the experiment, two groups of subjects all were asked to read a newspaper article that reported a study issued by a panel of scientists from major universities who found definitive evidence that the temperature of the earth is increasing, that the cause of the increase is manmade, and that the consequences of continued global warming would be catastrophic for the environment and the economy (☞ Fig. 28.17). In one treatment group, the newspaper article indicated that the study had called for the institution of stronger antipollution controls, a policy proposal *threatening* to the identity of individualists and hierarchs. In the other treatment, however, the newspaper article reported that the study had proposed removal on restrictions on nuclear power, so that American society could substitute nuclear power for greenhouse gas emitting fossil fuel energy sources. Nuclear power is *affirming* to the identity of individualists and hierarchs. Obviously, the proposed policy solution to the problem of climate change bears no logical or empirical relationship to whether the earth is heating up, whether man is causing the temperature rise, and whether global warming will have bad environmental and economic consequences. Nevertheless, consistent with the cultural-identity affirmation hypothesis, we found that individualists and hierarchs were both significantly more likely to credit the reported studying findings on these facts in the nuclear power than in the antipollution condition (☞ Fig. 28.18).

Indeed, we found that individualists and hierarchs who received the newspaper report that recommended antipollution controls were even more skeptical of the reported factual findings of the study than were individualists and hierarchs in a control group who received no newspaper story on the findings of the scientists. This is biased assimilation with a vengeance.

The practical lesson, then, is pretty clear. Don't simply bombard people with information if you are trying to make them more receptive to risks. Doing that can actually provoke a cultural-identity-protective backlash that makes certain groups even more disposed to disbelieve that the risk is a real or a serious one. Information can help, but it has to be framed in a way that *affirms* rather than threatens the cultural identities of potential risk skeptics. One way of doing that is through policy solutions that are culturally affirming of the skeptics' identities.

Or in other words, don't try to convince people to accept a solution by showing them there is a problem. Show them a solution they find culturally affirming, and then they are disposed to believe there really is a problem in need of solving.

## Further Research: Collective Management of Cultural Bias

Discussion of the last two mechanisms suggests yet another distinction between cultural cognition and various other conceptions of the cultural theory of risk. Cultural cognition suggests that the influence of worldviews on risk perceptions can be collectively managed in

## Scientific Panel Recommends Anti-Pollution Solution to Global Warming

By Jeffrey Cohen  
November 15, 2006

The American Academy of Environmental Scientists, a panel consisting of leading U.S. experts, today recommended stronger anti-pollution regulations as a response to global warming.

"Fossil fuels such as coal, natural gas, and oil are the leading cause of global warming," explained Dr. Jonathan Brasil, head of the Academy. "To reduce the volume of heat-trapping gas generated by such fuels, we recommend that the government adopt stronger anti-pollution regulations, ones strengthening ones adopted in 1970s and 1980s," Brasil said.

The group's recommendation was made in a report that examined the extent and causes of global warming and the likely consequences that would occur if global warming were not reversed.

The American Academy of Environmental Scientists, a panel consisting of leading U.S. experts, today recommended revitalization of the nation's nuclear power industry as a response to global warming.

### Highlights of AAES Report

- Fossil fuels such as coal, natural gas, and oil are the leading cause of global warming.
- Scientific evidence furnishes *irrefutable proof* of global warming. Some of the most obvious effects are visible in the Arctic, where rising temperatures and melting ice have dramatically changed the region's unique landscapes and wildlife.
- Global warming is caused by carbon dioxide and other heat-trapping gases that are emitted primarily by the burning of *fossil fuels*. These gases remain in our atmosphere for decades or even centuries.
- If it continues, global warming could have *catastrophic environmental and economic consequences*. Among the results will be extreme heat and drought, rising sea levels, and higher-intensity tropical storms. Such conditions will endanger coastal property and resources, diminish the habitability of major cities, and curtail the productivity of our farms, forests, and fisheries.
- Fossil fuels such as coal, natural gas, and oil are the leading cause of global warming. According, we strongly recommend that the government adopt *stronger anti-pollution regulations* to reduce the volume of heat-trapping gas generated by such fuels.

Fig. 28.17

Alternative versions of newspaper article reporting scientific findings on climate change. Subjects were assigned to one of three conditions, in two, they read one of the featured newspaper articles, each of which summarized scientific findings, in the red inset, indicating that climate change was occurring, was caused by humans, and was likely to have catastrophic effects unless reversed. Subjects in the third, control condition read a newspaper article about debate on the need for a new traffic signal at a busy intersection (Cultural Cognition Project 2007)

**Fig. 28.18**

**Effect of framings on hierarchical-individualist skepticism on global warming facts.**  $N = 500$ . Bars denote the size of the difference between egalitarian and hierarchical individualist subjects' beliefs in climate change facts, as measured by z-scores on a composite scale that combined responses to questions on whether climate change is occurring, whether it is caused by human activity, and whether it would have adverse environmental impacts if not contained or reversed. Derived from linear multivariate regression in which worldviews and experimental condition were treated as predictors. Confidence intervals reflect 0.95 level of confidence (Cultural Cognition Project 2007)

a manner that simultaneously advances the interests of persons of all cultural persuasions. Identifying the means by which this end can be realized, I'm convinced, should be regarded as the priority of future cultural-cognition research.

The meta-worldview of Douglas and Wildavsky features necessary and permanent cultural conflict. Because there is no culture-free perspective, it is not possible for individuals to "overcome" reliance on their worldviews in apprehending risks. As a result, it is not possible for society to overcome the persistent struggle of opposing cultural groups to designate forms of behaviors associated with their rivals as sources of danger that must be repressed. One or another group might gain the upper hand, and thus impose its view, at least for a time. One might even form a temporary rooting interest for one or another on grounds that are seemingly utilitarian in nature (Wildavsky 1991). But the idea of brokering a peace between them – of formulating a positive-sum outcome to their bitter competition – would seem to defy the logic of cultural theory.

Cultural cognition is more catholic. Nothing in its account of the mechanisms that connect culture to risk perceptions implies that those dynamics are exclusive of others that might inform individual apprehension of risk. Nor does anything in that account entail that the contribution that alternative cultural worldviews make to risk perception are static and relentlessly oppositional.

This stance, then, creates the possibility, at least as a matter of theory, that adherents to competing ways of life might converge on shared understandings of societal risk and the most effective means for abating them. One strategy for promoting such an outcome involves the adroit framing of information, and of policies, to make them bear a plurality of meanings that can be simultaneously endorsed by opposing cultural groups. There are seeming historical examples of this dynamic – ones involving convergence of cultural groups on environmental policies in the USA and abortion policy in France, for example – which my collaborators and I call "expressive" or "social meaning overdetermination" (Kahan and Braman 2006; Kahan 2007).

Working within the logic of cultural cognition, we have tried to systematize “social meaning overdetermination” as a strategy for generating positive-sum solutions to cultural conflicts in political life. At least one other group of scholars working within the broad outlines of “group–grid” theory have proposed a similar approach, which they call “clumsy solutions.” (Verweij and Thompson 2006).

Another strategy, one unique to cultural cognition and reflecting its emphasis on mechanisms, suggests the value of structuring democratic deliberation in ways that effectively lessen participants’ *reliance* on culture. Many of the mechanisms of cultural cognition involve the use of cultural cues as a heuristic or mental shortcut. But as experimental studies show, it’s possible to disable or blunt culture’s heuristic influence: when people’s cultural identities are affirmed, they don’t experience the threatening affective response, or are less influenced by it, as they consider information that challenges beliefs that predominate in their group; when they can’t discern a consistent connection between the cultural identity of advocates and positions on some risk issue, they can’t simply adopt the position of the advocate whom they perceive as having values most like theirs. At least in theory, then, it should be possible to build into policymaking institutions and procedures devices that similarly stifle the sorts of cues that the mechanisms of cultural cognition depend on. When that happens, individuals will be forced to process information in a different way, maybe in a more considered way, or maybe in a way that reflects other cues that are reliable but not culturally valenced. In the resulting deliberative environment, individuals might not immediately converge on one set of factual beliefs about risks and risk mitigation. But they won’t spontaneously split into opposing cultural factions on those matters.

If there is a meta-worldview for cultural cognition, it is that this state of cultural *depolarization* is a good thing (Kahan 2007). It’s a good thing, to begin, morally speaking. Because culturally infused disagreements over global warming, gun control, vaccination of school girls for HPV, and the like *is* experienced by all as a form of conflict between contesting cultural factions, the polarizing effect of cultural cognition poses a distinctive sort of threat to liberal political life.

But neutralizing cultural polarization is also a good thing instrumentally speaking. Nothing in cultural theory, as Wildavsky and Douglas originated it or as it has been refined thereafter, implies that there are no real facts about risk or that we can’t, through the best information we can discover on the workings of our world, form better or worse understandings of those facts. Regardless of their differences about the ideal society, hierarchs and egalitarians, communitarians and individualists all have a stake in policymaking being responsive to that information; regardless of what lives they want to live, they can all live those lives better when their health is not threatened by contamination of their food or air, when their economy is insulated from disruptive influences (including governmental ones), and when they are free of domestic and external security threats. These culturally diverse citizens then would presumably all agree that they ought to structure their political institutions and processes in a manner that counter cultural polarization on issues of risk, because when society is culturally polarized the best understandings we have about risk are *less* likely to become operative as *soon* as they would otherwise.

Or at least they sometimes would agree, behind a cultural veil of ignorance as it were, that that’s what they want. The possibility of self-consciously managing cultural cognition presents a host of complicated moral questions in large part because the moral status of beliefs we form as a result of our cultural identities is complicated. Only a fool – a moral idiot – would regard those beliefs as *uniformly* unworthy of his or her endorsement. We don’t *just* want to live or

even live well (in a material sense); we also want to live virtuously and honorably. There's no way to figure out how to do that, I am convinced, without certain moral insights that *only* cultural infused modes of perception can afford (Kahan 2010).

So part and parcel of any project to manage cultural cognition is an informed moral understanding of when, as individuals and as a democratic society, we *should* be responsive to cultural cognition and when we *shouldn't*. Like Douglas and Wildavsky, I don't think it makes any sense to believe we can "overcome" our cultural commitments in considering that issue. But I see nothing that makes me believe that persons of diverse cultural persuasions will inevitably be driven into irreconcilable disagreement over how to resolve it. Until I *am* presented with evidence that forces me to accept that sad conclusion, I will pursue a conception of cultural theory that sees dissipating conflict over risk as the very point of explaining it.

**Abstract:** This chapter exemplifies risk communication projects and aims at illustrating the specificity of each risk communication task as well as what general conclusions can be gained from such work. Tools for risk communication include the selection of strategic and theoretical approaches as well as a number of considerations in applied settings. The examples show the influence of social and historic events that embed a communication setting or a conflict situation resulting in a risk communication project, and how values, attitudes, and feelings steer thinking and behavior in intergroup interactions. The examples also generate some ideas for the improvement of risk communication work. The RISCOM model of transparency is presented shortly, although most described projects were based on the less elaborate designs of group discussions. It is concluded that risk communication always takes place in a social setting, involving various interests, power relations, and actors' own agendas, but that the aim to communicate about specific risks nevertheless can be focused on clarification, understanding, and learning. The described tools for risk communication aim at achieving clarity in dialogues characterized by openness and interaction regarding risk issues to enhance problem solving and democracy.

## Introduction

---

Communication is vital for all aspects of life. In addition to every individual's personal communication experiences, there are many academic fields that systematically describe the nature of communication and communicative processes. A review of such theories is not the approach of this chapter, but examples can be found in several excellent contributions in this handbook. From the point of view of describing "tools for risk communication," the early and well-known question by Lasswell (1948) – "Who says what to whom with what effect?" – may be a good enough starting point. Risk communication projects are often initiated when some risk aspect has already been highlighted, often as a controversial issue, and when problems have surfaced in the interaction between parties that hold different views, or when there is a strong suspicion that serious conflict is approaching due to localization of an establishment, e.g., in the "Not in my backyard" (NIMBY) attitude context (see, e.g., Dunlap et al. 1993).

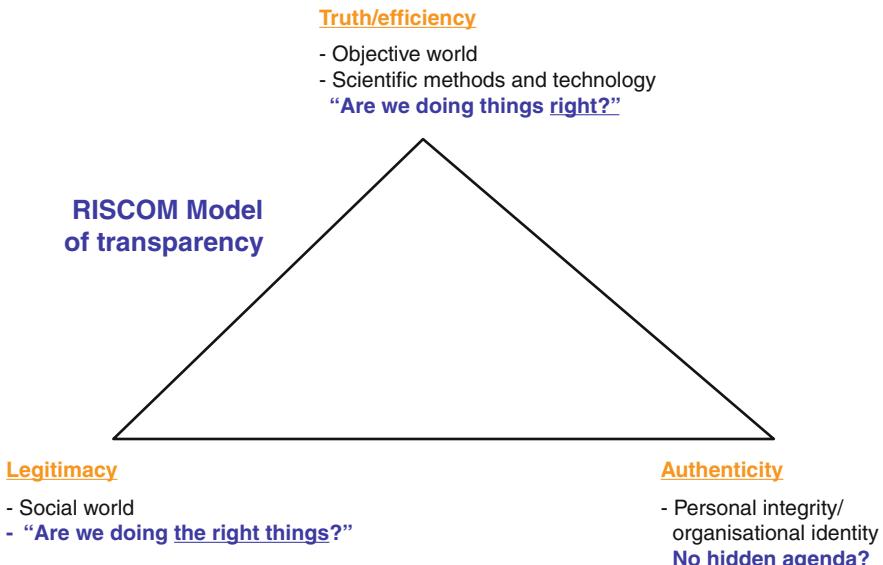

There are obvious challenges in the work, but also not so obvious challenges, and the latter may constitute the real challenges in practical work. Research literature on communication usually provides composite theoretical frameworks, and interaction models including senders and receivers, turn taking in dialogues, and elaborations on the cognitive processes of interpretation and understanding (e.g., Krauss and Fussell 1996; Littlejohn 1999). The necessity of presenting clear messages using common words is also often underlined in risk communication. Thus, these ordinary communication aspects are not unimportant. However, even if a communication situation meets obvious interaction requirements it may present challenges of different kinds. One of those is the situation where one or several persons in an exchange actually do not understand that he or she does not understand. It may take some time before highly specialized experts, or excited protagonists, come around to ask, e.g., "What do you mean with that?" or "How do you define that?" Misunderstandings can easily result from different conceptualizations of terms within specialization areas, lack of knowledge, or simply be based on unwillingness to consider an opponent's point of view. If a misunderstanding is not observed at all, the involved will keep their own interpretations of the exchange and may later discover that others act in ways that are inconsistent or contradictory to how they had understood the

results of the discussion. If such a development takes place and is not rectified, it is not uncommon that those involved lose interest and trust in each other. If a misunderstanding is not observed, or not corrected, the interacting parties might choose to disregard one another's comments, leave the communication situation in frustration, or try to gather support from others for the own perspective, and thus escalate a misunderstanding into a social conflict.

A related unobtrusive challenge is the type of situation that involves the determining of whether or not a misinterpretation was intentional or not. Words and concepts are often laden with multiple meanings, and therefore involve ambiguities, and it is not uncommon to misinterpret sincerely produced statements. Skilled demagogues or change agents, however, are talented in the choice of words and ambiguities so that they favor their own goals or rhetorical points. Since risk communication projects often are developed on the basis of already existing group polarizations or social conflicts, and are more often introduced reactively than proactively, it is of extreme importance to approach such work with a clear understanding of not only the intricate communication challenges but also of the simultaneous social interaction processes that frame the situation that involve individuals and groups.

Risk communication work is much trickier than one would expect at first glance. The definition of what is a hazard, or a risk, is not unproblematic and ordinarily a communication process also involves many social, interpersonal, and personality aspects. In addition to *defining* the relevant risk issues in a certain *social situation*, risk communication has the main goal to *capture* and *discuss* the particular risk issues around which a project is based. "Risk" will here be defined in terms of perceived risk, i.e., a phenomenon evaluated by an individual to have some kind of negative effect or consequence attached to it. However, perceptions and subjective evaluations can, for many reasons, be erroneous. For example, they can be based on selective or incorrect information, inadequate knowledge, and be more or less influenced by feelings and emotions. Therefore, communicating about risk is related to investigating and clarifying the correct or the optimal answer based on perceived risk and available information. If enough valid knowledge about a risk can be made available, the risk communication task can be focused on elucidating that knowledge in a dialogue process aiming at increased understanding and management of the risk. Risks are communicated by words as well as by numbers and symbols. Thus, the risk communication task is related to clarifying concepts and estimates from risk or safety analyses, i.e., quantitative calculations of the probabilities of the involved negative outcomes. For example, a local residence area has received the information that the communal water supply contains a health risk, i.e., a certain type of parasite. The perceptions of this particular risk will differ, due to, e.g., the information given, previous relevant knowledge and experience, responsibility for others, personal health status, etc. Risk communication, in this water contamination example, will involve an exchange of various perceptions, and different types of reactions, but also expert estimates of the health risk to various categories of water users or groups of individuals, and regarding different uses of the water such as drinking or washing. Thus, risk communication goes beyond ordinary exchanges of personal views on a subject matter since it also aims to communicate to what degree there is a danger, to whom, and what can be done to avoid or to mitigate negative consequences.

This chapter gives examples of the layers of complexity in communicating about risk. As noted above, risk communication projects are often started when there is already an explicit problem, often highlighted by very different interpretations or perceptions of a risk or situation. Such situations are often characterized by severed trust between the interacting parties. It may therefore be the case that sources that ordinarily are judged as providing valid

**Fig. 29.1**  
The RISCOM model of transparency

information, e.g., expertise, authorities, or decision-makers in various contexts, no longer are trusted, putting an information recipient in a situation of uncertainty, discomfort, and maybe worry. Without sufficient trust in information sources, a person may not be willing to apply the everyday “rules of thumb” that facilitate choices and behavior. Instead, much more deliberate thinking is required to sort out premises, options, and actions. This step is difficult because it involves the application of knowledge gathering skills, time to process new information, and motivation. It is in this phase of active information processing that risk communication projects may be helpful. However, people react differently to challenges and dangers. Some try to find answers, others seek comfort among similarly inclined, and yet others may instead prefer not to be reminded of the hazard or simply deny a risk. One challenge in a risk communication project is therefore to provide a neutral arena that allows the voicing of different perceptions, opinions, and reactions but which, at the same time, strives at clarification of the risk issue.

A theoretical framework that incorporates the simultaneous communication of scientific facts or expertise information, social norms, and personal characteristics is the risk communication model of transparency, RISCOM, developed and used by Andersson and colleagues (Andersson et al. 1998, 1999, 2006). It is based on Jürgen Habermas’ writings on communicative action (e.g., Habermas 1988) that claim that in order for an action to be communicative the statements must be true, right, and truthful. That is to say that every competent speaker raises three claims: about the “objective world,” i.e., “What I say is true” (theoretical interest, scientific quest), about the “social world”, i.e., “What I say is legitimate” (practical interest, societal norms), and about an “inner world,” i.e., “I am truthful and speak from conviction” (emancipatory interest, values held by individuals or groups). The RISCOM triangle is presented in Fig. 29.1.

The RISCOM model was developed in a number of projects in the 1990s, and it has been tested in European Union projects in the 2000s (ARGONA, IPPA). The RISCOM model of

transparency is based on four principles: a multi-perspective starting point, “stretching capacity,” impartiality and fairness, and the public sphere as the working arena, i.e., the *transparency forum*. The concept of transparency is defined as an outcome of an ongoing learning process in a given policy area, which increases the participants’ or stakeholders’ appreciation of related issues and provides them with channels to challenge, or to *stretch*, other participants’ positions regarding, e.g., to meet requirements for technical explanations, proof of authenticity, and legitimacy of actions. Transparency, in this context, requires a *guardian* to secure process integrity. The transparency forum includes a *reference group*.

The reference group builds on stakeholder participation, e.g., industry, academia, authorities, NGOs, and is established by a formal agreement between the participants. This reference group agrees on a structure for the communication process, i.e., defines the “levels of meaningful dialogue.” It also arranges the overall process, including seminars, hearings, etc. The second phase involves the communication activities, e.g., a hearing, seminars, and group work, in a tailored format made as public as possible and preferably with media attendance. The third phase involves documentation and dissemination of results. The transparency forum does not end with recommendations to decision-makers. The sole aim is to create an arena where all stakeholders increase their awareness and learning. After that, the ordinary political system takes over. In the context of this chapter and the examples given below, i.e. the ARGONA project was designed in line with these ideas.

The approach to *tools* for risk communication in this chapter, attempts to provide a basis for enhanced understanding of the challenges in communication about risk and what could be useful approaches, or tools, in those situations that need to consider both context and content. Risk communication projects are always situated in a larger social and political context, and core beliefs and values acting in that larger context will seep into individual views and group discussions. However, a risk communication project also has a specified task. That task defines the central content. The context and the content interact in many ways. This chapter presents examples of challenges and lessons learnt from a few selected risk communication projects.

## Background

---

Communication has, on the one hand, been described as an interaction impossible not to perform, i.e., “one cannot not communicate” (Watzlawick et al. 1967), and on the other hand as mere transmission of information which is not necessarily received or understood (for theories of human information processing, persuasion, and communication see, e.g., Petty and Cacioppo 1986; Petty and Wegener 1998; Littlejohn 1999; McQuail 2000; Chaiken 2003). Very often, we believe that a sent message was clear and unambiguous although responses and reactions may later indicate totally different and unexpected interpretations. Such unintended communication exchange is quite common in ordinary life. In person-to-person exchanges, it is usually possible to correct mistakes during the interaction, but, of course, that requires mutual interest and willingness to listen. Imagine a situation involving reluctance to listen in combination with the intricate challenges in communicating specific definitions, or the intended meaning, of abstract concepts such as “hazard,” “risk,” and “uncertainty.” Furthermore, imagine discussing these basic concepts in situations where people feel unjustly exposed to risk and fear for their health or safety or in a situation where various groups actively pursue campaigns to achieve specific goals, e.g., exaggerating or minimizing threats in order to

influence a decision. The examples highlight the importance of pedagogical skills as well as the need to achieve mutual respect to enable dialogue and understanding in risk communication projects.

There are excellent reviews of the history, contents, and development of the research field elsewhere (Plough and Krimsky 1987; Covello et al. 1989; Fischhoff 1995; Renn 1998; North 1998; Fischhoff et al. 1993; Boholm 1998; Gurabardhi et al. 2005; Wright et al. 2006; Breakwell 2007) and here it is suffice to say that the risk communication area has very rapidly gained in scope and content, especially since the 1990s. Today it represents a well-established field of research with contributed knowledge and experience from many scientific disciplines, civic organizations, and other contributors. It presents numerous theoretical models and risk communication applications related to highlighted societal challenges and events, e.g., faulty consumer products, chemical contamination, radioactive fallout, oil spills, nuclear waste, GM crops, utilization of gene and nanotechnologies, etc. (e.g., Dunlap et al. 1993; Levidow et al. 2000; Kennedy et al. 2010). There are also numerous studies related to local concern and conflict attached to existence, development, or change of infrastructure and industrial production (e.g., Moffatt et al. 2003; Prades et al. 2009; Kari et al. 2010).

It is not possible to present a recipe for success of a risk communication project. However, there are many risk communication failures to learn from which, together with common sense, can help steer strategies and practical considerations between the rock and the hard place. Thus, it is easier to predict failure than it is to predict success and some indicators of failure or initiatives leading to negative results are exemplified below. Large projects affect a number of people and may involve many actors or interest groups. Comments from participants usually include reflections on the design of the process as much as its content. It should also be mentioned, however, that change in itself is perceived to involve more uncertainty than is an “undisturbed” status quo. Suggestions involving change may therefore be perceived as more risky than suggestions aiming at refraining from action. Thus, a risk communication project will have to handle reactions to change as well as to the process design and the specific risk issue content.

The road to failure involves not giving any, or sufficient, information to the directly affected or the general public before an important event or decision takes place. Lack of early notification before an important event, forgetting to mention, or to strategically withhold information regarding plans or decisions related to an important issue, cause discontentment. An example could be to execute plans of investigating a municipality for uranium ore without prior notice and open debate, or to start an expansion of an existing industrial establishment without prior information. Another golden road to problems is to allow, or participate in, non-transparent decision processes, or to be obscure or ambiguous regarding responsibilities so that information about what, when, how, and by whom is not clear. To increase the level of irritation one can classify, or treat as confidential central documents, such as detail plans or results of risk analyses. Other options involve hindering insight in an ongoing decision-making process by blocking, or otherwise not making available, communication channels for information, questions, and responses. It is also usually helpful in achieving public outrage or distrust to force a decision, or complete a political decision process, before participation processes or a public debate have been initiated or sufficiently thorough.

With respect to risk events, or projects in local communities that specifically concern local groups of inhabitants, one path to irritation and possible future failure goes via media, i.e., to allow the first information about a change or decision to reach the directly concerned groups through ordinary news and media channels. It is a failure path to avoid early contacts with

central stakeholders, and to insist, e.g., via media, that there is no risk at all, or at least none that is known so far. If this is not enough to stir inflamed debate, an actor can certainly also make sure there is no available service arrangement responding to public inquiries, by phone, letter, or electronic media.

If a communication or participation process is underway, a failure predictor includes to avoid or disregard the most creative or farfetched “worst-case” scenarios that critics come up with. A response saying that such events will almost certainly not happen so why waste time and energy in looking into the matter, will quickly impact the process. Also, to avoid responding to inquiries about rumors or examples of other actual or possible mishaps or accidents usually increase the interaction temperature. Generally, to approach individuals and groups as if they were totally ignorant and without any possibility to understand the extreme complexity of the issue at hand usually helps create major communication problems. However, avoiding these paths leading to communication failure and maybe social disruptions does not necessarily guarantee success. Successful approaches instead seem to involve active involvement, early communicative approaches, comprehensive strategies, and systematic work to achieve success instead of mere clinging to strategies of avoiding problems.

It must be added here, of course, that communicative processes described in this chapter are embedded in social systems based on democratic values. If a society does not adhere to values of equality, free speech, and political participation, etc., or have not accepted international conventions or, e.g., EU directives on safety and information (cf. the [Seveso II directive](#); see also De Marchi 1991; De Marchi and Funtowicz 1994; Stern and Fineberg 1996), then the content of this chapter is not applicable. Thus, the cases presented further below aim at illustrating some challenges that may be encountered in risk communication processes related to vital societal projects conducted in democratic societies.

Access to information and the right to voice one’s opinion are basic principles in democratic societies. Rather recent developments, of special relevance to risk communication projects, include the opening up for concerned persons to *participate* in decision processes. For example, the Aarhus convention (1998) with specific relevance to environmental issues builds on earlier declarations related to humans, environment, and development. It states, e.g., that the parties to the convention (Convention on Access to Information, Public Participation in Decision-Making and Access to Justice in Environmental Matters, Aarhus, Denmark, June 25, 1998. See <http://www.unece.org/env/pp/documents/cep43e.pdf>) are

- ▶ *Recognizing that, in the field of the environment, improved access to information and public participation in decision-making enhance the quality and the implementation of decisions, contribute to public awareness of environmental issues, give the public the opportunity to express its concerns and enable public authorities to take due account of such concerns*

*Aiming thereby to further the accountability of and transparency in decision-making and to strengthen public support for decisions on the environment, . . .*

The following quote from later work underlines the importance of public participation processes (“Vision and Mission” of the Aarhus Convention Strategic Plan, paragraph 4, adopted by the Meeting of the Parties to the Aarhus Convention, in Riga, Latvia, on 13 June, 2008. <http://www.unece.org/env/pp/>): “The serious environmental, social and economic challenges faced by societies worldwide cannot be addressed by public authorities alone without the involvement and support of a wide range of stakeholders, including individual citizens and civil society organizations.”

Environmental issues directly affecting health and safety, and issues that involve the continuous interactions of humans, the environment, and societal and technological developments, make the Aarhus convention and similar international declarations or conventions, e.g., Agenda 21 from the 1992 Rio conference, basic guides to values enhanced in risk communication work. In 1985, the European Union introduced the *Environmental Impact Assessment Directive* ([EIA, 85/337/EEC](http://eia.85/337/EEC)) for analyses of environmental effects of certain planned activities. A summary provided on the Internet states that the EIA “must identify the direct and indirect effects of a project on the following factors: man, the fauna, the flora, the soil, water, air, the climate, the landscape, the material assets and cultural heritage, and the interaction between these various elements.” ([http://europa.eu/legislation\\_summaries/environment/general\\_provisions/128163\\_en.htm](http://europa.eu/legislation_summaries/environment/general_provisions/128163_en.htm)) The EIA includes consultation processes with locally affected and other stakeholders. A 25-year anniversary EU conference on the theme “Successes – Failures – Prospects” was held in 2010 for evaluation and discussion of the directive.

The European *Strategic Environmental Assessment*, the SEA Directive 2001/42/E, also known as strategic environmental impact assessment, applies to an authority (at national, regional, or local level) and relates to a wide range of public programs and plans. It requires, e.g., consultation with environmental authorities and assessment of reasonable alternatives. The European Commission (<http://ec.europa.eu/environment/eia/sea-legalcontext.htm>) states as follows:

- ▶ The SEA procedure can be summarized as follows: an environmental report is prepared in which the likely significant effects on the environment and the reasonable alternatives of the proposed plan or programme are identified. The public and the environmental authorities are informed and consulted on the draft plan or programme and the environmental report prepared. As regards plans and programmes which are likely to have significant effects on the environment in another Member State, the Member State in whose territory the plan or programme is being prepared must consult the other Member State(s). On this issue the SEA Directive follows the general approach taken by the *SEA Protocol* to the UN ECE Convention on Environmental Impact Assessment in a Transboundary Context. (Convention on Environmental Impact Assessment in a Transboundary Context done at Espoo (Finland), on February 1991; <http://live.unece.org/fileadmin/DAM/env/eia/documents/legaltexts/conventiontextenglish.pdf>)

Decision-making and participation processes are often studied and carried out under the broad umbrella conception of *governance* in the research field (European Commission 2001; OECD 2003; Pierre 2000; Renn 2008). The development in the field clearly shows the necessity of multidisciplinary and multi-stakeholder approaches for capturing the wide scope of important perspectives, as well as the detailed accounts of risk matters. The basic assumptions and general approach presented above in relation to the RISCOM model should be seen in that wider context. ➤ *Figure 29.2* gives examples of types of forums used in discussions of various environmental risk issues. An example from the Select Committee on Science and Technology in the United Kingdom, House of Lords (2000) clearly states the preferred future development of public dialogue:

- ▶ *That direct dialogue with the public* should move from being an optional add-on to science-based policy-making and to the activities of research organizations and learned institutions, and should become a normal and integral part of the process (paragraph 5.48) House of Lords (2000).

The following part of this background will give a short account of the methodological approach of small group discussions, i.e., techniques including, e.g., focus groups, dialogue

Forms for participation	Only experts	Individual "stakeholders" & decision-makers	The general public	Public decision-makers
Informative		Dialogue	Science shop	
Advisory	Science court Expert committee	Team synergy	Consensus conference	Strategic Environmental Assessment (SEA) EIA forum

Fig. 29.2

Examples of various forms of participation, types of groups involved, and aim of participation. Based on Andersson (2001), in the context of nuclear waste management. For elaboration see Andersson (2008)

groups, and group interviews. The reason to exclusively deliberate on group discussions, although there are many methodologies that can be and are used in risk communication work, is that each project is unique to a high extent, and it is usually necessary to start with getting an overview of what ideas, perceptions, and actions that are involved. Pilot projects are therefore often designed to extract as much qualitative information as possible from the involved participants using interviews and group discussions. Results from such projects can later on be utilized in new and more structured data collections that allow for many participants, e.g., questionnaires. Large projects can also deal exclusively with information collected from various kinds of interviews and group discussions.

Various forms of group discussions are exemplary ways to get personal views and collective reflections from participants in a project. Group discussions have the advantage of saving time as compared to personal interviews with the same number of individuals. A group discussion is different from a face-to-face encounter since several persons interact at the same time and thus influence each other. It is therefore neither an optimal choice of methodology if the goal is to investigate, e.g., individuals' attitudes or personal values, nor an ideal forum for exchanging thoughts of an intimate personal nature or for extremely timid persons to express their views. Group discussions are effective, however, for achieving a broad overview of an issue by the sampling of comments and, e.g., information needs. The reflecting and commenting on thoughts introduced by others in the group usually provide additional information in comparison to several isolated interviews. The research literature presents much scholarly material and insight of how to structure discussions and how to evaluate results (Merton 1987; Glaser 1992; Denzin and Lincoln 2005). Only a skeleton version is presented here to give a flavor of goals, work considerations, and requirements.

For research, and for information purposes, the goal of the group discussion often involves eliciting comments, ideas, and perspectives from several participants at the same time. Focus groups can take many forms (see, e.g., Kamberelis and Dimitriadis 2005). Groups can be “homogeneous” or “heterogeneous” in composition. For example, the design of a study could differentiate discussions of youth and adult groups, use separate groups of experts and non-experts, or have as a goal to involve representatives of a variety of interests in the same discussion. The choice of how to organize the composition of the groups involved in a project depends on the aim of the study, the type of issue discussed, and, e.g., actual or potential conflicts between groups or persons. Sometimes it can be helpful to start out with separate homogeneous groups to make sure that each stakeholder’s interest or perspective is fully investigated and captured before moving on to a second round of group discussions involving representatives from various perspectives to develop the discussion.

Preparation is essential! Before the actual meeting, there have been considerations of the “design” of the group(s) and discussion themes, the preferable time and place, what is enough time for a good result, and how to follow up. There are also a number of practical questions that need to be taken care of, e.g., who is the host, who pays what (e.g., about invitations and travel, localities, refreshments, etc.), and what information should be provided to the participants (e.g., financier, responsible organizer, person in charge, time, and locality) so they have access to a correctly presented situation when they decide on whether or not to be involved. Participants have been contacted, e.g., by letter and phone, and given information, descriptions of practical arrangements, topics, and types of questions.

A “good” or effective group usually involves five to eight persons. Note that the more persons involved, the more time must be allocated for the discussion. A group process takes time and due consideration must be taken to create a comfortable situation where project information, presentations of the participants, and time for their questions on the project and proceedings are parts of the starting up phase. Introductory information also describes the project, ethical rules in research, how the meeting will be structured, the future use of the information, and the expected use of the results. It is important to have clearly formulated themes and questions. Written material clarifying such matters may have been sent to participants in advance.

The degree of structure in the actual work, and the interaction rules, must be outlined and found in accordance with the aim and design of a project. The design of the group discussion usually involves one or a few central topics. The group leader distributes the turn taking in the discussion. And although the term “discussion” involves an open exchange format it is nevertheless important to impose a certain structure on the discussion for time reasons. Usually it is favorable to discuss one topic exhaustively before moving to the next. “Exhaustively” means that each participant has had the possibility to present his or her view without interruption, using reasonable time. Comments and reflections related to the views presented by other participants can be welcomed and encouraged if time allows, but such additions must aim at contributing new substance, not at evaluating others’ views. The session is *not* about establishing the “right” or “wrong” opinions. It is an exercise of acquiring information on the participants’ views with respect to a specific topic, with as much explanatory argumentation as possible.

The group discussion leader must be well prepared to follow up and ask for clarifications during the interaction. It is also common that the leader of the discussion summarizes the main results of the work before asking the participants for final comments. The time allocation and

degree of structure of this feedback depends on the design of the project. The information collected from a group discussion should also be summarized in writing in a way appropriate to the project's aim. The presentation format of such summaries can vary between verbatim transcriptions of everything uttered in the group to structured overviews of central ideas or responses. See the research literature for more detailed accounts of analysis and presentations of qualitative data (e.g., Denzin and Lincoln 2005). A written summary or report in the native language of the participants is usually expected in this kind of project. The publication of articles in scientific journals makes the results available to the larger research community for criticism and inspiration, in accordance with the idea of cumulative development of knowledge. The results from a project will in such a manner contribute directly and indirectly to the research field, and be available when considering new tasks and projects.

## Current Research

---

This section presents examples of social challenges, group interactions, and basic problem dimensions in selected research projects. It aims at highlighting the complexity of the situations where risk communication is introduced, as well as at exemplifying risk communication strategies and tools in fieldwork. Most examples illustrate work in local communities where reactions among the citizens were important for the initiation of the risk communication projects. One example emanates from an international European Union project that is included to highlight similarities and differences in relation to the same type of task across countries.

### Social Challenges: An Example of Public Reactions to Inviting a Geological Investigation

---

In an attempt to carry out geological investigations for a repository for spent nuclear fuel, the operator, Swedish Nuclear Fuel and Waste Management Co (SKB), reached out to Swedish municipalities in the beginning of the 1990s and suggested a dialogue on the issue. The geological investigation aimed at determining whether or not the bedrock conditions were suitable for further industrial explorations. The company received the first invitation from the municipality of Storuman in the north of the country. When the invitation became publicly known it quickly became a major political issue eventually resulting in a local referendum. The result of the referendum was a clear vote against the geological investigation (72%) and the invitation to the operator was withdrawn. The municipal board's initiative caused an unexpected social turbulence in the vast and sparsely populated northern municipality. It was of interest to the company to investigate the reasoning behind the outcome of the referendum in more detail and they therefore initiated a project (Drottz-Sjöberg 1996, 1999). The results were based on interviews with people who had been active in the campaign preceding the referendum. The participants were initially grouped into the two major interest categories of voting for or against the site investigation. Those who voted against a geological investigation emphasized values such as traditions, personal control, preference for small-scale business and decentralization, as well as keeping nature untouched, and they did not want to be dependent on large entrepreneurs. Those who voted in favor of inviting the operator instead

emphasized the need for major investments in the local area and jobs for people, economic expansion, and increased centralization.

However, the results also indicated influences from a major value dimension, i.e., “collectivism-solidarity vs. individualism-personal success.” This dimension split the main pro and con groups into subgroups. Thus, in the group promoting the geological investigation the municipal authority, with many years of firmly rooted social democratic solidarity values and the collective interest in mind, was found on the same side as the established business and industry part of the society. Those who had voted against in the referendum formed two major subgroups as well; one which especially emphasized traditions, decentralization, solidarity and the safekeeping of an intact wilderness, and one of small-scale business and potential entrepreneurs that disliked dependence on large entrepreneurs, but emphasized small family controlled businesses and making use of nature in a restricted way for personal gain.

Thus, the political initiative to invite the geological investigation, based on evaluations of the future common good of the municipality, found itself on the same side as the established industry in the referendum process. Small private entrepreneurs, afraid that their business offers, advertising clean and untouched nature, would be tainted by images of radioactive hazard and influential large-scale industry, came to side with strong local traditional values and village community groups. One lesson learned from this work was that there are various layers of values guiding opinion and action, such as deeply felt personal values and values guiding more strategic goal attainment. Another lesson was that a process that is not solidly anchored in the local population before a strategic decision is taken may quickly get out of hand, politically and socially, increase group polarization, sustain apprehensions of hidden agendas and block discussions and dialogue.

## **Group Challenges: An Example of Concerns of Politicians and Nuclear Experts**

---

The following example emanates from the “Communication 2000” project initiated by the Nordic Nuclear Safety Research (NKS) framework (Andersson et al. 2002). It aimed at studying problems in risk communication involving different professional groups. The project idea was triggered by a media event in 1998 when results from a probabilistic safety analysis (PSA) related to a Swedish nuclear power plant (O2) in the south-eastern part of the country was unfavorably compared to PSA results of a Lithuanian nuclear power plant. The background includes a standard report from the former plant to the Swedish Nuclear Power Inspectorate (SKI), written by experts for the same type of experts, which was publicly available in accordance with Swedish law. A freelance journalist compared these PSA results to PSA results available from the Ignalina nuclear power plant, and the resulting headlines announced that the risk of an accident was significantly higher in the Swedish plant.

The headlines and articles following this comparison caused concern at the national level, and especially in the O2-reactor’s home community of Oskarshamn. Politicians of the local government, and specifically the members of the local safety council responsible for the safety in the municipality, were suddenly, rather forcefully and very early in the morning faced with complex technical questions about PSA results, risk comparisons, and the quality of their overview work.

However, the turmoil was based on a misunderstanding, i.e., the assumption that PSA analyses from different plants could be compared. This is not the case since such analyses are uniquely related to each specific construction. The media event, subsequently denoted a “nonevent” because it lacked substance, nevertheless had its social effects and stimulated further interest in communication problems. The “Communication 2000” project aimed especially at identifying the circumstances, factors, and issues that after the media event were seen as essential in problematic information and communication situations related to nuclear safety. The steering principle of the project was based on the RISCOM idea to enhance transparency (Andersson et al. 1998, 1999).

Focus groups and questionnaires were used to identify and measure the problems encountered by persons involved in the situation. A pilot study engaged two focus groups mixed with respect to participants’ background, i.e., personnel at the nuclear power plant and politicians of the local safety board. The subsequent empirical data collection utilized central categories of problems elicited from the focus group discussions, and involved similar groups of nuclear power plant personnel, politicians, and administrators in the local community as respondents. The results showed, e.g., that both groups found it problematic to understand the way media works. Furthermore, nuclear power plant personnel highlighted the difficulty of explaining a subject matter in their field in a comprehensive way, whereas politicians and administrators were more concerned about the distribution of information. A significant difference was that the group of politicians and administrators rated information leaks as more problematic than the other group did. The theme “Problems in information transmission” could be used to construct two subindices measuring “structural problems” and “human problems” in information transmission respectively (For details, see Drott-Sjöberg 2001).

Situations that were perceived as especially difficult to handle included to explain something in front of national TV cameras, and to find the time to thoroughly study a subject matter. The politicians found it more difficult to understand mathematical formulas and expressions, and the nuclear power personnel found it more difficult than the politicians to present selected issues in front of a larger group of the general public. Five subindices could be constructed on the basis of responses to the theme “Handling situations” and these were “communication ability,” “competence,” “ability to synthesize information,” “context uncertainty,” and “bridging ability” (i.e., to evaluate subject material outside the own profession, to discuss with colleagues who usually have a different view, and to be confronted with aggressive persons at a meeting). Finally, the study pointed out three areas for improvement of the communication situation: to enhance understanding and clarity, to work with relations and contexts, and to intensify professional development and feedback.

Thus, this project revealed several aspects of the problematic side of communicating in general and about communicating risk in particular. It was noteworthy that the two groups highlighted different aspects of problems related to information presentation, e.g., nuclear plant personnel mentioned problems of presenting complex issues from their field of expertise in an easily accessible way and the politicians mentioned problems connected with comprehending core subject matters, as well as inappropriate, or strategic, information leakage. The discussions in the mixed focus groups were important for many reasons. For example, they improved the personal knowledge of other individuals, their roles and tasks. The discussions dwelled on what information was the most essential for various actors, how to read and especially how to write a technical report so that nonexperts could make use of it, etc. The various theoretical categories or indices mentioned above outlined problematic

communication aspects in situational, structural, interpersonal, and personal/professional areas. The specification of such sub-domains suggests that communication is relevant on many levels and that managing a specific risk situation is related to the identification of its unique challenges as well as the ability of the involved professional groups to communicate in all these areas.

## Challenges of Contents of Risk Information: An Example of Localization of a LNG Storage Tank

---

This example highlights risk communication work in relation to reactions to the localization of a liquefied natural gas (LNG) storage tank in Risavika, Sola municipality, neighboring the city of Stavanger, Norway (Vatn et al. 2008). Natural gas from the North Sea is transported through pipelines to shore, and then liquefied at a process plant before storage in a huge tank. The natural gas is then distributed from the facility to local consumers by LNG ships and LNG lorries. The initial approval process included two steps, firstly the facility plan was approved according to the development plan by Sola municipal in June 2006, and secondly were the technical aspects of the facility approved by central authorities according to the fire and explosion law in Norway in December 2007.

The planned localization nevertheless gave rise to an active debate in the surrounding municipalities via the media, as well as among neighboring residents. According to the SEVESO II Directive, the involved company shall develop a strategy for risk communication and information related to the emergency preparedness measures established. The relevant company did therefore arrange and invite to several public meetings as a part of this strategy. However, several factors contributed to an intense debate in this context. One aspect was that the company had claimed that the facility did not represent any risk to third parties at one of the public meetings, another that substantial critique was raised by profiled safety researchers in the region. Early risk analyses had shown a very low risk, but disclaiming the risk resulted in a serious mistrust of the company. The media attention, including a series of articles and letters to the editor in the local press, indicated that the risk communication process hardly was on the right track. In this context, and based on previous studies related to societal security and risk communication, the organizations of SINTEF/NTNU in Trondheim were approached by the company and asked to jointly assist in a risk communication process as an independent subcontractor.

The risk communication project was conducted in 2008. It aimed at explicitly identifying the risk issues that were considered the most demanding in various groups, and also to identify aspects of relevance to future risk analyses. The work involved the following steps:

- Explicit discussions with the funding company about work methods to be used, and about research independence regarding the carrying out and reporting of the work, before a contract was signed. For example, the report should summarize and present contributions in such a way that identification of individuals was not possible, and the raw data material was to be available only to the researchers.
- The company invited to a public meeting through announcements in local media. The meeting was held in the evening to allow participation for as many interested persons as possible. The chosen locality was situated in a school building to enhance a neutral ground for the meeting.

- The public meeting involved presentations by the company of the current situation and plans, by the research team on planned risk communication work, as well as unlimited time for questions and answers. The public meeting facilitated the identification of key interests. Individuals were approached for participation in focus group discussions later in the process.
- Further elaboration of key interests and central types of stakeholders, and on how focus groups should be designed to facilitate a thorough data collection and discussion. Four groups were eventually formed, i.e., groups of *risk analysts*, *neighbors*, i.e., individuals who lived in the vicinity of the harbor and the planned facility, persons working in *neighboring companies* localized in the harbor area, and personnel from the *fire brigade*.
- Focus group discussions were conducted separately in each group at times convenient to the participants to enable an in-depth penetration of all aspects considered important from their perspective (2–4 h per group).
- Summaries, including citations from the discussions, were sent to all participants of each relevant group for their comments and clarifications. These summaries constituted the basic materials of the final report on communication.
- There were two reports from the project, i.e., one report focusing on risk analytic aspects and one focusing on the risk communication process (Vatn 2009; Drottz-Sjöberg 2008). These were sent to all participants, and later made available on the Internet.
- A public meeting was held to inform about the results, and invite comments.

The results of the risk communication process showed that all groups wanted more information, including additional risk and safety analyses of the planned industrial site and the related transports, and on emergency planning. Concerns for “third parties” were central, e.g., potential accidents involving the neighboring area of housing and businesses. The participants had questions and comments related to the preceding decision-making process and to the status of local preparedness and rescue efforts. Other concerns involved the possibility of a future expansion of the planned capacity of the plant, the safety of regular passenger traffic, and leisure activities in the harbor area.

Some comments and requests from the focus group discussions related to the risk analysis. These included suggestions to provide more scenarios in the analyses, including “worst-case” scenarios, to better specify uncertainties, to improve the dispersion analyses (which were considered incomplete), to investigate possibilities of “domino effects,” i.e., sequences of negative events, and to consider effects of lightning, sabotage, and terrorism. The participants wanted explicit comparisons to international standards, and asked for inclusion of comments showing how previous mistakes or faults in similar facilities were followed up. They also asked for descriptions of what happens in the LNG-process, evaluations of possible problems in the process, including safety distances and potential hazards related to transports by sea and land. Maintenance aspects were brought up together with safety culture issues, training, and preparedness plans. Long-term health consequences were an issue as were possible effects of minor accidents. It was stated that, of course, it is the most terrible accident that is the most feared, but that also fear of losing competency in the own or surrounding businesses due to uncertainties attached to the risk issue is of importance, as is the inability to provide employees with information about risks to health and safety.

In addition to the mentioned aspects of expected risk information contents, there were comments on the information availability and decision process, especially related to the time

preceding the initiation of the LNG tank construction. The participants pointed out that 4,000–5,000 persons were in jobs in the area and that 6,000–7,000 persons worked or lived within a 3 km radius. Many felt unsafe and wanted more specific information, which they had not received so far. They criticized that the early risk analysis report was not officially available, and asked about the reasons for not informing thoroughly the neighboring businesses and the inhabitants in the residential area. Some perceived the entrepreneur as a “strong actor” with respect to resources, but a party that nevertheless had acted more unresponsive or reactive than proactive and forthcoming with respect to various concerns. The lack of information, unavailability of the preliminary risk analysis, and a decision process involving several municipalities lacking transparency put the trustworthiness of several actors into question. In short, the results showed discontentment with the availability, amount, and quality of the early risk information as well as with the transparency of the decision process. A number of scenarios and additional considerations were suggested to be included in the future risk analytical work, and the need for increased transparency of the decision-making process was highlighted. (For details see Drott-Sjöberg 2008; Vatn 2009.)

## Challenges of Contents of Risk Information: An Example of Safety Data Sheets

Risk communication is a major risk management strategy, and involves also written information. The project summarized here was part of a larger program called Achieving GREater Environmental Efficiency (AGREE), based at the Royal Institute of Technology, in Stockholm, Sweden, with funding from the Swedish Environmental Protection Agency. We investigated professional users' familiarity and views of safety data sheets, how they understood and evaluated the information presented, and their need for additional information.

Safety data sheets are provided by manufacturers of chemical products to professional users and include health, environment, and safety information. Such information may, e.g., include statements like: *the substance may cause irritation to eyes, skin, and respiratory tract. Repeated contact with the skin may cause dermatitis in sensitive individuals. Handling of this product may be hazardous.* What does this mean?

A pilot study asked a number of participants to give their personal interpretations of central concepts widely used in the field, e.g., “ordinary caution,” “chronic effect,” and “dangerous (classified) chemical.” We also wanted to investigate effects of inclusion or omission of specific information in the safety data sheets. In the main study, 70 individuals in professions handling chemicals on a frequent basis (personnel in the rescue services, the chemical industry, and safety personnel) participated in the study (Drott-Sjöberg and Drott 2004). The results showed that professional users were well aware that the handling of dangerous chemicals poses risks, and that experience of risk and uncertainty were more pronounced for long-term health effects. However, we also found quite large knowledge variability in professional user groups, and they understood selected expressions and concepts in a variety of ways. For example, the term “carcinogenic” was understood in two major ways. Most respondents explained in their own words that such a substance “might cause cancer” whereas a minority believed that it meant that the substance “causes cancer” – thus a difference between a risk of a health effect and an actual health effect when handling the substance. Some gave more unspecific answers, such as that the substance is dangerous and should be handled with

outmost care. The understanding of the concept “classified” was especially problematic. When asked about the interpretation of the expression “the substance is not classified” a majority believed it meant that the substance had not been investigated or tested, others thought that it was a warning, or that it was not dangerous, and still others that the substance was not approved by authorities.

The results also showed that if specific information on health or environmental effects was not provided in a safety data sheet the omission caused uncertainty, specifically among personnel with more experience with chemicals. However, a fair amount of the participants interpreted such omissions as indicating that, e.g., health or environmental effects were irrelevant to the context since they were not mentioned. Omissions of specific information generally resulted in lower ratings of the importance of such information for the handling of dangerous chemicals. Overall the study identified problems related to the information given in safety data sheets, e.g., lack of detailed and easily interpreted information, the ambiguity inherent in certain concepts, or in abbreviated information presentations. Thus, the results underline the importance of clarifying written information, e.g., ambiguous or technical concepts, and to test written information to better meet users’ information needs. The safety data sheets provide a specific type of challenge since useful information preferable is crystal clear as well as brief. And although these information leaflets are produced mainly for professional users the sheer number of chemical substances and products, as well as the variation in background knowledge, indicate that there are good reasons to continue the work to enhance information clarity. The recommendations from the project included to explicitly explain the intended meaning of terms and concepts, to provide better descriptions and characteristics of the attached risks, and their proper handling in normal use as well as in an emergency situation.

## International Challenges: Examples from the ARGONA Project

Four years of collaborative work, including a risk communication part (WP4), within the project Arenas for Risk Governance (ARGONA) resulted in more detailed knowledge and understanding of different countries’ nuclear waste management (NWM) strategies and achievements (Päiviö Jonsson et al. 2010). The countries investigated more closely in the risk communication work package were the UK, the Slovak Republic, the Czech Republic, and Sweden. The countries provided an interesting diversity with respect to historic developments, and strategies for information and communication on risk and safety aspects of nuclear waste management, as well as regarding organizational and governance structures. A few comments on similarities and differences across the countries are mentioned here, together with trust issues, the challenge of keeping a communication process alive, and lessons learnt with respect to strategies and tools in risk communication.

The intention of WP4 was to delineate good risk communication approaches across national borders, as well as to identify circumstances that require more specific considerations. The international workshop in the last project year, aimed at an in-depth discussion of risk communication related to management of nuclear wastes based on experiences from various stakeholders from the involved countries (Drottz-Sjöberg et al. 2009), as well as to go more deeply into communication of quantitative estimates related to risk and uncertainty (Bolado 2009). Only the former task is exemplified here.

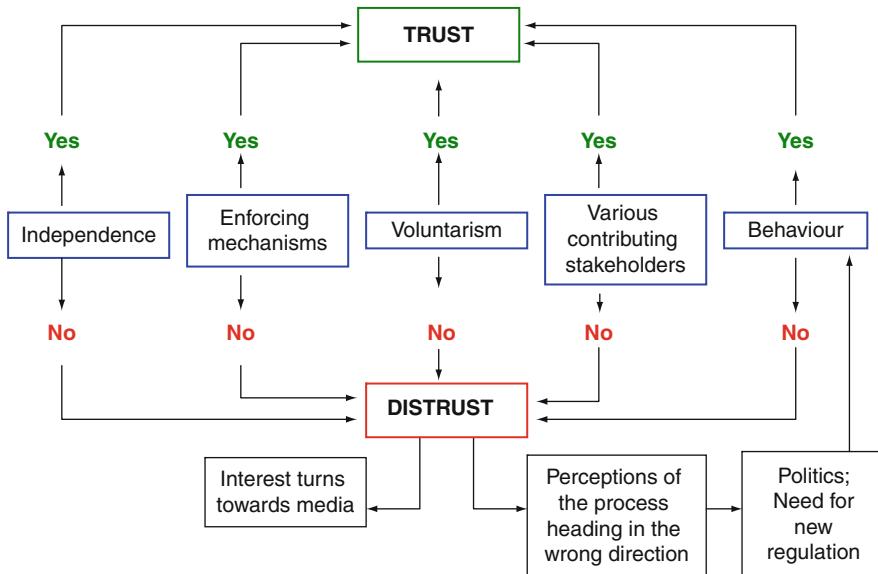

A number of stakeholders from the participating countries had the task to provide comments on strategies for risk communication that have emanated from various interest groups in different countries. Their engagement also aimed at eliciting comments on strengths and weaknesses associated with various risk communication techniques and more composite risk communication strategies. The work performed in the project fits well into the transparency framework provided by the RISCOM model, successfully used in Sweden and later applied in the Czech Republic within the ARGONA project.

Similarities of the participating countries included that they all are democratic European Union countries, and that NWM is a national issue and responsibility. International standards are guiding the work, including the use of Environmental Impact Assessments (EIA), and the countries collaborate with IAEA. There is also the similarity of awareness of the importance of information to a larger public, and that nuclear waste policies and management attract media attention. All participating countries have high qualification requirements of experts working in the field and the general population has an overall high educational level.

There are several differences between the countries as well, including what type of wastes that must be managed, the economic situation, the availability and status of funds for financing repositories, and the governance systems of NMW management. Differences also relate to historic events that influence current attitudes, levels of trust in various actors, the structure and functioning of the overall social system, e.g., with respect to openness, transparency, and traditions of communication, and last but not least, expected developments in the foreseeable future, especially if new nuclear power plants are considered to be built or not.

The discussions very quickly focused on the importance of trust. An exchange of views took place on the differences in trust in various countries and possible reasons for the differences. It was considered how much authority and official bodies are trusted, and to what degree such organizations are seen as *independent* from an implementer. It was noted, e.g., that historical events and decisions have affected trust in authorities. In some countries there seemed to be a view that “independence” involves not only acting separately vis-à-vis an implementer but also not being related to the government. In contrast, municipalities involved in the siting process in Sweden had chosen to use state authorities as “their experts” for addressing long-term safety issues and safety assessments. Regarding the UK, however, it was stated that much of what emanated from the authorities was perceived as “smoke and mirrors,” and that people instead tended to turn to the media for information. It was seen as hard to know and to understand what agendas the different actors pursued. A comment related to the Slovakian experience pointed out that trust actually may lead in the wrong direction and that certain skepticism is necessary. There was agreement that for trust to develop there is a need for *enforcing mechanisms* to follow up on mistakes or bad conduct irrespective of actor.

A comparison between the UK and Canadian approaches was made, and a proactive local risk communication approach was suggested as being more productive than situations where nuclear waste management organizations tour municipalities to feed information into a process. It was added that there is a danger in “forced risk communication” with respect to achieving trust. An example of how trust is enhanced in an unobtrusive way was provided from the UK, and the Seascate area in particular, where people working at Sellafield subsequently have chosen to retire in the coastal village. Their choice of staying close to the plant and industrial area was seen to provide an unspoken example of their attitude. Current activities in the UK involve *volunteers* (municipalities), and it was suggested that progress will be made due to development of a “partnership” approach in the UK (in West Cumbria).

**Fig. 29.3**

A summary of key factors in the discussion related to judgments of trust and distrust

However, it was also noted that the NWM issue can be politically very unpleasant. Examples to support this notion can be found in several countries. Sentiments and examples of unpleasant events and conflicts were related to historical contexts and cultural settings, and differences between generations were discussed. It was suggested that the extent to which various "generational cultures" exist across and within countries, e.g., with respect to interests, concerns, or environmental attitudes, influence overall strategies and trust levels.

The composition of participants influencing a decision process, in terms of what type of interests or "stakeholders" that are involved, should be considered. The issue initiated a discussion on the importance of *representative* participation. For example, it was suggested that an attempt to involve environmental NGOs in the European Nuclear Forum failed because the former groups held that the Forum consisted of 90% industry-related individuals, resulting in a very strong focus on industry issues, which some NGOs felt unable to support.

The figure below summarizes the key factors mentioned in the discussion, and suggests that *independence* of actors, functioning *control mechanisms*, *voluntarism*, and the involvement of a *variety of stakeholders* and what they *represent* can influence the balance of trust and distrust. In addition, the behavior and actions of participants also influence the process. The figure illustrates that all the central aspects influence the process by strengthening either "trust" or "distrust." It must be noted, however, that a "trust" or "distrust" outcome was not seen as good or bad *per se*, but as a judgment within a complex situation also related to, e.g., goals and achievements (Fig. 29.3).

It was noted in the workshop that *trust* is imperative and that *voluntarism* is a necessary basis for risk communication and participation processes. However, it is important to ask the

question “Risk communication about what?” What is the *subject matter* and what is the *goal* of the communication? Is it about safety issues, specific analyses, information about plans, or decision processes, etc.? Again the importance of clarity of goals as well as contents was underlined and it was suggested to make use of, and to improve, already available materials of good examples from work in different countries. When discussing *trust* it is also important to differentiate between various kinds of trust, e.g., trust in information regarding what science claims to contribute or solve (epistemic trust), and social trust, e.g., in authorities or institutions (Sjöberg and Wester-Herber 2008). Issues related to different kinds of trust may elicit different kinds of responses.

With respect to knowledge and interest in knowledge acquisition, it is valuable to distinguish between local communities and a larger or the national population. Local groups and people living in a community tend to be better informed of local circumstances and events, their history and role, and there is more at stake for them than for others. Such knowledge is especially relevant to consider when risks can be geographically determined, and it is linked to interest and attitudes (see, e.g., Sjöberg 2008; Kari et al. 2010). The result of trying to get a message across to a group with little interest or no experience of the matter at hand would to a higher extent depend on generalized views, social trust, and credibility factors attached to the communicator. The type and context of a hazard or risk should therefore be taken into account in the information or communication situation.

The figure below aims at illustrating some central concepts of importance for keeping a risk communication process alive, and arrows pointing to the center support a continuation of the process. If a prerequisite for communication is not fulfilled, that aspect will contribute to the moving away from the core goal, i.e., drift into the surrounding area of “no-participation.” The arrows between the central concepts do not suggest causal flows but aim at illustrating that prerequisites for communication are interlinked and continuously influencing each other. It is also suggested that each central concept is available as a starting point for an improved communication process, as well as an end point if expectations are not met. Note, also, that if the goal of a communication process foremost is to keep the process sound and alive, then the maintained interaction itself represents the positive outcome (☞ Fig. 29.4).

Previous work in WP4 had shown that there exists a vast amount of information with respect to risk communication processes, and that it is important to continue to enhance democratic governance processes to develop the work. The project also found that there is a need to inform more precisely with respect to details, account for various levels of knowledge and involvement, and that a variety of approaches can be used in such work. It was suggested that interconnecting knowledge and experiences from different risk management areas and practices regarding threats to health, safety, and the environment may offer fresh perspectives. Broader approaches could help increase “the tool box” useful to risk communication work and also help to test what approaches fit best in diverse subject areas and contexts. The main conclusion from the discussion was: *Think European but pay attention to local detail*. Regarding the question if it is reasonable to compare risk communication processes across countries the conclusion was “yes” in relation to certain general approaches and communication tools, but “no” with respect to the feasibility of comparisons for approaching requirements of unique situations.

The table below structures some of the central input from the workshop in a different way. Five steps of a possible NWM process are outlined, together with some notions of content and requirements (☞ Table 29.1).

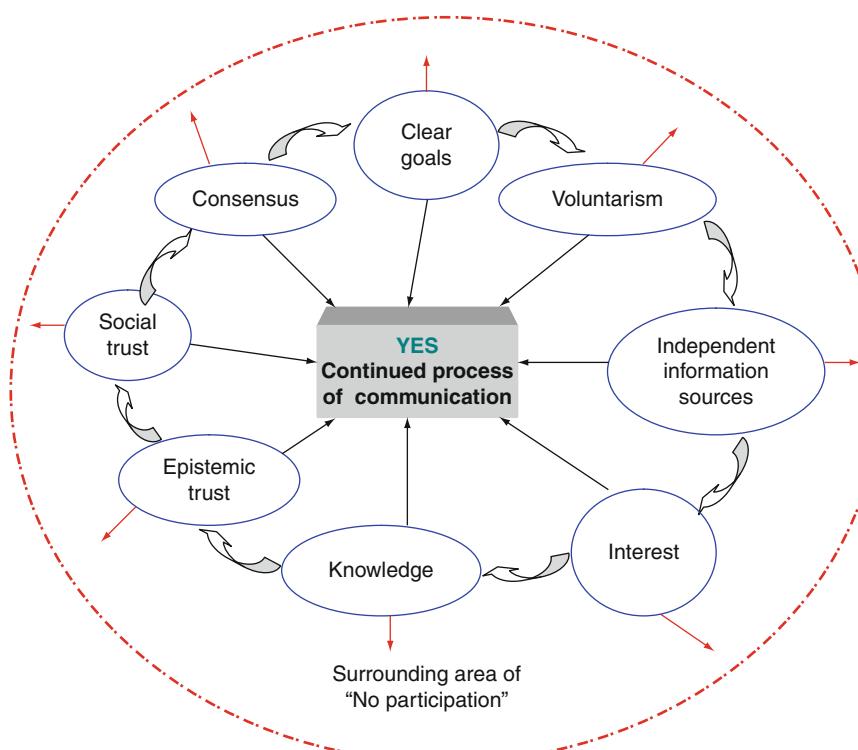

Fig. 29.4

A loop of prerequisites, and perpetual influences, in continuous communication processes

## Further Research

The examples provided above aimed at illustrating some of the reasons to initiate risk communication projects as well as aspects to consider in the work. The Storuman example showed, e.g., that a strategic political decision aiming at benefiting the public good did not gain public acceptance for many reasons, including that the decision to invite SKB to do a geological site investigation was not thoroughly discussed and broadly anchored in the municipality. It also showed that providing citizens with a dichotomous choice in a referendum effectively shadowed underlying considerations of importance for making that choice and instead intensified group polarization.

The “nonevent” media example highlights the social interconnectedness of professional groups carrying out very different functions, and points out the necessity of cross-disciplinary insights in tasks and functions to be able to perform well in the own professional field. It also shows that alarmist news can trigger very quick public responses and that media contents may affect daily life irrespective of the validity of the information.

The projects used to illustrate the importance of early and clear communication of risk information show, e.g., that there is a formidable source of perspectives, as well as expertise, outside of the more strictly defined boundaries of an industrial project, and that such

**Table 29.1**

**Overview of important major steps, and examples of contents and requirements, regarding a possible nuclear waste management process focused on implementation of a repository plan.**  
**Extracted from the ARGONA workshop 2009**

Steps	Content	Requirements
Strategic consideration	Provide reasons for planning a repository	Independence (reviewers, decision-makers)
	Clear definition of "safety case" and evaluation of feasibility	Transparency; independence; trust
	Choice of governance perspective of process	Functioning enforcing control mechanisms
	Clear criteria for regarding/disregarding a site	Consideration of "all" aspects
	Creation of inclusive social communication process	Social acceptance, openness
Agenda setting preparations	Clearly define the agendas for the technical and the social processes	Overview of uncertainties and clarification of "representativeness"
	Consider pace of development	Distinguish short- and long-term issues
	Proactive information	Information availability; understandable to target groups
	Prepare for involvement of stakeholders	Procedure perceived as fair
Contacts and discussions	Create interest	Preparatory work
	Invitation to participate	Voluntary processes
	Present uncertainties	Availability of pedagogical experts
	Discussions on, e.g., "the right community," "partnership"	Interested local communities
	Investigate possibilities of local steering mechanisms	Availability of local control mechanisms, e.g., veto-right
Recommendations on risk communication	Provide and keep available information in various formats	Clear goals of each intervention
	Use correct and understandable information materials	Invite to feedback on information materials
	Involve key group members	Extensive (local) network
	Collect and improve on available materials and experiences	Compilation of research results; new research
	Development of presentation techniques and skills; training in dialogue settings	Understanding of novel perspectives in the personal expertise area
	Work with "translations" of scientific terminology and ambiguous concepts	Cross-disciplinary collaboration; involvement of lay people
Implementation	Developments of concrete plans and work	Continuous updates of key factors related to technological and social developments

perspectives and expertise can be utilized to develop and refine analyses as well as to better meet information demands. The examples also show that it has consequences if information is presented or not. The LNG project involved social and psychological consequences of early information deficiencies enhancing distrust and worry. However, it is noteworthy that omissions of information in safety data sheets, e.g., regarding health or environmental aspects, instead seemed to lead users to conclude that omitted information was irrelevant to product use. The examples may suggest interesting research projects.

Is it the case that we ordinarily nourish a mental shortcut mode of thinking, i.e., rule of thumb or heuristic, which holds that if there is any danger at all someone will provide us with “the whole truth and nothing but the truth”? The existence of such a heuristic would help explain the current focus in the research area on the role of trust – an issue especially highlighted in the risk communication workshop of the ARGONA project mentioned in this chapter. Could it be argued that, in contrast to much current theorizing, we are not living in a “risk society” but in a “safety obsessed” society? Not because there are no hazards – there certainly are – but due to expectations based on unreflected beliefs that the world should be pure and safe and that any alteration of that state is due to external forces outside personal control and responsibility. Hence, *receiving* information from *trustworthy* sources becomes more vital than actively making sense of, or checking the validity of, information received. However, a person or a citizen cannot be reduced to filling only an information receiving function. The risk communication area provides ample examples of not only demands for information but the willingness – and sometimes the demand to be allowed – to provide input to a decision process. Thus, there seem to be possibilities to enhance and develop interactive communication, as well as personal control and management of risks, all in line with the wording of international conventions on participatory contributions.

Among the major challenges in the risk communication field lays the task of how to shift the attitude of information processing related to specific risks from a shortcut, heuristic thinking mode to deliberate cognitive processing. In accordance with dual-processing theories (e.g., Petty and Cacioppo 1986; Chaiken 2003) we become better decision-makers, and less vulnerable to unobtrusive influences, if we process information in a systematic and thorough way. Less cognitive effort due to use of heuristics is, of course, time efficient in everyday life, but there are no standard heuristics available that effectively manage risks. It seems as if trust has been tried as a surrogate heuristic and that its failure to meet expectations has led to a rather unproductive distrust discussion rather than a sharpened focus on information processing and risk mitigation efforts. If trust represents social capital, what does distrust signify? If distrust reflects decay of the social web, there ought to be intensified efforts to better understand the surrounding world for sheer survival reasons. Thus, to better prepare for encounters with hazards and for managing potential negative consequences we must participate, voice concerns, and present suggestions; as citizens we must collect information, scrutinize the validity of the information, discuss with others, and find ways to evaluate the identified risks and what needs to be done. Risk communication projects are one type of excellent arenas for communicating about risks and for acquiring knowledge as well as find links to additional information sources.

Openness, transparency, voluntariness, and participation are currently highlighted concepts in the risk communication and governance literature, as in society more generally. However, the use of the concepts in the literature sometimes involves more rhetoric and theorizing than information of concrete practical usefulness in risk communication work.

This state of affairs presents a challenge to research of following up on principles and theories by extracting their substance and systematically test it out in concrete settings. The importance of operationalization of concepts becomes very clear in such concrete work. For example, in these and other contexts it is useful to clarify that *openness* often refers to information access (and not some principle demanding exposure of inner secrets), *transparency* often aims at achieving clarity which enables understanding, e.g., of the structure of a task or framework, or the path and development over time of a decision process. *Voluntariness* is an important principle to respect in participatory processes and the concept highlights the challenges to motivate interest and to make interesting the subject matter that invites to participation for achieving a good solution.

Participation is discussed here from a somewhat different angle. In an essay in the booklet “Ethical and philosophical perspectives on the nuclear waste issue – eight essays by Sven Ove Hansson (2010)” the author addresses, among other issues, expert power, acceptance, voluntary risks, and steps in a decision process. In this context, it is of interest that Hansson argues that “risk decisions” cannot meaningfully be distinguished from other kinds of societal decisions and that almost all kinds of decisions in a society are to some extent “risk decisions.” He also notes, however, that in discussions on overall political decision-making the central concept is *democracy*, whereas in discussions on risk and risk decisions the central concept is *acceptance*. The former concept aims at decisions being in line with the view of the majority whereas *acceptance* focuses on what risks the general public, or those directly affected, can be made to accept. Hansson furthermore makes use of the French philosopher Condorcet, who in 1793 developed a suggestion to the French constitution to illustrate steps in the decision process. Condorcet outlined three steps in democratic decision processes: (1) Discussions of the general principles that will constitute the basis of the decision, investigation of the various aspects of the issues, and the consequences of different ways to take the decisions. (2) A second discussion where views are developed and combined with the purpose of generating a smaller number of general views. (3) The voting when the decision is taken. Hansson notes that, in relation to risk decisions, the discussion often focuses solely on the third step. The general public is presented as a group whose acceptance or agreement shall be obtained. He underlines that a reduction of the public’s influence to the third decision step regarding risk issues is inconsistent with the principles that generally apply in a democratic society.

Similarly, it was noted above that a citizen cannot be reduced to an information receiver. Is it possible to bridge the gap between science (including those with expert knowledge on risks) and society (including all citizens)? The European Commission (2009) has devoted some thought as well as research funding to this topic. The Directorate-General for Research, Science in Society set up the MASIS expert group to dwell on the issue and in 2009 they presented their report “Challenging Futures of Science in Society – Emerging trends and cutting-edge issues.” As can be noted they put science firmly *into* the society.

In the context of risks and communication, it could be noted that the communication concept indicates more input to an interaction process than one-way directed information messages. Risk communication involves the tasks to identify the risks, estimate them, and try to avoid them or manage them. The goal of risk communication is to eliminate or minimize the identified risks. It seems as if we live in a “risk society” with heightened risk awareness there may be less problems ahead than if we live in a “safety obsessed” society lacking trust in others. The emphasis in the research area, and in international guiding principles and conventions, on participation in decision processes could possibly point out a means of narrowing the gap

between passive information recipients and informed citizens, between science and society, and between acceptance and democracy.

The main point here, however, is that risk communication means to *communicate* about *risks*. This chapter has tried to highlight that the core of this type of communication is centered on the identification, estimation, and management of risks. In practice, however, there are several additional aspects to consider. Risk communication projects have, in addition, to managing situations ranging from doomsday beliefs to total disinterest, from inaccessibly rare expertise knowledge to pure ignorance, and from strong active stakeholder interests to deeply experienced injustice or victimization. These dimensions exemplify aspects that bring risk communication into the realm of the multifaceted and fascinating “real world.” And although the aspects are intimately attached to risk communication work, they must be kept at arm’s length from the central aims of identifying, estimating, and managing risks.

<i>Conclusion</i> .....	803

**Abstract:** Although risk is a fact of life, it was not extensively discussed in moral philosophy before the 1970s. Robert Nozick's classic discussion of risk drew philosophical attention to the special problems created by actions that create risk but which may or may not result in any harm. This chapter begins with a description and analysis of Nozick's argument. It concludes that familiar concepts in moral philosophy like harm, compensation, and individual moral rights cannot by themselves give a satisfactory analysis of the unique ethical problems created by activities that impose or attempt to regulate risk. This discussion leads to further examination of the relation between risk and consent. Appeals to consent are important in the justification of techniques of risk analysis used to reveal individual preferences for comparing risks, costs, and benefits in policy decisions. This discussion is followed by a review of issues involving justice and the distribution of risk. It focuses especially on some distributional issues that are unique to risk and reveal important differences between looking at the ethical dimensions of risk from an individual and from a societal perspective. The chapter concludes with some speculative remarks about future research into the ethics of risk that is prompted by increased awareness of risks imposed by new technologies, the prospect of reducing or mitigating the effects of anthropogenic climate change, and the increasingly likely prospect that decisions today may impose significant risks on future generations.

## Introduction

---

Until fairly recently, moral philosophers have largely ignored questions about the ethics of activities which create risk that may or may not result in actual harm. This is curious, since so many of our actions obviously involve taking risks and imposing risks on others. Nevertheless, the history of moral philosophy, at least in the modern era, has been predominantly concerned only with actual harm and the rights, obligations, and reasons for blame or compensation that arise with respect to benefit and harm. The subject of this chapter is the ethics of risk. We begin with a brief review of references to risk in the philosophical literature before the last quarter of the twentieth century. Then we examine the problems that have dominated philosophical discussion of the ethics of risk since that time, beginning with Robert Nozick's classic discussion of the particular ethical issues posed by risk. This is followed by a discussion of some of the leading issues involving risk, including consent, distributive justice, and issues raised by applying formal techniques of risk analysis in the context of public policy decisions.

## History

---

In the few instances in which philosophers writing before the last half century have mentioned risk, they have seldom paused to consider the special issues that it raises. This is not to suggest that risk has not been a traditional concern of moral and political philosophers. Indeed Hobbes's political theory can be described as aiming above all to remove the central risks of human life and provide the security that comes from entering into civil society (Hobbes 1660/1996). But neither Hobbes nor later moral and political philosophers pay much attention specifically to risk. For example, in his discussion of government action that permissibly restricts individual liberty, John Stuart Mill writes, "Whenever, in short, there is a definite

damage, or a definite risk of damage, either to an individual or to the public, the case is taken out of the province of liberty and placed in that of morality or law" (Mill 1859/1978). Clearly, on Mill's view, it is permissible to restrict a person's liberty to prevent harm to others, and those who are harmed through negligence may demand compensation or restitution. But what is a proper response for those who have been exposed only to the risk of harm? Mill's example of risky behavior gives us little help in answering this question. He writes: "[W]hen a person disables himself, by conduct purely self-regarding, from the performance of some definite duty incumbent on him to the public, he is guilty of a social offense. No person ought to be punished simply for being drunk; but a soldier or policeman should be punished for being drunk on duty" (Mill 1978, pp. 79–80). The actions of the drunken policeman increase risk to the public, of course, but the policeman is also in breach of a duty, which is itself a wrong. So the example tells us little about what special problems, if any, are caused by risk-imposing actions per se or by actions that impose risk but do not otherwise violate a duty or responsibility.

Henry Sidgwick says a bit more than Mill about the ethics of actions that impose risk and our different responses to those actions. Alluding to Mill, Sidgwick writes, "Again, certain practices dangerous to others – such as the drinking of alcohol to the point of intoxication – may be tolerated in private but repressed if the drunkard appears in public" (Sidgwick 1904, ch. 9, sec.2). But the perspicacious Sidgwick, who was a more thoroughgoing utilitarian than Mill, carries the argument further. He sees no problem with inhibiting individual liberty for the sake of reducing or managing risk of harm to a greater public, thus justifying "an extension of governmental interference, in the way of regulation." Sidgwick continues: "The easiest and most effective way of preventing harm is to prescribe certain *precautions* against it – i.e., to prohibit acts or omissions not directly necessarily mischievous to others, but attended with a certain risk of mischief." This statement is followed by a number of examples, ranging from government inspections for safety or requirements for standardized weights and measures that reduce the risk of fraud, to "restrictions on the manufacture and carriage of explosive substances and rules against importing cattle from countries where disease is rife. It is not certain that any given cargo of suspected cattle or carelessly carried explosives would do any harm: but most prudent persons see that the risk is too great to run" (Sidgwick 1904, ch. 9, sec. 2).

To philosophers whose views are more libertarian or rights based than Sidgwick, the idea that it is permissible to restrict or regulate activities simply in order to reduce risk, especially when the risks may never result in actual harm, is more problematic. And although many philosophers have found inspiration in Immanuel Kant's philosophical writings to develop a Kantian framework for thinking about the ethics of risk (Gillroy 2000), one cannot find any explicit discussion of risk in the writings of Kant or most other nonutilitarian philosophers before the 1970s.

## Risk and Rights

In contemporary philosophy, Robert Nozick was the first to discuss ethical issues involved in risk extensively (Nozick 1974, ch. 4). Acknowledging that "no natural-law theory has yet specified a precise line delimiting people's natural rights in risky situations," Nozick considers

three possible responses to actions that impose risk (Nozick 1974, pp. 75–76. For clarity, I substitute the phrase “rights violation” for his “boundary crossing”):

1. The action is prohibited and punishable, even if compensation is paid for any [rights violated], or if it turns out to have [not violated any rights].
2. The action is permitted provided compensation is paid to those persons whose [rights actually are violated].
3. The action is permitted provided compensation is paid to all those persons who undergo a risk of a [rights violation], whether or not it turns out that their [rights are actually violated].

(3) has both advantages and disadvantages compared to (2). If people are compensated for being exposed to a risk of harm, they may decide either to keep that gain or to pool their gains in order to provide greater compensation to those who are actually harmed. Thus, (3) gives people a greater degree of liberty to respond to risk imposition. But to compensate people for being exposed to *risk* is to treat the expectation of harm as itself a bad thing, which is puzzling. Someone who is under a risk or threat of harm may experience fear or anxiety, which is an evil, but it is not clear why the risk itself should be considered a kind of harm or evil that deserves to be compensated, especially if the actual harm never occurs. This is especially true if the person exposed to risk is unaware of this fact, and the risk never results in harm. These may be reasons for favoring (2) over (3).

But (2) has other problems. First, some of the risks that are imposed on people involve a risk of death, and if that harm occurs, then the victim cannot be compensated. Moreover, some of the risks we face are caused by the collective actions of many people in such a way that the action of any individual creates only a minuscule risk while the similar actions of many people create substantial risk, as in the case of standard kinds of “nonpoint source” air or water pollution. These risks are created by the collective actions of many people, and they fall on many others, sometimes at great distances from their source. The idea that those who suffer the harms from such risk-imposing activities – for example, those who contract cancer or some other disease as a result of exposure to nonpoint source pollution – can be compensated in a proportionate way by all the individuals who create the risk, is of course entirely impractical.

Finally, (2) taken by itself might be interpreted to permit any risk-imposing activity so long as the actor was willing and able to compensate victims who suffer harms as a result. But imagine someone whose only source of enjoyment comes from playing Russian roulette on people walking by his residence in a crowded city. To make the example more troubling (if not more realistic), imagine that his gun has a million chambers with only one bullet in it and, to avoid the problem of the impossibility of compensating those who might die from his actions, suppose also that he aims only at the pedestrians’ legs. He is very wealthy and willing to compensate anyone who loses a leg as a result of his amusement. Surely, as Sidgwick claims, this is a kind of mischief that we would properly prohibit, and not necessarily because the risk is “too great to run.” We would not feel differently if our imagined agent agreed to add yet another million chambers to his gun.

Our intuitions in such cases may lead us to favor Nozick’s response (1) and say that, just as we properly prohibit activities that cause harm or violate the rights of others unless we have their prior explicit consent (which we will discuss below), so we should prohibit activities that impose the risk of harm or rights violations without the consent of those who bear the risk. But that principle would make life as we know it impossible. When we heat our homes or cook our

meals, most of us cause pollution that increases the risk of harm to others. If we drive a car, we impose risks not only on other drivers but also on pedestrians, some of whom, like children, do not themselves engage in a similar risky activity and so cannot be interpreted as giving their consent to the risk that such activities impose. Moreover, we are not willing to forego altogether the benefits from the mining and manufacturing activities that impose significant risks on many people but produce the goods we consume.

## Permitting Productive Risky Activities

---

Nozick considers another possibility for a principle of compensation for risk. Begin with a person who engages in a productive activity that imposes some risk on others. Someone may start a business that pollutes some nearby water; someone else may drive a car, either to get to work or as part of a business that involves transporting or delivering goods. Because we want to allow such activities, we might argue that they should not be prohibited simply because they impose some risk of harm on others. We might further insist that the person engaged in these activities must prove herself able to compensate others if her risk turns out actually to harm them, perhaps by buying insurance. This proposal is compatible with at least two reasons for prohibiting risk-imposing activities that are congenial to rights-based ethical theories. First, if people oppose being exposed to risks that are imposed as a by-product of productive social activities, either because the probability of harm is too great or because they oppose the nature of the risk, they may decide to prohibit the activity provided they compensate the party who is now prevented from engaging in it (Coase 1960). If people are not willing to compensate actors whose productive but risk-creating activities they wish to prohibit, then they must accept the risk with the understanding that they will be compensated only if they are actually harmed. Referring back to Sidgwick's examples, this proposal would mean that a society that wanted to restrict the manufacture and carriage of explosive substances or prohibit the import of cattle from countries where disease is rife would have to compensate the manufacturers or importers for keeping them from engaging in these activities. The justification for regulating risk in this way, through laws or policies, is that these regulations mimic the behavior of individuals freely engaging in the exchange of goods and services in a market.

The second reason this proposal allows for prohibiting risk addresses nonproductive mischief. The person who wants to play Russian roulette on pedestrians is engaging in a nonproductive activity, which we may prohibit without compensation. In contrast to this example, if we want to prohibit an epileptic from driving, assuming she would impose the same level of risk as the person playing Russian roulette, we would have to compensate her for this loss of liberty. This reason for prohibition without compensation, as Nozick describes it, would also justify prohibiting someone from practicing extortion by proposing to begin a risky activity only in order to obtain compensation from others who want him not to engage in it. Extortion is properly illegal and ethically prohibited. Prohibition relieves the victims from the risk of harm, and the extorter is made no worse off except for being unable to benefit merely from threatening others.

There are nevertheless several problems with this proposal, which sees risk regulation primarily in terms of the justifiable restriction of individual rights and liberties. Describing these problems also highlights the issues that have dominated philosophical discussions of the ethics of risk over the past 40 years.

One problem, already mentioned, is that people cannot be compensated when the harm that results from a risky activity is death. It is not obvious why, on a rights-based theory, people exposed to a risk of death through someone else's productive activity must either accept the risk or compensate the producer to halt it. A second problem with the compensation proposal arises when we consider the distribution of risk and benefit. The proposal insists that risk producers should be compensated for prohibitions that result in their losses. But risk-imposing activities that benefit the creator of the risk may cause harms to others that collectively greatly exceed the benefits to the producer. Why should the victims be required to pay compensation to halt activities that produce more overall harm than benefit? It is not obvious why liberty should have this kind of priority over welfare.

A third problem with this proposal is that it does not help us to deal with "zero-infinity risks," the kinds of activities that produce a very small probability of very great harm, such as nuclear power. When nuclear reactors are properly constructed and maintained, with adequate safeguards, the chance of a catastrophic accident is very low – but it is not eliminated or reduced to zero. And if a catastrophic accident occurs, the producers would be unable fully to compensate everyone who is harmed. According to the proposal we are considering, the failure to be able to compensate is sufficient reason to prohibit the activity. But a society might decide that the benefits of nuclear power – a plentiful supply of reasonably priced and (except for the unsolved problem of permanently disposing nuclear wastes) relatively environmentally benign source of electricity – is a risk worth taking. One of course hopes that few nuclear accidents will occur and that none will be catastrophic, but whether or not nuclear power is a reasonable risk for a society to accept is not something that the rights-based compensation proposal we are considering can help us decide.

Finally, as Nozick himself recognized, the problem of determining what is and what is not a productive activity is not obvious and is inevitably subject to framing effects or how an activity is described. Playing Russian roulette for fun on non-consenting pedestrians is not a productive activity; but engaging in the only kind of activity that one finds enjoyable may be. Restricting our thought to more realistic examples does not diminish this problem. Is allowing people to drive whatever cars they prefer, regardless of the emission of greenhouse gases, a productive activity? Does the reduced regulation of financial institutions, which vastly increased both profits to the banks and risk to everyone else, count as contributing to productive activities? Perhaps "productive" is not the most important concept for determining when societies may reasonably regulate or prohibit certain risk-creating activities.

---

## Risk and Consent

---

Individuals accept risks all the time. We willingly engage in rock climbing, skiing, and other adventures; we put our money at risk for the chance of greater gains; we accept the risk and cost of air travel for the benefit of greater and more convenient mobility; we risk death from surgery for the chance of curing a disease or relieving pain; we get married; we divorce; and so on. Life is full of risks, which we try reasonably to manage far more often than we try to eliminate. Presumably, these risks are acceptable because we consent to them. If we have thought carefully about some prospect, we may reasonably judge that the expected benefits outweigh the cost and risk involved. In some areas, such as medical treatment, the consent process tends to be formal and elaborate. This may be because, in the context of surgery, consent clearly distinguishes a medical procedure from assault with a deadly weapon.

If consent justifies exposure to risk, then the problem for social risk-management decisions and policies, where it is impossible to get unanimous explicit consent, is to find some surrogate, hypothetical, or implicit justification. The practice has been to assume that a policy that monetizes risk, costs, and benefits and can be shown to maximize net benefits is a policy to which rational individuals would consent. But this assumption is not always reasonable, for the measures that show expected net benefits may ignore considerations of justice and the moral demand to show respect for each individual. Relying simply on a social cost-benefit analysis could allow, for example, that the lives or health of some people may be sacrificed for marginal benefits to a great number of other people, because the overall benefits outweigh the overall costs. Instead, the ethical justification for using different methods of risk-cost-benefit analysis to justify a decision or policy depends on showing how the analysis reflects the preferences of those affected by the decision. The justification appeals to the implicit or hypothetical consent of the affected population. This is consent to accept some level of risk in exchange for certain benefits, or an agreement that reducing or eliminating some risk is too costly (MacLean 1986a). If this justification is to succeed, at least two kinds of problems must be solved.

The first problem involves our understanding of individual preferences for risk. Consider a typical case in which we are able to reduce a risk by reducing exposure to some dangerous substance, but the marginal cost increases for each increment of reduced exposure. It may be cost-effective to begin to reduce the amount of mercury in a community's drinking water or to reduce exposure to a carcinogenic substance produced in the manufacturing process at some factory. But the cost typically rises as we continue to reduce these exposures, and it may be prohibitively expensive to try to eliminate them altogether. The question then becomes, "How safe is safe enough?" At what point do people exposed to the risk find it reasonable to accept a given amount of risk rather than pay the cost of further reduction? The easiest way to answer this question would be to monetize the value of an increment of risk, so that we can compare it to other costs and benefits. We explore various methods proposed to do this below, but we must also ask whether all risks – that is, identical probabilities of similar harms – should be valued the same. If we can determine what people generally regard as safe enough in one area, can we generalize this result and apply it to other risks? It turns out that studies show that most people value different kinds or sources of risk differently, so that preferences for risk-cost-benefit trade-offs are to some extent independent of a simple function of probability and magnitude of harm. Individual risk preferences vary among other qualitative dimensions of risk (Slovic et al. 1979). Thus, a person might ride a motorcycle to attend a rally to demonstrate against nuclear power. If he knows what he is doing and is not deemed irrational, then we must conclude that his concern for risk is not merely a function of his perceived probability of a given harm.

So perhaps we should manage risk in a way that recognizes the qualitative differences of their source and nature. But when we learn, for example, that we spend far more to reduce an increment of risk in the workplace than we do to reduce an increment of a similar risk in regulating automobile and highway safety, should we not at least consider reallocating resources to achieve greater or more efficient overall risk reduction? After all, the person who works at the factory may be the same person who drives to and from work each day. The question of what role, if any, qualitative differences in the source of risk should play in risk-management decisions is one that only ethical reasoning and argument can resolve. It remains a central problem in the ethics of risk analysis and risk management.

The second problem in answering the question, “How safe is safe enough?” concerns specifically the risk of death. Recall the suggestion in earlier sections of this chapter that compensation for exposure to risk should be correlated with compensation for the harm involved. Most methods of risk analysis are based instead on finding out what people regard as compensation for being exposed to different levels and kinds of risks. But of course we cannot be compensated for being killed, so how can a compensation test be used to justify decisions that permit imposing a risk of death? This is a problem that governments especially must confront, because their decisions about when it is too costly to reduce some risk often imply that a predictable number of preventable deaths within a large population will be tolerated in exchange for other benefits to society. Thus, in many social risk decisions, the question, “How safe is safe enough?” is equivalent to the question, “What is the economic value of human life?”

Fifty years ago, some economists proposed a solution to this problem, which has shaped the subsequent development of risk analysis (Mishan 1971; Schelling 1968/1984). While no amount of money can compensate a person for being killed, these economists argued that people in fact manage, within some normal range of risk tolerance, to compare the value of small increments of the risk of death to other costs and benefits. If we can discover and use these preferences to make regulatory or policy decisions, then perhaps we can justify risk policies by claiming that they maximize the satisfaction of preferences. In this way, policy decisions are supposed to rest on the implicit consent of those who are affected by them.

Nobody is proposing that we consider the cost of a rescue mission before deciding whether to try to save the life of an identifiable individual who is known to be in danger. That would be to treat human life as exchangeable for other resources in an ethically unacceptable way. But risk policies often cover large populations where the individuals who will in fact be killed or harmed as a result are not identifiable *ex ante*. In some cases, the victims of a risk decision will not be identifiable *ex post* either. When we decide to permit some risk of an accident, for example, and an explosion occurs later that kills some workers, we will know the identities of the victims of that decision, but only after the fact. When we decide whether or how much to reduce an air pollutant that causes a common disease like lung cancer, however, we will never know more than the number of premature cancer deaths saved or lost by our action. We will not know of any victim whether or to what degree the particular pollutant we tolerated caused the cancer. The “value of human life” in these cases is merely a statistical measure aimed at making more reasonable decisions. It is to be applied in contexts where we do not know, at least *ex ante*, who the victims will be. The harm may fall to a few, but the *ex ante* risk may be spread equally to an entire population.

When citizens learn that a proposed regulation will cost a specified amount of money but will save ten lives per year in a population of 100,000, the only thing any of them may know *ex ante* is that if the regulation is put into effect her annual risk of premature death will be reduced by  $1 \times 10^{-4}$ . If the cost is \$100 per person per year in increased taxes to reduce this risk, then the question can be framed as what people are willing to pay for this kind of risk reduction. The same question can be framed to ask whether the social value of one (statistical) human life is greater or less than \$1 million. The social value of human life is thus determined by individual preferences for risk reduction.

When Thomas Schelling first made this argument in defense of a social value of human life, he suggested two methods for uncovering and measuring these preferences, each of which has been developed over the succeeding decades. The *revealed preference method* claims that

individual economic behavior reveals risk preferences. People make decisions about how much to spend on safety equipment for their homes or automobiles; they spend more money for comparable houses in less polluted or less dangerous neighborhoods; they demand more in wages for comparable jobs in more risky environments; and so on (Viscusi 1992). Of course these data may be very rough and approximate, but proponents of revealed preference studies claim that they give us information that can be used to help government agencies make policies that satisfy citizen preferences.

But even making allowance for the roughness of the data revealed by these studies, critics argue that they rely on further assumptions that are rarely warranted. They assume, for example, that people are generally aware of the levels of risk they are facing; they assume that people have genuine options for what they purchase or where they work so that their choices do in fact reveal their preferences; and they assume that consumers, homeowners, and workers are satisfied with their current levels of risk. In addition to these practical difficulties, moreover, philosophically minded critics have also challenged the assumption that consumer preferences accurately reflect our deepest values (Hausman and McPherson 2009; Marglin 1963; Sagoff 2004). These critics claim that we express different things when we act privately as consumers and when we act publicly as citizens. A reasonable person might shop for the least expensive car while simultaneously supporting legislation to make cars safer and more fuel efficient, even if these regulations drive up the price of automobiles. Laws and social policies can express values in ways that are not available to citizens acting privately in the market. Skeptics about this argument might claim that it is easy and not particularly revealing of values to express a preference in a public way when one is not being asked to pay the cost directly, but serious questions remain about the accuracy of reading off a person's values from her market transactions.

An alternative to looking for economic data to reveal preferences is to ask people directly how much they value risk reduction and what they are willing to pay for it. These techniques, which have been called both the *expressed preference method* and the *contingent valuation method*, have the advantage of getting people to focus explicitly on the issue at hand. They have the disadvantage of taking on the difficulties of discovering preferences through surveys and interviews, rather than examining behavior, especially when no real money is at stake. And in determining preferences for risk, contingent valuation methods have the added difficulty of being susceptible to framing effects, which are numerous and often very subtle (Kahneman, et al. 1999). For example, economic theory tells us that the value of a commodity is what a person is willing to pay for it. This means that what a rational agent is willing to pay to obtain a commodity or benefit should be roughly equal to what he would accept in exchange for it, which implies that what a rational person is willing to pay to reduce some increment of risk should be roughly the same as what he would demand in exchange for accepting an increased identical increment of the same risk, within the normal range of risk that we tend to accept and live with. But willingness-to-pay measures for risk reduction tend to differ from willingness-to-accept measures for an increase in risk, often by a very large amount (Kelman 1981). Since most contingent valuation studies are framed in terms of what people are willing to pay to reduce risk, the results of these studies may be seriously biased. The framing problems are difficult, and no widely accepted solution to them has yet been proposed.

There is one further important objection to relying on individual preferences to determine an acceptable social value of human life. Many philosophers would argue that ethically justifiable decisions about tolerating risk-imposing activities that kill people could be made

only through deliberative processes that appeal to ethical reasons and arguments (Broome 2008; MacLean 2009). The techniques of risk analysis that rely on methods for revealing or expressing individual preferences tend to substitute observation and measurement for deliberation and argument. Their defenders claim that these methods are more scientific and thus ethically neutral. Individuals express their preferences, and the risk analyst's job is to measure and aggregate them. But these claims to neutrality can be challenged. It should be clear from the discussion so far that preferences for risk depend on what people accept as full compensation for harm. And, as we have stated, there is no amount of money or other benefits can fully compensate for the harm of being killed. If we know after the fact the identity of the victims of a policy that tolerates some level of risk, then we also know *ex ante* that the victims, whoever they turn out to be, cannot be fully compensated. To ask people what they would demand in compensation for a policy that will result in the deaths of some of them only before the results are known is to demand that they express their preferences in ignorance of the most relevant facts. When all the facts are known, however, the compensation test will fail. So the preference-based argument depends on imposing a degree of ignorance.

This argument further supports the conclusion that the only justifiable way to make decisions that impose a risk of death on a population is through explicit moral deliberation and discussion that results in some agreement that can be interpreted as explicit social consent to accepting a risk. But this kind of deliberation is difficult, and it may not result in agreement. It is perhaps for this reason that proponents of risk analysis are drawn to eliciting or measuring existing preferences for risk reduction and relying on a compensation test under an imposed veil of ignorance.

## Justice and the Distribution of Risk

---

Social risk decisions, like most other social decisions, will not always result in an equal distribution of risks, costs, and benefits. Thus, we confront questions about fairness. If we locate a hazardous waste site in a disadvantaged community (where a “community” can be a neighborhood or a nation), because those who live in the community seek the benefits, say, of added jobs that come with constructing and maintaining the site, or because, being disadvantaged, they demand less in compensation for imposed risk than residents of wealthier communities, the decision may be economically efficient but ethically unfair. Similarly, decisions to engage in activities that benefit us today but impose serious risks on future generations may be popular but unjust. In these and other ways, risk decisions raise familiar issues of distributive justice. We will not discuss these familiar or general issues here.

But risk decisions also can have unique distributive characteristics that are ethically relevant. These can be seen when we distinguish the individual's perspective on a risky prospect from the social perspective. Imagine a society consisting of ten people who are considering a proposal that would increase the risk of death to each person by .10. This, of course, is an unusually great increment of risk, well above what Schelling had in mind in characterizing a normal range. The example is unrealistically stylized in order to highlight for illustration a point about distribution. A risk analyst might try to decide whether the proposal should be adopted by determining what would compensate the average individual for the amount of increased risk. But there are different sources of risk, with different social profiles, that are consistent with imposing a .10 risk on each individual. Consider just two possibilities, which we can call *strongly dependent* and *strongly*

*independent.* In the strongly dependent possibility, one person will be chosen to die, and the risk of being chosen is distributed to each person equally, for example, by drawing straws. We call this a dependent risk because what happens to each individual partially determines what happens to all the others. If we determine that the first person will survive, then the risk to the remaining nine increases; or if the third person dies, the others will survive. Alternatively, a strongly independent possibility may involve imposing a separate .10 risk of death on each person, for example, by having each person draw a ball from an urn that contains one black ball and nine white balls, then replacing the ball and passing the urn to the next person. In this situation, the outcome for each person has no effect on the outcome for any of the others.

Clearly, both of these situations impose an identical and equal risk on each individual, but from the social perspective the risks are different. In the strongly dependent case, there is no social risk – one person in the group of ten will die for sure. In the strongly independent case, there is an *ex ante* expectation that one person will die, but this means that one death is merely statistically more likely than other possibilities. There is some chance (approximately .35) that all ten will survive, and also a small risk (one in  $10^{10}$ ) that everyone in the society will be killed. These different social profiles are clearly relevant to determining what is best from an ethical or normative perspective. Of course, we would need to know many details about the social situation in order to reach a reasonable ethical conclusion. If it is important that the society continues to exist, then the dependent risk proposal might be better. The person who dies might be honored as a martyr. If there are strong bonds of solidarity among all the members of the society, however, then the independent situation might be better. The citizens of this society might believe that it is important to maximize the chance that none of them will die, even if this makes some worse social outcomes possible. The point is that risk can be distributed in ethically relevant ways that may not be apparent and may not be taken into account by techniques that measure only individual willingness to pay and then try to aggregate these results to reach a social decision (Broome 1982; Keeney 1980; MacLean 1986b).

## Current and Further Research

---

Ethical issues involving risk, as we have explained, are different in important ways from issues involving harm and raise significant challenges for traditional moral theories. Moral philosophers started calling attention to these issues in a serious way beginning only in the 1970s, but the ethics of risk has not yet become a well-studied subfield of moral philosophy or a subject that is included in the curricula of most moral philosophy classes. There is reason to think that this situation is beginning to change.

Beginning in the 1960s, mainly in response to concerns about risks inherent in technologies like nuclear power, engineers and decision theorists developed analytical methods of risk analysis to provide information and help in guiding the decisions of regulatory agencies charged risk management. These methods were developed as variations of decisions theory and cost-benefit analysis. Philosophers who followed these developments were primarily those with interests in decision theory or in regulatory and tort law. With few exceptions, the ethical issues were discussed only in the context of environmental policies, where the values and risks are particularly hard to quantify and monetize, (Shrader-Frechette 1980; 1990) or in the context of the philosophy of law, where issues surrounding the use of risk analysis to settle matters of liability received much discussion (Cranor 1997; Perry 2001; Sunstein 2002).

But concerns about technological risk are again beginning to capture the attention of moral philosophers more generally (Roeser and Asvelt 2009). The renewed interest is due in part to developments in environmental ethics and the philosophy of law, but it is also related to the dramatic growth of public awareness of the anthropogenic causes of climate change and the need to take measures now to mitigate risks to future generations. This in turn leads to looking more closely at energy technologies like offshore drilling for oil and carbon sequestration for coal, which exacerbate the risks of climate change for current and future generations, and technologies like nuclear power, which holds out promise of an energy source that does not contribute to climate change but poses other well-known risks. How will research in the ethics of risk respond to these issues? Some of the themes are beginning to come into view. We will end this chapter by briefly describing three of them.

First, debates already underway about the adequacy of formal risk analysis or cost-benefit analysis to guide us to reasonable decisions will continue and intensify. Some philosophers have argued that there simply is no alternative to relying on these formal techniques as a framework for thinking rationally about the ethics of risk (Sunstein 2005). Other philosophers, however, continue to highlight the problems involved in quantifying and comparing all the relevant values that go into an ethically justifiable decision (Hansson 1993, 2003, 2007a, b). Some of these problems involve trying to quantify or apply probabilities to scenarios that are possible but whose likelihood is genuinely uncertain. Philosophers and others are becoming increasingly aware of the need to distinguish risk or frequency from genuine uncertainty.

A second set of issues, especially prevalent in thinking about climate change, arises in considering risks we are imposing on future generations. The ethical problems of dealing with future generations has been a philosophical topic for some time, but the importance of assigning discount rates to risks, costs, and benefits as they occur further into the future is especially dramatic in proposals for responding to climate change (Parfit 1984; MacLean 1983; Broome 2011). The fundamental ethical issue is whether there is any justification for incorporating “pure time preference” into analyses of risks that have long time horizons. The implication of pure time preference is that costs and benefits – including the value of human life – count for less as they occur further into the future. Many philosophers and increasingly some economists argue that pure time preference has no ethical justification. But other philosophers and economists claim that discounting for time reflects the preferences of current citizens, and if our analyses did not include discounting for time, the burden of costs that ought to be borne by the current generation becomes excessively great. Issues about assigning discount rates, which have traditionally been confined to technical discussions of dynamic economic models, are likely to become increasingly central to many ethical discussions.

Third, the uncertainties of many risk issues have led to proposals to constrain risk-benefit analysis as a framework for making trade-off decisions with a more conservative precautionary principle. Again, climate change has been the issue that prompts much of this discussion. In an early effort to coordinate an international response to climate change, the United Nations, in the *Rio Declaration* of 1992, approved a version of a precautionary principle. The *Rio Declaration* states, “In order to protect the environment, the precautionary approach shall be widely applied by States according to their capabilities. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation” (UNEP 1992). The idea of a precautionary principle as an ethically justifiable principle to guide policies and laws is the subject of much debate. This principle seems to be more widely accepted on ethical grounds in

Europe and the developing nations than in the United States, where it is widely criticized by philosophers and decision theorists. The heart of the debate seems to be, on the one hand, a distrust of the more formal techniques of risk analysis for dealing reasonably with genuine uncertainties and potential catastrophes and, on the other hand, skepticism on the part of its critics that a precautionary principle can be formulated in a way that can be applied objectively without implying unreasonable conclusions about how we should respond to what might be very remote and unlikely possibilities that someone has imagined, nobody believes is very likely, but which cannot entirely be ruled out.

## Conclusion

---

In this chapter, we have been describing some of the ethical issues that are specific to risk. We have not defended any particular ethical principles, but the discussion does support an important conclusion. Risk analysis has come to be closely identified with the process of estimating risk, determining what people are willing to pay for reducing risk, and using this information to guide government or social policies and regulations. If the arguments above are correct, then the aims of risk analysis should be modest. It can give us important information, but in most cases it cannot be used alone to determine what is an ethically justifiable risk decision. Measuring and aggregating individual preferences for risk is not always an ethically neutral activity, even when it is carefully done. If we are to make decisions that are ethically justifiable, we cannot simply replace ethical deliberation, reasoning, and argument, by techniques that measure and aggregate individual preferences. Those techniques also need to be ethically justified, and considerable work remains to be done to determine the nature of justification in situations involving risk.

# **31 Toward a Premarket Approach to Risk Assessment to Protect Children**

*Carl F. Cranor*

University of California, Riverside, CA, USA

<i>Introduction</i> .....	<b>806</b>
<i>History</i> .....	<b>806</b>
<i>Risk Assessment and Postmarket Laws</i> .....	<b>807</b>
<i>The Need for Premarket Toxicity Testing and Risk Assessment</i> .....	<b>811</b>
<i>Further Research</i> .....	<b>815</b>
<i>Conclusion</i> .....	<b>816</b>

**Abstract:** Postmarket laws and risk assessments seemed to be a good idea in the 1960s and 1970s when the public and Congress in the United States were widely alerted to environmental health harms. And, they were an improvement on existing regulatory laws, of which there were few, and an improvement over torts or the criminal law to protect the public's health.

By now, scientific developments have revealed the substantial shortcomings of such laws. Given the number and kinds of diseases and dysfunctions that may be attributable to in utero or early childhood contamination, postmarket laws and risk assessments will no longer serve to protect children. Premarket toxicity testing and any needed risk assessment before commercialization will have to supplant existing postmarket laws and risk assessment.

## Introduction

---

Historically in the United States, and very likely in many other countries, risk assessment has been combined with postmarket legislation which together aim to protect the public's health from hazardous substances. Postmarket laws permit 80–90% of industrial chemicals to enter commerce *without any legally required testing*. Risk assessment is “the use of the factual base to define the health effects of exposure of individuals or populations to hazardous materials and situations” (NRC 1983).

Because of recent scientific developments in understanding disease processes showing that some diseases and dysfunctions begin in the womb or in childhood, postmarket laws combined with risk assessments fall quite short of protecting the public from toxicants. Consequently, the use of risk assessment and its legal context needs to be reconceived. To the extent that risk assessment has a significant role to play in public health protections in the future, I argue that it should be much more a part of premarket assessment of the toxicity of products in legal contexts in which substances are tested for their toxicity before entering commerce. However, postmarket risk assessments likely will not disappear, because there will continue to be some use for them in limited circumstances, even after laws are amended to require adequate premarket toxicity testing for industrial chemicals.

## History

---

In the late 1960s and early 1970s when environmental concerns came to the forefront of public awareness, the U.S. Congress (and legislatures in many states) sought to address environmental and environmental health issues. These legislative bodies passed various kinds of legislation aimed at protecting people's health and the environment. At the time, this legislation endeavored to remedy shortcomings of existing institutions and to address better and more comprehensively risks to public health and the environment.

The US Congress passed the Occupational Safety and Health Act aiming to protect employees from workplace harms and toxicants. It also sought to protect against pollutants posing risks in the air, surface waters, or drinking water. The Consumer Product Safety Act addressed risks from consumer products. It also amended the pesticide laws and the laws concerning food additives, food contaminants, and drugs (U.S. Congress, OTA 1987).

By 1976, legislators recognized that these efforts were inadequate because they tended to focus on pollutants one media at a time – surface waters, or drinking water, or the air, or the workplace – or they addressed a small number of substances with each law, for example,

pesticides, drugs, food additives, and consumer products. A major shortcoming was that media-by-media or venue-by-venue legislation did not address toxicants more comprehensively. Thus, in 1976 Congress sought to close this gap with the Toxic Substances Control Act (1976) (Applegate 2009). It also passed various laws to guide safer creation, use and disposal of toxicants from cradle to grave, and to clean up toxicants that had been poorly disposed in the ground or groundwater (U.S. Congress, OTA 1987).

As a result of this legislation, “postmarket” laws govern a very large percentage of substances in the market. Thus, Congress authorized public health agencies to “police” exposures to substances once they are in the market to try to identify substances that pose risks to the public or workforce (Merrill 2004). Similar to a policeperson identifying a legal violation and issuing a citation or arrest warrant for the offender, a regulatory agency has a legal burden of proof to identify a risk, develop a scientific case that exposures to the substances pose risks, and then produce a legally binding regulatory response to reduce or eliminate the risks before (any or too much) harm occurs (Wagner 2008). Traditional risk assessment is the key to postmarket prevention of harm (more on this next section).

Other products are subject to premarket testing and approval laws. For pharmaceuticals, new food additives, and pesticides – a relatively small number or substances (about 10%, perhaps up to 20% of the chemical universe) – Congress required companies seeking to commercialize such products to test them for various adverse effects *before* they can enter the market. Once those tests are completed the company must petition an agency, such the Food and Drug Administration (for drugs and new food additives) or the U.S. Environmental Protection Agency (for pesticides) to review the test data and to license the company to sell its product in the market. These are “pre-market testing and approval laws” (U.S. Congress, OTA 1987).

## Risk Assessment and Postmarket Laws

---

How can postmarket laws “prevent” harms? That is, they do not authorize legal action against substances that may be toxic until after they are in commerce and pose risks to the public. How can these be protective?

The critical idea is the concept of a risk. Risks are merely the *chance* of harm or some other untoward or undesirable outcome occurring (Rescher 1983; NRC 1983). By definition a risk has not yet resulted in harm, but is merely a possible or probable adverse outcome. Consequently, if there were reliable techniques for identifying risks before they materialize into harms, Congress could authorize agencies to be alert for products that pose *risks*, identify those as early and as quickly as possible, and then expeditiously reduce or eliminate them before they caused harms. The agencies typically would be authorized to “issue a rule” that provides the health protections against risks required by law in question.

Some laws might require that an agency identify substances that posed risks to human health and then identify technologies that would reduce the risks as much as the technology permitted. These are so-called technology-based laws. Other laws might require an agency to identify risks to human health and then issue public health protections that reduced exposures in the environment to a legally mandated level, for example, so that it did not constitute an “unreasonable risk,” (typical of pesticide laws or the Toxic Substances Control Act) or so that it provided health protections to the public with “an ample margin of safety,” taking vulnerable subpopulations into account (the Clean Air Act) (U.S. Congress, OTA 1987).

The focus on risks was typically supported by experimental animal studies and other nonhuman scientific data so humans would not need to suffer harm in order for an agency to develop health protections (U.S. Congress, OTA 1987). In principle studies conducted on animals would reveal potential risks to people so exposures could be reduced before harm occurred, although the use of animal data has become sufficiently controversial in some areas, for example, in Europe in particular, that governments are trying to find alternatives to animal studies for this purpose.

Congress also seemed to envision that a public agency could issue a health regulation to protect citizens from a toxicant fairly quickly. Overall, this approach seemed to be a clever idea. As a result of legislation targeting risks identified by animal and other nonhuman studies, a new field of risk assessment was born. If the laws and their procedures functioned well, the identification of risks followed by quick regulatory action could prevent harm. In fact, early on some risk assessments were done comparatively quickly (U.S. Congress, OTA 1987).

Some legislation imposes much greater legal burdens on public health agencies than other laws. *Ambient exposure laws* require public health agencies to determine whether existing exposures cause risks to the public, and then assess what levels of exposures, given the potency of the substance, will result in an acceptable risk under the legislation. Conducting a risk assessment under ambient exposure laws requires all four stages of a full-fledged risk assessment. Public health agencies first must identify substances that are hazardous. Hazard identification consists of the “determination of whether a particular chemical is or is not causally linked to particular health effects” (NRC 1983). The idea is whether the chemical has intrinsic “built-in ability[ies] to cause an adverse effect” (Faustman and Omenn 2001; Heinzw 2009). Next, they must determine what exposure levels can cause adverse effects. This is the estimation “of the relation between the magnitude of exposure and the probability of occurrence of the health effects in question” (NRC 1983). This is sometimes called a “potency assessment,” because it reveals the toxic potency of the substance.

Third, health agencies would conduct an exposure assessment. This is the “determination of the extent of human exposure before or after application of regulatory controls” (NRC 1983). Typically, this would constitute the level of exposures in the relevant environment at which people would be exposed. Finally, agencies must provide an overall risk characterization. This is the “description of the nature and often the magnitude of human risk, including attendant uncertainty” (NRC 1983; Cranor 1993).

In contrast to ambient exposure laws, when the U.S. Environmental Protection Agency must protect the public health under a *technology-based statute*, such as the Clean Air Act or Clean Water Act, its risk assessment steps are comparatively minimal. The EPA need only conduct a *hazard* assessment, that is, to determine whether the chemical in question has intrinsic toxicity properties that can cause adverse health effects. It need not go through the other three risk assessment steps. Once it has found that a substance has such toxic properties, such as being a carcinogen or a reproductive toxicant, it would typically require technology to bring exposures to the chemical to the lowest level the technology can achieve (U.S. Congress, OTA 1987). The moral view underlying such legislation is that companies must “do the best they can” to reduce exposures to toxicants with existing or achievable or the best technology (different laws have different standards) (Wagner 2008).

Risk assessments under *ambient exposure laws* are much more data intensive, science intensive, labor intensive, and time consuming. A public health agency must conduct all four steps in typical risk assessments, and it might even have to provide two risk characterizations:

One before exposures are reduced and then one assuming reduction in exposures with the second used to show that steps taken to protect the public health would indeed do so and how much protection would be achieved.

Unfortunately, postmarket risk assessments to protect the public health have not lived up to the proposed ideal. Postmarket regulatory processes are not quick. Agencies do not quickly find or develop data from animal or other studies. There are numerous incentives in postmarket laws and procedures for affected companies to slow the process. Agencies also have limited personnel to devote to developing protections because they are too underfunded. Consequently, these efforts have bogged down in scientific and other disputes. Issuing health standards to better protect the public can easily take several years, sometimes much longer and occasionally decades, as it has so far with regard to dioxin in the US. Legislation based on postmarket regulation is especially inadequate for protecting our children (Cranor 1993).

When there is insufficient scientific data about toxic hazards from products under postmarket laws, public health agencies find it difficult to provide better health protections. They need enough data to identify risks before technology-based laws can be issued. And these agencies must have even more evidence to issue protective ambient exposure standards. These circumstances create temptations for companies not to test their products for toxicity. If there is no data, a company could say that it had no evidence of adverse effects. If the EPA seeks to require a company to provide the data, it must go through a burdensome legal process to do so (Cranor 2011).

A second postmarket temptation, utilized as early as the 1970s by the tobacco industry, is to raise doubt about the science that shows the toxicity of a product (Michaels 2008). Since a public health agency has a legal burden of proof to find and assemble data about the toxicity of a substance, a company has strong incentives to challenge the data. As an internal memo from a tobacco company expressed it, “Doubt is our product since it is the best means of competing with the ‘body of fact’ that exists in the minds of the general public. It is also the means of establishing a controversy” (Brown and Williamson Tobacco Company 1969). Casting doubt on the science also challenges any attempt to improve health protections, because it gives the appearance that the science is not settled, even if it largely has been. And this tactic can substantially delay better health standards. Moreover, challenging scientific results can be done without disagreeing with public health standards, an important public relations point. The end result is a significant delay in health standards (Cranor 2011).

In addition, companies can be tempted to demand “proof” of toxicity from public health agencies before exposures are reduced (Michaels 2008; Cranor 2008). The idea of proof is more typical of deductive math, where logical certainty is required, but is an alien idea in the biological sciences, where public health officials typically make decisions based on the weight of the scientific evidence. To the extent a party subject to regulation can persuade a regulatory agency that the agency must meet very high standards of proof before it modifies the legal status quo, this can erect obstacles to improved health protections even higher than the particular statute in question may require.

Companies might also urge public health agencies to require myriad kinds of evidence in support of better public health protections, for example, mechanistic data about how a substance functions at the molecular level. This is usually evidence that is very difficult to provide and ordinarily that is simply not known. For example, scientists understood numerous adverse and beneficial effects of aspirin for approximately 100 years without understanding the mechanisms by which either result was achieved (Santone and Powis 1991, p. 169). Or if there

were some epidemiological evidence showing associations between exposures to toxics and adverse effects, companies might still argue that there should be more epidemiological studies to corroborate existing data. Even if there were human data showing adverse effects, firms might argue that there should be animal studies as well in order to have a model for toxicity effects.

Such requests might be appropriate in the world of academic science, where issues of modest moment could be at stake. However, when protection of the public's health is at stake unreasonable demands for scientific studies can have undesirable consequences. When a product is hazardous and poses risks, such additional demands leave the public at risk while studies are carried out because if substances pose risks or are actually harmful this risks type II errors (not treating a toxic substance as toxic) [See Hansson on type I and type II errors]. Of course, an agency must have appropriate data to support its recommendations for improved health standards. However, excessive demands for more evidence, spurious claims criticizing the science, and demands that conclusions must be supported with greater certainty all delay health protections. Postmarket laws create all these temptations (Cranor 2011).

Regulated industries have also sometimes utilized less creditable means for opposing improved public health protections. Company experts sometimes mislead public health agencies and scientific journals about the science. Scientists or their employers have sometimes modified studies so that they can claim that there are no or only minimal risks from their products (Michaels 2008).

As David Michaels has noted, companies may "salt the [scientific] literature with questionable reports and studies... which regulatory agencies have to take seriously." However, he argues that the major goal of such studies is "to clog the [regulatory] machinery and slow down the process" (Michaels 2008). At other times, research projects have been proposed and seemingly designed to find no adverse health consequences, even if independent scientists have found they exist. For instance, the petroleum industry was quite explicit that studies assessing whether benzene contributed to blood and bone marrow cancers would be designed to find results that could be used to fight health protections for its workers and used in fighting toxic tort suits (Cappiello 2005; Bohme et al. 2005).

Finally, postmarket laws have resulted in a chemical world in which little is understood about the toxicity of industrial chemicals to which we are all exposed. Since the vast majority of substances are subject to postmarket regulation, there is no toxicity data for about 70% of these substances. In 1984, about 75% of 3,000 substances produced in the highest volume and likely having the greatest exposures had no toxicity data (NRC 1984). There has been slight improvement since that time, but only very recently and it appears there is no toxicity data for about 50% of the substances produced in the highest volume.

In addition, for about 50,000 new substances entering commerce since 1979 approximately 85% lacked health effects data. For a majority of 50,000 even their chemical identity is hidden by confidential business information claims (Guth et al. 2007, pp. 237–238). If there were an effort to test substances already in commerce at the rate such tests occur this could take hundreds of years. Moreover, many substances are more toxic than might appear. A sampling of 100 chemicals in commercial use and a sampling of 46 chemicals produced in more than a million pounds revealed that about 20% of each group was mutagenic. Mutagenicity tests are comparatively quick and inexpensive to conduct, yet these have not been performed on most substances. A mutagen has a substantial likelihood of being a carcinogen in mammals (Claxton et al. 2010).

The above discussion suggests that postmarket laws combined with risk assessments utilizing nonhuman data are inadequate to protect human health well. If human data were required as companies sometimes urge, this would defeat the purpose of disease prevention. This concern is even of greater urgency when one understands some new developments in biology called the developmental origins of disease.

## The Need for Premarket Toxicity Testing and Risk Assessment

---

Recent scientific developments have revealed that people are extensively contaminated by a variety of human made chemicals substances, and that because of contamination during development fetuses and children can experience disease, dysfunction, and death as a consequence. Developing children are at even greater risk than adults.

Each of us is contaminated by hundreds of substances. Industrial chemicals, pesticides, cosmetic ingredients, and other products can enter our bodies and then infiltrate our tissues, organs, and blood. The US Centers for Disease Control (CDC) has developed techniques for detecting them by measuring the amounts in our blood or urine; this process is called biomonitoring (U.S. Department of Health and Human Services, CDC 2005).

Biomonitoring directly measures the “levels of chemicals that actually are in people’s bodies” (Sexton et al. 2004). This procedure reveals “which chemicals get into Americans and at what concentrations,” the percentage of people exposed to toxic concentrations, and the range of body burdens (U.S. Department of Health and Human Services, CDC 2005). It can also provide an integrated effect of “all routes of exposure – inhalation, absorption through the skin and ingestion, including hand-to-mouth transfer by children” (U.S. Department of Health and Human Services, CDC 2005).

At present, the CDC can reliably identify about 212 substances in US citizens’ bodies. As protocols for detecting industrial chemicals are developed, this number will certainly increase because all but the very largest molecules will enter our tissues (Needham 2007; U.S. Department of Health and Human Services, CDC 2009). The CDC investigates these compounds because they are known or suspected hazardous substances or represent substantial exposures to US citizens (U.S. Department of Health and Human Services, CDC 2005; Heinzow 2009; Faustman and Omenn 2001). Whether hazardous compounds will pose risks depends upon other considerations such as their concentration in people’s bodies.

The substances CDC is investigating include the gasoline additive, methyl tertiary butyl ether (MTBE), perchlorate, a discarded rocket fuel component, polychlorinated biphenyls (PCBs) that were used as industrial insulating and cooling compounds, polybrominated diphenyl ether fire retardants (PBDEs), numerous pesticides, perfluorinated compounds (PFCs) that were used in Teflon, among other products, as well as arsenic and lead. (U.S. Department of Health and Human Services, Fourth Annual Report, U.S. Department of Health and Human Services, CDC 2009). Most of these compounds can cause toxic responses in animals or humans at some level of exposure: estrogen-mimicking substances and other hormone-disrupting chemicals; thyroid disruptors; neurotoxicants, which can damage the nervous system; developmental toxicants; immunotoxins, which can damage the immune system; as well as known or probable human carcinogens.

Some of these substances are persistent and will remain in people’s bodies for years. PCBs have a half-life of about 8 years. The half-life of a substance is the time it takes for one-half of its

concentration to leave the body. In addition, perfluorinated substances have a half-life of about 7 years (Calafat et al. 2007). The PBDE flame-retardants can reside in fatty tissues for several years. Together PCBs and PBDEs can cause neurological effects including behavioral disorders (Costa and Giordano 2007). These two plus perchlorinated substances affect different neurological pathways that could contribute to similar problems (Woodruff et al. 2008). Because each has a long half-life in human bodies, they have an extended period to adversely affect children's health. For example, experimental animals studies PFCs and PBDEs appear to have neurotoxic effects, causing deranged behavior in rodents (Eriksson et al. 2009).

Some substances including bisphenol A are transient in human bodies. However, studies reveal that more than 90% of the populace older than 6 are contaminated by BPA, with children being the most highly contaminated (Calafat et al. 2008). This finding indicates that US citizens have almost continuous exposures. Other kinds of substances that have short half-lives in people's bodies include the gasoline additive, MTBE, other solvents as well as plastic additives such as phthalates.

Whether persistent or transient, toxic substances can pose heightened risks to children during development. Because children have increased vulnerability during development their risks from toxicants are heightened. In addition, many substances in a pregnant woman's body will cross the placenta and enter her developing child. Many of the same compounds will also contaminate her breast milk and be transmitted to her child through nursing. Whether in utero or through nursing she will offload some of her body burden of industrial chemicals onto her child. Newborns have up to 232 industrial chemicals in their bodies (Fimrite 2009). Thus, industrial compounds sully children prenatally, and postnatally this body burden is increased from external exposures, including mother's milk. Some of the same compounds may be found in formula milk, but formula could also contain other substances of concern.

Perhaps this would be of lesser concern, if developing children were no more susceptible to diseases than adults. However, they tend to be more susceptible to diseases, dysfunctions, or premature death as a result of prenatal or early postnatal exposures. They are typically more highly exposed than adults both prenatally and immediately postnatally, but at the same time have lesser defenses against toxicants. They also have more of their lifetime for diseases to manifest themselves (Cranor 2011).

Thus, researchers have documented a number of developmental toxicants. Thalidomide and anticonvulsive drugs cause morphological defects obvious at birth. Other toxicants contribute to long-delayed, but typically less visible adverse effects. Lead can lessen children's IQ and contribute to aggressive behavior (Lanphear 2005) [In adults and at low levels it can also cause cardiovascular risks and strokes (Navas-Acien et al. 2007; Silbergeld and Weaver 2007)]. In utero exposures to pesticides, probably lead, and other neurological toxicants appear to hasten Parkinson's disease decades after contamination. Estrogen-mimicking substances have been documented as leading to early onset of cancer (from diethylstilbestrol [DES]), and some appear to increase the chances of its occurring, or contribute to other diseases, but years after exposure. BPA crosses the placenta, becomes more toxic in the fetal environment, changes how important genes are expressed, and damages placental cells (Balakrishna et al. 2010, p. 393. e6; Bromer et al. 2010). Experimental studies also suggest that it can contribute to breast, uterine, and prostate cancer as well as obesity and diabetes (Heindel 2008). It can also adversely affect the immune system, probably permanently (Dietert and Piepenbrink 2006).

Some known developmental toxicants (in addition to the above) include mercury, sedatives, arsenic, tobacco smoke, alcohol, and radiation. Two hundred known human neurotoxicants that adversely affect adults are likely toxic to children as well. Based on animal research other industrial

chemicals are of substantial concern, including phthalates, PBDEs, and cosmetic ingredients (Grandjean and Landrigan 2006). Many carcinogens, lead, tobacco smoke, disinfectant by-products, and radiation appear to have no known safe level (Wigle and Lanphear 2005).

These contributors to disease have been revealed comparatively recently, although the developmental toxicants, thalidomide, methylmercury, and DES, have been known for more than 40 years (Cranor 2011). Many of the diseases that once plagued the United States have disappeared as a result of public health advances and vaccinations. Cleaning up water and sewage reduced cholera and typhoid fever. Vaccines reduced or eliminated other diseases, including smallpox, polio, measles, and mumps. Children born today are likely to exceed their ancestor's lifespan by 2 decades (Landrigan 2009).

Consequently, although most people are living longer, more subtle diseases remain caused by exposure to various toxicants. These more subtle adverse effects might not have been seen when people had shorter life spans or died from more obvious diseases.

Nonetheless, there remain various diseases, including “cardiovascular disease, diabetes, obesity, respiratory ailments, and injuries” that are of concern. As the above discussion suggests there are also a number of morbidities that can affect children. Some are “intellectual impairments” such as “lowered IQ, poor memory, mental retardation, autism, attention deficit hyperactivity disorder (ADHD).” There are also documented “behavioral problems, asthma, and preterm birth...” (Lanphear 2005). Both groups, according to Lanphear, appear to be related to low-level exposures “to... noninfectious environmental factors or gene-environment interactions” (Lanphear 2005). In addition, obesity, which might be thought to result from behavior or unhealthy foods, can also have contributions from toxicants that enter our bodies without our choice.

For many of these diseases recent research has focused on what are called the “developmental origins of health and disease.” Since diseases typically result from a combination of genetics and environmental influences, and since a person’s genetic code does not undergo rapid change, researchers believe that environmental influences, including particularly molecular exposures, contribute to these adverse effects. Consequently, they are investigating the view that some contaminants, while not modifying a person’s genome, affect its functioning, or how it “expresses itself.” Such effects on the genetic code are the so-called epigenetic effects. Environmental influences, including early life contamination by toxicants, on how genes are expressed, they find, can lead to disease (Jirtle and Skinner 2007; Heindel 2008).

Existing postmarket laws that permit these conditions are reckless toward the public. The policies in the legislation appear to reflect lack of thought about possible undesirable consequences. If companies that commercialize products without testing for toxicity are aware of the contamination of adults and the vulnerability of developing children, they also act recklessly.

The scientific discoveries of contamination and disease in the context of postmarket laws suggest that if a community seeks to reduce risks to its children, the law must change to require appropriate premarket toxicity testing and review by a public health agency before the substances enter commerce. This suggestion resembles in some respects laws governing pharmaceuticals or pesticides in the United States. Most risk assessments that would be done would also be premarket, before industrial chemicals entered commerce. This approach would be somewhat different from postmarket risk assessment. It is also a much more precautionary approach to preventing diseases (See [Chap. 38, The Precautionary Principle](#), in this handbook).

Consider a few of the issues. If premarket toxicity testing revealed that a substance was hazardous, that is, had intrinsic toxic properties, a next step would be to inquire about its potency and whether it operates by means of a threshold or a nonthreshold mechanism. That is, is there some level of exposure to developing children below which the substance would not be toxic or is there no lowest level below which it is toxic, similar to lead or radiation? Moreover, this question should be pursued assuming that pregnant women are contaminated by other substances, some of which might well plausibly interact with the new industrial chemical. That is, toxicity testing should be pursued, assuming the world as it is, namely, that people are already contaminated by other industrial chemicals. In addition, researchers should allow for wider genetic variation in humans than in animal models or test tube experiments in which products are tested (Hattis and Barlow 1996; Woodruff et al. 2008; NRC 2006). They should assume that people including both pregnant women and developing children are already exposed to other toxicants and that they exhibit the full array of susceptibility of which researchers are aware (Cranor 2011).

In addition, to protect developing children researchers should determine whether the substance can cross the placenta or enter breast milk. If it is intrinsically hazardous, is a nonthreshold toxicant, and can cross the placenta or enter breast milk exposing developing children, this is a strong presumptive reason to prevent its commercialization. Testing under such circumstances should both approximate real-world conditions and better protect people and their children from industrial substances that were toxic and proposed for commercialization.

The next step in a premarket risk assessment would be to determine what exposure levels, if any, could be permitted once a substance were in commerce consistent with protecting developing children. For postmarket risk assessments, exposure assessments would seek to determine what existing exposure levels were. For premarket risk assessment, what exposures could be permitted consistent with protecting developing children? Premarket risk assessments would assess some overall characterization of what risks, if any, would exist under exposures that would provide substantial protections to developing children.

Premarket testing and any needed risk assessment would change incentives so that private companies are more likely to act in the public interest than frustrating it as currently occurs under postmarket laws. There would be no incentives to delay the production of scientific data; quite the contrary, companies would seek to have their products enter commerce as quickly as possible. There would be no insistence on multiple studies to document risks or harm. Instead, companies would seek to reduce the number of studies and data requirements to lower costs. Companies would not likely demand that high standards of proof must be satisfied before products could enter the market. More likely, they would argue for lesser standards of proof.

There would still be temptations to produce false or misleading toxicity data as sometimes occurs with premarket pharmaceutical or pesticide testing. Public health agencies would need to be alert to such problems. Moreover, a testing and approval process would need to be designed to minimize this to the extent that it could. For instance, companies might transfer funds to a public health agency sufficient to support needed testing and the agency would then pick a laboratory with a reputation for using credible science to carry out needed testing (Cranor 2011). The institutional structure needed for such purposes would need to be developed in some detail, which I do not have the expertise to do. However, the National Research Council has sketched some of the main features (but even there more details will be needed) (NRC 2008).

Another aspect of premarket testing should consider pollutants. Typically, since risk assessments are usually conducted after toxic pollutants have affected a geographic area, there is no reason that risk assessments could not be conducted in advance of exposures in

order to assess and reduce risks. To illustrate this consider a recent report about pollutants from the Tacoma copper smelter. The EPA had to conduct a risk assessment to determine *after the population was exposed* what concentrations of toxic substances, such as lead, arsenic, and cadmium, had been deposited on the land and homes and how contaminated the populations were, and what risks these posed (State of Washington 2005). The EPA needed this post-deposition risk assessment to assess and clean up the surrounding community. It sought to determine how much damage was being done to the population and the wider environment and how stringent should the pollution emissions be.

Legislatures, now alerted that such problems can occur, should require risk assessments of potential pollutants from industrial facilities *before* damaging effects occur. Reasonable risk assessments could be undertaken in advance by companies to determine how the population would likely be affected, whether the company would need to reduce effluents, and whether public health protections would need to be undertaken as a consequence.

If legislatures required appropriate premarket toxicity testing for new and existing products as well as for major pollutants from industrial facilities, labor-intensive, science-intensive, and slow risk assessments that at present obstruct public health protections under postmarket laws would be needed much less. In the current legal environment, public health agencies employ the scientific community to study health problems or risks with experimental or epidemiological studies or both, assess exposures, and then digest the data to judge public health risks. Premarket testing of products in principle should reduce such time-consuming postmarket studies.

Scientists would continue to have plenty of studies to conduct, but most of them would need to be performed prior to industrial chemicals entering the market. Researchers would still need to conduct tests on experimental animals in order to test for carcinogens or developmental toxicants, for example (at least until these were superseded by more efficient toxicity tests). They would also need to conduct many short-term tests, as well as developing new ones both to avoid animal studies and to find better and quicker means to alert companies and public health agencies to toxicants. There would even be a continued need for exposure assessments, only they would more closely resemble preexposure pollution assessments (described above), during which researchers would need to estimate as best they could what exposures were likely to occur so that they could provide, if needed, an overall estimate of risks from substances if they were commercialized.

It seems to me that there is also a profound paradigm shift that must accompany the enterprise of science in a world in which much greater premarket toxicity testing occurs. Scientists that currently conduct postmarket risk assessments may be committed to studying an existing toxicity problem, discovering its scope, and determining the degree of toxic potency in order to protect the public's health. This paradigm will seem appropriate if most of the risk assessments are conducted before products enter the market. Researchers likely will need to rethink somewhat how they perform studies for premarket risk assessments (but there would be considerable similarities between premarket and postmarket studies) and their sources of funding might be different.

## Further Research

Researchers should be asking what tests and procedures should be used to identify toxicants before they enter commerce and so that diseases do not result from contamination in utero or

perinatally. The emphasis should be on avoiding such risks in the first place. If premarket testing and risk assessments were successful, there would be fewer existing problems to identify and solve, but there would be toxicants to identify before they become public health problems that needed identification and solutions.

Answering these questions will require additional research. Some of it is suggested in the immediately proceeding paragraphs. The generic idea would be to conduct testing and any needed premarket risk assessment to identify risks to developing children before substances enter commerce. For example, since currently we are all contaminated by various industrial chemicals, some toxic, testing should incorporate current contamination during animal studies when a new substance is considered for introduction into commerce. Will the new substance interact with existing contaminants to increase risks, particularly for children? For example, researchers from Andreas Kortenkamp's lab have found this for synthetic estrogens as well as some anti-androgens (Hass et al. 2007; Kortenkamp 2007). Moreover, Woodruff et al. have reported that even when substances do not act by particular cellular receptors, they can affect the same endpoints, for example, reduce thyroid production, which can damage the neurological development of children in utero (Woodruff et al. 2008). Researchers designing testing protocols for premarket testing and any needed risk assessment will need to be imaginative in creating tests that mimic actual exposures to developing children and any other contamination that they might have because of their parents existing contamination.

## Conclusion

---

Postmarket laws and risk assessments seemed to be a good idea in the 1960s and 1970s when the public and the U.S. Congress were widely alerted to environmental health harms. And, they were an improvement on existing regulatory laws, of which there were few, and an improvement over torts or the criminal law to protect the public's health. (Moreover, to the extent that other countries developed similar laws, they too will have the same problems that are now apparent in the United States.)

By now, scientific developments have revealed the substantial shortcomings of such laws. Given the number and kinds of diseases and dysfunctions that may be attributable to in utero or early childhood contamination, postmarket laws and risk assessments will no longer serve to protect children. Premarket toxicity testing and any needed risk assessment before commercialization will have to supplant existing postmarket laws and risk assessment.

**Abstract:** Risks arising from technologies raise important ethical issues for people living in the twenty-first century. Although technologies such as nanotechnology, biotechnology, ICT, and nuclear energy can improve human well-being, they may also convey risks due to, for example, accidents and pollution. As a consequence of such side effects, technologies can trigger emotions, including fear and indignation, which often leads to conflicts between experts and laypeople. Emotions are generally seen to be a disturbing factor in debates about risky technologies as they are taken to be irrational and immune to factual information. This chapter reviews the psychological literature that seems to support this idea. It then presents an alternative account according to which this is due to a wrong understanding of emotions. Emotions can be a source of practical rationality. Emotions such as fear, sympathy, and compassion help to grasp morally salient features of risky technologies, such as fairness, justice, equity, and autonomy that get overlooked in conventional, technocratic approaches to risk. Emotions should be taken seriously in debates about risky technologies. This will lead to a more balanced debate in which all parties are taken seriously, which increases the chances to be willing to listen to each other and give and take. This is needed in order to come to well-grounded policies on how to deal with risky technologies. The chapter discusses various recent examples of hotly debated risky technologies and how an alternative approach of emotions can help to improve debates about the moral acceptability of these technologies. The chapter ends with suggestions for future research in the areas of financial risks and security risks.

## Introduction

---

Risky technologies often give rise to intensive public debates. Examples of risks that spark heated and emotional debates are cloning, GM-foods, vaccination programs, carbon capture and storage, and nuclear energy. While large parts of the public are often afraid of possible unwanted consequences of such technologies, experts typically emphasize that the risks are negligible. They often accuse the public of being emotional, irrational, and wary to objective information. Policy makers usually respond to this gap between experts and public in either of two ways: by neglecting the emotional concerns of the public in favor of the experts or by accepting the emotions of the public as an inevitable fact and as a reason to prohibit a controversial technological development. Both of these responses are grounded on the assumption that the emotions of the public are irrational and block the possibility of a genuine debate. However, the assumption that emotions are irrational is far from obvious. To the contrary, many contemporary emotion scholars challenge the conventional dichotomy between reason and emotion. They argue that emotions are a form or source of practical rationality. This chapter argues that this alternative view of emotions can lead to a different understanding of emotional responses to risk. Risk emotions (i.e., emotions evoked by or related to risk or risk perception) can draw attention to morally salient aspects of risks that would otherwise escape our view. This alternative approach can shed new light on various controversial debates about risky technologies by showing the reasonableness of risk emotions. In addition, it can provide for a new approach on how to address emotions in debates about risky technologies. By taking the emotions of the public seriously, the gap between experts and laypeople can eventually be overcome, leading to more fruitful discussions and decision making.

## Historical Developments

---

Research into public risk perceptions started in the late 1960s and early 1970s with the rise of empirical decision theory. The initial focus was not so much on emotions, but on the way people make judgments under risk and uncertainty. It turned out that the risk judgments of people deviate substantially from the then academically dominant approach of rational decision theory, which was based on formal methods (see Part 3: “Decision Theory and Risk” of this handbook). Not only laypeople, but also experts, turned out to make decisions in ways that deviated from these strict rules, and to have problems processing statistical information (Tversky and Kahneman 1974, also see Gigerenzer 2002). This gave rise to a whole industry of investigations into the biases to which people are prone in risk judgments, under the header “heuristics and biases.” This research would eventually result in a Nobel Prize in economics for Daniel Kahneman in 2002.

## Risk Perception

---

Since the 1970s, Paul Slovic and his colleagues have conducted numerous psychometric studies into the risk perceptions of laypeople. This research began with the assumption that in so far as risk perceptions deviate from rational decision theory, they are biases. However, eventually Slovic started to develop an alternative hypothesis, namely, that it was possible that laypeople not so much have a *wrong* perception of risk, but rather a *different* perception of risk than experts. Maybe there was something to be learned from laypeople’s risk perceptions (Slovic 2000, p. 191). This hypothesis was supported by the finding that if asked to judge annual fatalities due to certain activities or technologies, laypeople’s estimates came close to those of experts. However, when asked to judge the *risks* of a certain activity or technology, laypeople’s estimates differed significantly from those of experts. Experts define risk as the probability of an unwanted effect, and most commonly, as annual fatality, so they perceive the two notions as by and large the same. However, apparently, for laypeople, these are different notions. They seem to have different connotations with the notion of risk that go beyond annual fatalities (Slovic 2000, pp. 113, 114). Slovic and his colleagues then started to conduct studies with which they tried to disentangle which additional considerations played a role in laypeople’s risk perceptions. They eventually developed a list of 18 additional considerations, including a fair distribution of risks and benefits, voluntariness, available alternatives, and catastrophic versus chronic risks (Slovic 2000, p. 86).

The question remains whether these considerations are reasonable concerns that should be included in risk assessments. The answer by sociologists and philosophers of risk to this question is positive. Whether a risk is acceptable is not just a matter of quantitative information but also involves important ethical considerations (see [Chap. 3, The Concepts of Risk and Safety](#), by Möller in this handbook) (cf. Krimsky and Golding 1992; Shrader-Frechette 1991; Hansson 2004). In the literature on ethical aspects of risk, the same considerations are brought forward as the ones that play a role in risk perceptions of laypeople.

Technocratic approaches to risk are based on the definition of risk as the probability of an unwanted effect and cost-benefit or risk-benefit analysis. Cost-benefit analysis resembles utilitarian theories in ethics, which state that we should maximize aggregate benefits or minimize unwanted outcomes. However, such approaches are subject to severe criticism in moral philosophy. Common objections against utilitarianism are that it ignores issues of fair

distribution, justice, autonomy, and motives. The same objections can be raised against cost-benefit analysis (Asveld and Roeser 2009). It is a morally important consideration how risks and benefits are distributed within a society (fairness, equality) (see also [Chap. 36, What Is a Fair Distribution of Risk?](#), by Hayenjelm in this handbook). Risks that are imposed against people's will are morally questionable (autonomy, cf. Asveld 2007). It is morally important whether a risk is due to intentional actions, negligence, or has occurred despite responsible conduct (motives) (see also [Chap. 33, Risk and Virtue Ethics](#), by Ross and Athanassoulis, and [Chap. 35, Risk and Responsibility](#), by Van de Poel and Nihlén Fahlquist in this handbook). A one-shot, catastrophic risk can be morally more problematic than a chronic, relatively small risk, even though the respective products of probability and effect might be similar. This is because in the case of a chronic risk, such as traffic risks, there are opportunities to improve outcomes, whereas in the case of a catastrophic risk, such as a nuclear meltdown, once it manifests itself, it can prove impossible to stop it, and the consequences can be disastrous for generations to come (Roeser 2006, 2007).

Hence, interestingly, laypeople, psychologists, social scientists, and philosophers share many of the same concerns when it comes to the moral acceptability of risk.

## The Affect Heuristic

---

Recently, another aspect of laypeople's risk perceptions has been investigated, namely, emotions. Melissa Finucane, Paul Slovic, and other empirical scholars have started to study the role of emotions, feelings, or affect in risk perception (cf. for example Alhakami and Slovic 1994; Finucane et al. 2000; Loewenstein et al. 2001; Slovic et al. 2002, 2004, and Slovic 2010). They have coined the terms "the affect heuristic" or "risk as feeling" to describe these perceptions (see [Chap. 26, The Role of Feelings in Perceived Risk](#), by Finucane in this handbook) (several journals have devoted special issues on this topic: *Risk Management* 2008, no. 3; *The Journal of Risk Research* 2006, no. 2). It turns out that emotions such as dread or fear significantly influence laypeople's risk perceptions. Some scholars see this as a reason to resist laypeople's risk perceptions, as they take emotions to be a disturbing factor for risk perception. Cass Sunstein (2005) emphasizes that emotions lead to what he calls "probability neglect." He proposes to use quantitative methods such as cost-benefit or risk-benefit analysis in order to come to a rational evaluation of risks. Paul Slovic thinks that "risk as feeling" should be corrected by "risk as analysis" (Slovic et al. 2004, p. 320). Others argue that we should respect the emotions of laypeople because we live in a democracy (Loewenstein et al. 2001), or for instrumental reasons, in order to create support for a technology (De Hollander and Hanemaaijer 2003). Hence, it seems like risk emotions constitute the following puzzle: the fact that emotions play an important role in laypeople's risk perceptions threatens to undermine the earlier claims about the broader risk rationality of laypeople. However, Slovic and his colleagues point out that emotions show us what we value (Slovic et al. 2004). It is this line of argument that this chapter explores in more detail in what follows.

## Current Developments

---

The idea that reason and emotion are diametrically opposed is deeply ingrained in our cultural and intellectual heritage, so much so that it is taken for granted and rarely questioned.

The same dichotomy can also been seen in the academic literature on risk and emotion. However, over the last decades, emotion-scholars have challenged the dichotomy between reason and emotion. Many leading philosophers and psychologists who study emotions argue that we need emotions in order to be practically rational. This idea can shed new light on the study of risk and emotion, which will be discussed in this section. This section will first discuss Dual Process Theory, the dominant approach to risk emotions. It will then discuss objections to this approach and present an alternative view.

## Dual Process Theory

---

The dominant approach in research into risk emotions is Dual Process Theory (DPT; cf. Epstein 1994; Sloman 1996; 2002; Stanovich and West 2002). According to DPT, people apprehend reality in two distinct ways: system 1 is emotional, affective, intuitive, spontaneous, and evolutionarily prior. System 2 is rational, analytical, computational, and occurred later in our evolution. System 1 helps us to navigate smoothly through a complex world, but it is not reliable, it provides us with heuristics, but also biases (cf. Gilovich et al. 2002). If we want to have reliable knowledge, we have to use system 2, but it takes more time and effort.

Neurological research by Joshua Greene is meant to support the framework of DPT. People who make utilitarian, cost-benefit moral judgments use rational parts of their brain; people who make deontological, respect-for-persons judgments use emotional parts of their brain (Greene 2003, 2007; Greene and Haidt 2002). Greene and also Peter Singer (2005) argue that this shows that utilitarian judgments are superior to deontological judgments, as the source of utilitarian judgments is superior, namely, reason rather than emotion.

DPT reflects the common dichotomy between reason and emotion: emotions are spontaneous gut reactions, but highly unreliable, reason is the ultimate source of objective knowledge, but it comes with the price of requiring more effort. This approach is commonly adopted by various scholars who study risk and emotion (e.g., Slovic 2010; Sunstein 2005). But the question is whether this is justified.

## Against DPT

---

There are developments in emotion research that cast serious doubt on DPT. Emotions are not contrary to knowledge and rationality, rather, they are a specific form of knowledge and rationality. Many contemporary emotion-scholars see emotions as a source of practical knowledge and rationality.

Groundbreaking research by Antonio Damasio (1994) has shown that people with a specific brain defect (to their amygdala in the prefrontal cortex; see [Chap. 27, Emotion, Warnings, and the Ethics of Risk Communication](#), by Buck and Ferrer in this handbook) have two problems: (1) They do not feel emotions anymore. (2) They cannot make concrete practical and concrete moral judgments anymore. This specific brain defect does not impair abstract rationality; people score equally high on IQ tests as they did before the injury or illness that caused the damage. These patients also still know abstractly that one should not lie, steal, or kill, etc. Their abstract moral knowledge and their abstract rationality are still intact. However, in concrete circumstances, these people do not know how to behave. They were initially virtuous, pleasurable people, but due to the brain defect, they changed into rude

people who act without consideration for others and cannot make concrete moral judgments. Their risk behavior is also affected. Damasio and his colleagues have developed the so-called Iowa-gambling task: an experiment in which people gamble in a lab setting. Where people without amygdala defects fall within a normal range of risk seekingness and risk aversion, amygdala patients have no risk inhibitions. They are willing to take major risks that normal people find unacceptable. Apparently, our emotions prevent us from taking outrageous risks, and they are necessary for making concrete moral judgments.

Other emotion scholars emphasize that emotions are not contrary to cognition but involve cognitive aspects (philosophers: e.g., de Sousa 1987; Greenspan 1988; Solomon 1993; Blum 1994; Little 1995, Stocker and Hegemann 1996, Goldie 2000; Ben Ze'ev 2000, psychologists: e.g., Scherer 1984; Frijda 1987; Lazarus 1991; Damasio 1994). Some scholars think that cognitions precede feelings which together constitute emotions (Reid 1969[1788]). Others propose the opposite model: Emotions are constituted by feelings that give rise to cognitions (Zajonc 1980; Haidt 2001). There are also scholars who argue that emotions are constituted by affective and cognitive aspects that cannot be pulled apart; they are two sides of the same coin (Zagzebski 2003; Roberts 2003; Roeser 2011a). Take the emotion of guilt. Experiencing this emotion involves feeling the “pangs of guilt.” Without the “pangs,” it is not genuine guilt. But it also means holding the belief that one did something wrong. The feeling aspect and the cognitive aspect of emotions go hand in hand. Emotions make us aware of moral saliences that would otherwise escape our attention (Little 1995; Blum 1994).

These insights can also shed new light on the research by Joshua Greene mentioned in the previous section. The fact that deontological judgments involve emotions does not undermine their status. Rather, this points to the limitations of utilitarianism and cost-benefit analysis, which is the predominant approach in conventional risk analysis. Making decisions based on utilitarian reasoning might sometimes be inevitable, but there are situations in which respect for persons should be the guiding line, for example in order to avoid deliberately sacrificing people to provide for a benefit for others (Roeser 2010a).

Based on this alternative understanding of emotions, we can say that moral emotions are needed in order to grasp moral aspects of risk, such as justice, fairness, and autonomy – aspects that cannot be captured by purely quantitative approaches such as cost-benefit analysis (Roeser 2006). Hence, rather than constituting a *puzzle* (see section [The Affect Heuristic](#)), emotions are the *explanation* why laypeople have a broader, ethically more adequate understanding of risk than experts: Because their risk perceptions involve emotions, they are more sensitive to the moral aspects of risk than the experts who mainly rely on quantitative methods (cf. Kahan 2008; Roeser 2010b).

## Emotional Reflection and Correction

The claim that emotions are necessary for moral judgments about risk does not entail that they are infallible. As with all sources of knowledge, emotions can misguide us. But whereas we can use glasses or contact lenses to correct our imperfect vision, there are not such obvious tools to correct our emotions. However, emotions can themselves have critical potential (Lacewing 2005). Sympathy, empathy, and compassion allow us to take on other points of view and critically reflect on our initial emotional responses. We can even train our reflective emotional capacities through works of fiction (Nussbaum 2001).

These ideas show how to correct misguided *moral* emotions. However, there are also emotions that are misguided about *factual* information, which may be especially poignant in the case of risk-emotions, because the information is complex and inherently uncertain.

In addition, there are ambiguous risk-emotions: emotions that can point out important moral considerations, but that can also be notoriously misleading. Prime candidates are fear and disgust. The question arises how we can distinguish between those forms of, for example, fear and disgust that point out moral saliences versus those that are based on stereotypes and phobias, and how to distinguish between them in political debates about risks.

The most visible and controversial emotion that is triggered by technological risks is fear (or worry or dread; cf. Slovic 2000). Ethical objections to new technologies such as cloning, human–animal hybrids, cyborgs, or brain implants are often linked to reactions of disgust. Where the alternative framework of emotions presented in this chapter can rather easily establish why moral emotions such as sympathy, empathy, and indignation should play an important role in political debates about the moral acceptability of risk, fear and disgust are more complicated. Fear and disgust are less clearly focused on moral aspects of risk, they can also be responses to perceived threats that might be based on wrong factual information. Fear and disgust might just reflect our unfounded prejudices and phobias, such as the fear of flying. Even in the light of contrary moral or factual evidence, we might still feel fear or disgust (cf. Sunstein 2005 for the irrationality of fear; cf. Haidt and Graham 2007 for the irrationality of disgust).

On the other hand, there are situations in which fear and disgust enable us to be aware of morally salient features. Interestingly, nanotechnology gives rise to greater worries within the scientific community than among the public (Scheufele et al. 2007). Given the newness of nanotechnology, we can assume that scientists are more knowledgeable than the public about nanotechnology and its concomitant risks. Apparently, their fears can be attributed to a rational understanding of the risks involved in nanotechnology. Fear can point to a source of danger to our well-being (Green 1992; Roberts 2003; Roeser 2009). In a similar way, disgust and the “uncanny” feelings we have concerning, for example, clones, cyborgs, human–animal hybrids and people with brain implants can point to our unclear moral responsibilities to them and the worry that they might develop in an unforeseen way. These are ethical concerns that need to be addressed in developing and dealing with such new technologies, and disgust can enable us to detect morally salient issues (cf. Miller 1997; Kahan 2000 on the rationality of disgust). Fear and disgust can be warning signs, making us aware of the moral values involved in new technologies. In so far as fear and disgust can sustain reflection (which can itself be an emotional process, cf. Lacewing 2005 and Roeser 2010c), they should inform our judgments.

Misguided risk emotions that are geared toward factual aspects of risk should be corrected by factual data. This is complicated by the fact that some risk-emotions function like stereotypes or phobias and can even be immune to factual information. Take the fear of flying; this emotion does not easily disappear in the light of evidence about the safety of plane travel. Factual information has to be presented in an emotionally accessible way in order to be able to correct misguided risk-emotions that are directed at factual aspects of risk (see [Chap. 27, Emotion, Warnings, and the Ethics of Risk Communication](#), by Buck and Ferrer in this handbook). One strategy might be to point out the benefits of a technology in cases where people focus on small risks.

However, it should be noted that not all biases in risk theory that are currently attributed to emotions are really based on emotions (Roeser 2010c). This might again be due to the

presupposition of DPT that irrational perceptions must be due to system 1, hence, emotion, but as argued before, this is an unwarranted claim (cf. Roeser 2009).

## Risk Emotions in Practice

---

This section discusses what the alternative approach to risk emotions means for the most important agents in risk society. Accordingly, it will discuss several areas of technology to illustrate how the alternative approach to risk emotions can shed new light on understanding the responses to these areas of technology. It will end with an alternative model for emotions in risk politics.

### Emotions of Agents in Risk Society

---

Research on risk emotions can focus on three main groups, i.e., the public, the experts, and policy makers. Each group has its own concerns, emotions, and moral considerations, but is also prone to potential biases, which can affect debates about risky technologies.

### Risk Emotions of the Public

Research on risk emotions mainly focuses on the public. In debates about risky technologies, public emotions are often the most visible and contrasted with the supposedly rational stance of experts. However, it is not clear that experts are free of emotions, nor is it clear that this is a bad thing, an idea that will be explored in the following section. In addition, as elaborated above, the fact that the public is emotional about risks might be the reason that they are capable of taking on a broader perspective on risk than the technocratic stance of experts and policy makers.

### Risk Emotions of Experts

It might be thought that experts take a purely rational, detached stance to risky technologies. However, scientists can be deeply emotionally involved with the research and technologies they develop (cf. McAllister 2005). As previously stated, experts are more worried about nanotechnology than the public (Scheufele et al. 2007). Experts are more knowledgeable about the scientific facts than laypeople, but that can also lead to increased moral concern and worry. Arguably, experts should take these worries and concerns seriously, which should lead to additional precautions (Roeser 2011c).

The emotions of experts can also be potential biases, for example, due to enthusiasm about their technologies or due to self-interested concerns, such as pressure on securing funding, positions, and prestige. Experts can control for these potential biases by also considering themselves as part of the public and trying to empathize with the point of view of potential victims of their technologies (cf. Van der Burg and Van Gorp 2005 who make this point based on an argument from virtue-ethics, which is extended to emotions in Roeser 2011c).

## The Role of Risk Policy Makers

Risk policy makers should ideally mediate between the insights of experts and the concerns of the public. However, in practice, there can be potential conflicts of interest that might be reinforced by emotions. For example, experts from industry lobby and often have close ties with the government when it comes to large infrastructural high-tech projects. Careers of policy makers can be at stake, which can lead to potential self-interested emotional biases. On the other hand, these same emotions can force politicians to follow the predominant views of the electorate. A virtuous policy maker should be someone who can balance the various considerations and emotions and take a wider perspective, based on feelings of responsibility and care for all members of society, in which risks and benefits of a technology and concomitant moral concerns are carefully balanced (cf. Nihlén Fahlquist 2009).

## Emotions and Risky Technologies

---

This section discusses two salient cases that show the practical applications of the theoretical framework sketched in the previous section, namely, nuclear energy and climate change.

### Emotions and Nuclear Energy

Due to the disaster at Fukushima, the debate about nuclear energy has taken an unexpected turn. In the last few years, there was a growing consensus that nuclear energy would be an important part of the solution to generate energy with decreased CO<sub>2</sub>-emissions. The probability of an accident was said to be negligible. However, now that an accident has occurred, nuclear energy has become controversial again and people argue that we should abandon it (cf. e.g., Macilwain 2011). Germany immediately shut down several nuclear reactors, and the German Green Party achieved unprecedented results in local elections due to its antinuclear position.

Despite this shift in focus, there seems to be one constant factor in the debate about nuclear energy: proponents call opponents badly informed, emotional, and irrational, using these notions more or less as synonyms. However, such rhetoric is denigrating and hinders a real debate about nuclear energy. In addition, it is simply wrong to equate emotions with irrationality, as they can be a source of practical rationality. A fruitful debate about nuclear energy should do justice to quantitative, empirical information as much as emotional, moral considerations. It should allow the public a genuine voice in which their emotions and concerns are appreciated, listened to, and discussed. By discussing the concerns underlying emotions, justified concerns can be distinguished from – morally or empirically – unjustified concerns (cf. Roeser 2011b).

### Emotions and Climate Change

Climate change is an urgent problem that will presumably affect the environment for generations to come, and it will also have effects on the health and way of life of present and future generations. Nevertheless, people seem to be unwilling to adapt their behavior. Several researchers who study the perceptions that people have of climate change have stated that

people lack a sense of urgency (Meijnders et al. 2001; Leiserowitz 2005, 2006; Lorenzoni et al. 2007; Lorenzoni and Pidgeon 2006).

Emotions are generally excluded from communication and political decision making about climate change, or they are used instrumentally to create support for a position. However, based on the account of emotions presented above, emotions can be seen as a necessary source of reflection and insight concerning the moral impact of climate change. In addition, emotional engagement also leads to a higher degree of motivation than a detached, rational stance on climate change (cf. Weber 2006). Hence, emotions might be the missing link in communication about climate change, in a twofold way: They lead us to more awareness of the problems and motivate people to do something about climate change (Roeser *under review*).

## Emotions and Risk Politics

---

Currently, many debates about risky technologies result in either of two pitfalls, namely what can be called the technocratic pitfall and the populist pitfall. In the technocratic pitfall, the debate is dominated by statistical, quantitative information, leaving no room for emotions and moral concerns. In the populist pitfall, the emotions and concerns of the public are taken for granted and seen as inevitable. If there is no public support, a risky technology cannot be implemented. Both pitfalls are due to the assumption that reason and emotion are distinct faculties. The technocratic pitfall favors “system 2,” reason and science. The populist pitfall favors “system 1,” emotion and gut reactions.

Sometimes both pitfalls occur in the same debate, for example, in the case of the debate about carbon capture and storage (CCS) in the Netherlands. Initially, CCS was to take place in Barendrecht. Experts told the concerned public that there were no risks involved. The concerns of the public were dismissed as being emotional and irrational. This can be seen as an instance of the technocratic pitfall. However, resistance was so strong that the initial plans were abandoned and rescheduled to the much less densely populated province of Groningen. However, the people there also rejected these plans from the start; why should they accept something that other people did not want in their backyard? Before there was even a genuine debate, politicians gave up this plan because there was apparently no “social support.” This can be seen as an instance of the populist pitfall: The will of the public is taken to be definite, with no attempt for a genuine dialogue on pros and cons.

However, the approach argued for in the previous sections offers an alternative to these pitfalls, based on a rejection of the dichotomy between reason and emotion. Emotions can be a source of moral reflection and deliberation. This allows us to avoid the technocratic and the populist pitfalls. Instead, we should endorse an “emotional deliberation approach” to risk. Emotions should play an explicit role in debates about risky technologies in the process of people discussing their underlying concerns. This approach may reveal genuine ethical concerns that should be taken seriously; it might also show biases and irrational emotions that can be addressed by information that is presented in an emotionally accessible way. This will enable a genuine dialogue. It will lead to morally better decisions, but as a side effect, it will also contribute to a better understanding between experts and laypeople. It is reasonable to assume that there will be a greater willingness to give and take if both parties feel that they are taken seriously. This procedure might seem more costly. However, it is likely to be more effective, and hence more fruitful in the long run. Currently, many debates about risky technologies result in

an even wider gap between proponents and opponents and in rejections of technologies that could be useful if introduced in a morally sound way. Genuinely including emotional concerns in debates about risky technologies can help overcome such predictable stalemates.

## Further Research

---

This section highlights a few possible topics for future research. The topics discussed in the previous sections are related to risky technologies. But the approach presented in this chapter might also shed new light on other debated risk issues in contemporary society, i.e., financial risks and the risks of terrorism (security risks).

### Financial Risks

---

The financial crisis that hit the world in 2008 has generally been attributed to the irresponsible conduct of the financial sector that was interested in short-term, self-interested gains only and a general disregard to long-term negative consequences for society. Based on the framework presented in this chapter, we can understand this as an example of how ethical considerations were sacrificed for supposedly objective, rational number crunching. Interestingly, the ideal of rationality in economics is self-interest. But from a philosophical point of view, the limited form of self-interest often celebrated in economics is frequently used as a justification to perform unethical actions (Powell 2010). In addition, selfishness can be a state fed by emotions. Such egoistic emotions should be corrected by moral emotions such as compassion and feelings of responsibility (cf. Frank 1988).

### Risk from Terrorism

---

Risks from terrorism (security risks) are often exaggerated and get disproportional attention as compared to other risks (cf. Sunstein 2005; De Graaf 2011). This phenomenon is usually blamed on emotions such as fear (Sunstein 2005). In response to terrorist risks, we can also observe the two pitfalls described earlier: either it is argued that we should ignore the fear of large parts of the population and respond to it with supposedly objective, factual, rational information (technocratic pitfall), or the societal unrest feeds into populist movements (populist pitfall). The approach presented in this chapter might open the way for an alternative approach, in which the emotions of the public are addressed in public debates but are open for revision. Such revisions could take place through factual information as much as through exercises in compassion with potential victims of measures that are supposed to limit the risks of terrorism but come at the price of xenophobia and disproportional measures that are insensitive to individual cases. Works of fiction might prove to be helpful for such exercises in compassion.

## Conclusion

---

This chapter has explored the role emotions do and can play in debates about risky technologies. Most authors who write on risk emotions see them as a threat to rational decision

making about risks. However, based on recent developments in emotion research, an alternative picture of risk emotions is possible. Risk emotions might be a necessary source of insights into morally salient aspects of risk. This view allows for fruitful insights on how to improve public debates about risk, and to overcome the gap between experts and laypeople that currently so often leads to a deadlock in discussions about risky technologies.

**Abstract:** In this chapter, we explain the nature of virtue ethics, differentiating it from competing moral theories – consequentialism or deontology – and arguing that it is superior to both when it comes to the moral assessment of risk. We explore in detail what a virtue ethics approach to the moral evaluation of risk taking would involve, focusing particularly upon the role played by character in such assessments. Our main argument is that individual instances of risk taking are not isolated events, but part of a pattern of behavior on the part of the risk taker. We argue, furthermore, that this pattern does not arise as a result of arbitrary, automatic processes over which individual agents have no control. Rather, risk-related behavior patterns are the product of a complex set of settled dispositions that constitute character. We argue that character dispositions are developed over time through education, which involves habituation, active reflection, and reflective self-modification. They bring together the influences of desire, emotion, and thought to provide explanations of actions and decisions, which are multi-dimensional and profoundly sensitive to the particularity of individual risk-involving actions and choices. Risk taking is both a necessary part of human life and a source of moral vulnerability – it is very difficult to make good choices about risk and there are a lot of different ways in which our risky choices could prove to be morally inadequate. It is our contention that only virtue ethics with its emphasis on character – character development, and character vulnerability – provides us with a sufficiently rich vocabulary to (a) furnish satisfying explanations of the sensible moral judgments we make about risks and risk takers all the time and (b) facilitate effective rational reflection about commonsense moral evaluations of risk taking. We illustrate the value of the virtue ethics approach using a hypothetical time-travel experiment in which an agent must choose whether to take some very serious risks and/or whether to expose others to risk.

## Introduction

---

Imagine the following scenario. You are a researcher at the Uber-Tech Institute. A friend and colleague of yours, Bob, whose knowledge and skill you respect enormously, takes you aside and reveals that he has secretly been designing and building a time machine. The machine is now ready to be tested, but the process requires three participants – one to stay at the controls, another to enter the machine and travel in time, and a third to be a back-up time traveler, in case the first one needs to be rescued. Bob would like you to help him test the machine. He has already recruited his super-bright 13-year-old sister and he offers to let you choose which of the three roles you would like to play in the test. Before you decide, however, he does warn you that time travel has never happened before so there is no way of knowing what effects it will have on the traveler's physical and mental health. In addition, the testing process would entail making small changes to the past/future, which have a small probability of adversely affecting the present for some unknown third parties in unpredictable ways. What would you decide to do?<sup>1</sup>

There are a number of decisions you would need to make in the above scenario: a decision about how much and whether the kinds of risk involved are of the sort and scale to which it is acceptable to subject yourself, a decision about whether and when it is right to condone and abet other people taking very serious risks with their own physical and mental well-being, and a decision about how much risk and what sorts of risk is acceptable to subject unknowing third parties to, etc. These are all complex and difficult decisions and it would be convenient if there was a formula for making good and right decisions about whether, when, and what to risk. It

will be the contention of this chapter that there is no such formula to be had. We will argue that the reason for this is that the sorts of decisions considered above are intrinsically moral decisions and that, while some moral theories do purport to offer formulae or rules for decision making about risk, to attempt to do so is misguided. In place of rules and guidelines, we recommend a virtue ethics approach to moral decision making. Virtue ethics focuses attention away from rules and upon the features of decision making itself, supposing that good decisions are made when the broad range of mental faculties involved function well and harmoniously. Such decisions will take into account and give appropriate weight to the context of choice, the role of the reasoner, historical and other constraints (e.g., rights) as well as potential consequences. However none of these criteria will alone act as a hallmark or determiner of morally good choices or have decision-independent priority over the others.

Virtue ethics draws upon the sort of approach to moral matters that was taken by the ancient Greeks and particularly upon the ethical works of Aristotle. This chapter begins with an introductory section, which presents some basic ideas in Aristotelian virtue ethics for readers who would benefit from some background to the theory. Readers who are familiar with virtue ethics may wish to skip to the section entitled: [❷ The Case for a Virtue Ethics Approach to the Moral Evaluation of Risk](#) which outlines the case for a virtue ethical approach to risk decision making. The section [❸ Character: The Basics](#) introduces the notion of moral character, which plays a central role in virtue ethics and accounts for the unique perspective to risk-taking decisions, which is afforded by a character-based theory. In the section [❹ Habit, Education, and Moral Development](#), we consider the long and gradual process of character development, while the section [❺ Decision Making](#) considers what is involved in making virtuous moral judgments. Links to how this distinctive virtue ethical perspective affects how we should reason about risk are made throughout the chapter, but the section [❻ To Time Travel or Not to Time travel?](#), in particular, returns to considering the time-traveling example introduced above in light of the claims we have made on behalf of a virtue ethical approach to making decisions about risk.

## What Is Virtue Ethics?

The modern revival of interest in virtue ethics began with the work of philosophers such as Elizabeth Anscombe, Bernard Williams, and Alasdair McIntyre. These authors raised a number of different ideas, many of them critical of the other two main alternative moral theories, deontology, and consequentialism, but if there is one thought which above all others captures the spirit of the discussion, it is this: modern virtue ethicists have redefined the kind of question we should ask about ethics. Ethical questions deal with practical matters and as such there is often a focus on specific problems. What should I do when faced with X? If I have to choose between Y and Z, which one should it be? What is the right thing for me to do *now*? Deontology and consequentialism give alternative, and in many ways incompatible, answers to these kinds of questions about practical issues. The advice of consequentialism is that decision making should be goal oriented and can be captured in one overriding rule, for example, do whatever maximizes the greatest consequences for the greatest number. The advice of deontology is that you may take any course of action, which is compatible with strict observance of the rights of others<sup>2</sup>. Both take it that the key question in ethics is “how ought I to act now?” Virtue ethics, on the other hand, holds that the rightness or wrongness of individual actions and choices,

whilst not insignificant, is not the key moral issue. Rather our attention ought to be focused upon questions concerning the sort of beings/persons we are (and will be) should we choose and behave in one way rather than another.

Virtue ethics, then, redefines the kind of question we should be asking in ethics. Instead of asking what is the right thing to do here, virtue ethics suggests we should be concerned with what kind of person we should become, and what kinds of lives we should live. Asking how one should live one's life gives ethical enquiry a different perspective. The object of the enquiry is now an entire life, a long project of self-reflection and self-development, which is both approached as a long-term commitment and judged as such. Good moral judgment is a product of this long process of reflection and development and getting a particular ethical call right on a particular occasion has as much to do with having a well-organized, appropriately responsive, and correctly structured/balanced character as it does with actual rights or consequences.

These ideas have their roots in Aristotle, so Aristotle's ethics is a good starting point for us as well. Aristotle begins his deliberations on ethics by reflecting upon the nature of his subject matter. He notes that ethics is a complex and varied subject, so when we ask questions about ethics we should expect our answers to be complex and varied too. It is no good attempting to capture a diverse and challenging subject in a simple and all-encompassing rule. A "one rule fits all" might sound like a good idea if we wish to dispense with ethical problems with the minimum amount of hassle and reflection, but such an approach is bound to fail as it cannot, by its very nature, capture the diversity of the subject at hand. So, we should expect to find complex, varied, and diverse answers to ethical questions and, clearly, such challenging answers are not going to be easy to come by (NE1098a). Virtue ethics then offers a radically different approach, both in the kind of question it asks, that is, how should I live my life, and in the kind of answer it expects to find, that is, a complex, varied, and imprecise answer that cannot be captured in an overriding rule.

Aristotle starts by noting that every action and pursuit aim at some good and that while some things are done for the sake of others, there must be something which is desired for its own sake, an ultimate goal for the sake of which everything else is done; that goal is *eudaimonia* (NE1094a). *Eudaimonia* is a challenging term to translate. "Happiness" is a popular translation, but it tends to suggest an ephemeral, transient feeling, which is easily affected by external factors and which has a specific target, for example, "I am happy today because I won at the riding competition" – this feeling is both generated by my win and dependent on it, as well as being likely to dissipate in time. "Contentment" is a slightly better translation in that it captures a sense of permanent and stable satisfaction with one's overall life, although it has connotations of passivity and resignation and there is nothing meek or weak about *eudaimonia*. Perhaps, "fulfilment" or "flourishing" is the best term, but it has to be understood within the Aristotelian context, which we explain in what follows.

*Eudaimonia* is not pleasure, for it is determined by the value of the activity which gives rise to it and we are looking for something, which is valuable in itself. Nor can it be honor, for that depends on those who confer it and we are looking for something which is truly characteristic of the person and not an external attribute easily given and taken away. Nor can it be wealth, for that is merely a means to other things and not an end in itself (NE1095a17-1096a15). Perhaps to discover what *eudaimonia* is, we need to consider our function or purpose. Aristotle observes that where a thing has a function, the good of that thing, that is, when we say that that thing is doing well, is to perform that function well. This idea is best understood by example. The knife has a function, which is to cut. The good of the knife, that is, when we say

that the knife is doing well, is to perform that function well, that is, to cut well. So, a good knife is a knife that cuts well (NE1096a25–33).

The same sort of argument, Aristotle suggests, can be applied to human beings. That is to say that in order to answer the question of how we should live our lives, we need to consider what kind of being human beings are and to discover what human life is for or what kinds of lives are characteristic of beings such as ourselves. Human beings, he thinks, have a function, so when we say that human beings are doing well it's because they are performing their function well. All we need to do now is to discover the function of human beings. To discover the function of human beings, we need to consider what is distinctive of human beings, what sets human beings apart from other beings, and is peculiar to us *qua* human beings. The answer is the ability to reason. The function of human beings is reason and the life which is distinctive of humans is the life in accordance with reason. If the function of human beings is reason, then the good human being is the human being who functions well, that is, reasons well, and reasoning well is the life of excellence for human beings (NE1097b21–1098a15, for a modern interpretation of these kinds of arguments from Aristotle, see Hursthouse 1999). Reason, according to Aristotle, takes particular forms depending upon what is being reasoned about; one of these forms is practical reasoning which occupies itself with questions of value and seeks to bring actions in accordance with values. Practical rationality is a key element of the complex psychology of action. So, part of what it takes to flourish is to exercise good practical rationality; the person who achieves this is called practically wise (*phronimos*). Aristotle famously describes two kinds of *eudaimon* life: the life of contemplation and the life of the *phronimos*. The former does not lack practical wisdom, but simply seldom encounters situations where it is necessary to deploy it; the latter is fully engaged in social and political life so that the exercise of practical wisdom is a major (perhaps primary) manifestation of its subject's capacity for reason (NE1102a). A person who is practically wise will also be virtuous. This follows because a practically wise person makes the best possible (all things considered) decisions about how to act and, in most cases, has the confidence and self-possession to enact them. *Eudaimonia*, then, consists in activity in accordance with reason, and leads to fulfilment and contentment with one's life and the highest activity in accordance with reason is virtue – moral goodness, moral excellence.

## **The Case for a Virtue Ethics Approach to the Moral Evaluation of Risk**

---

Actions involving risk have a particular nature, one that makes moral judgments about these actions particularly problematic. Actions involving risk are hostages to fortune, in that, by definition, the results of one's actions are not (at least not entirely in some cases) under one's control. Risky outcomes may or may not actualize, but whether they do so or not, is (at least partly) outside the control of the agent who instigated the risky actions<sup>3</sup>. This very nature of risky actions poses problems for moral responsibility. We hold people morally responsible and subject them to moral praise or blame because we fundamentally assume that they had control over their actions. This thought captures what is distinctive about judgments of moral responsibility and ties in with our understanding of agency. Agents are free beings who demonstrate their agency, that is, their wills, their choices, their reasoning, etc., in their actions, which is exactly why we hold them responsible for these actions. Where agency and control come apart, for example, in cases of people who are severely mentally ill or people who are not

yet fully formed moral agents, that is, children, we accept that there is limited scope for attributions of moral responsibility. This creates a problem for moral judgments of risky actions, for how are we to hold agents responsible for risky outcomes, which materialized due to the vagaries of luck rather than the effects of agency?

The nature of the problem is made clear by consideration of how inadequate some consequentialist theories are for assessing risk. Consequentialist theories evaluate the morality of actions based on the value of their consequences so that a morally good action is one that, for example, produces the greatest utility for the greatest number of people. However, it is exactly this focus on consequences that produces distorted results when applied to actions involving risk. Situations involving risk involve, of necessity, uncertainty; therefore the outcomes of one's actions will be uncertain. One possible response to this problem is to evaluate an action based on the actual consequences, those consequences that come about once the risk has actualized. However, this is clearly counter-intuitive in terms of moral responsibility. Consider the vice of recklessness, that is, the indifferent disregard for the consequences of one's actions, which becomes a lot more problematic when one's actions affect others. A reckless action is reckless because of the character trait it displays, rather than because of the actual outcomes it produces. Suppose an agent chooses to neglect his/her car's routine maintenance out of sheer boredom, then gets drunk out of sheer self-indulgence knowing he/she is likely to drive him/herself home and then speeds on his/her way home out of sheer extravagant enjoyment of fast driving. This fast, drunk driving in an unsafe car, is reckless because of its irresponsible disregard for the safety of other road users, the well-being of whom could have been better safeguarded had the driver in question been concerned enough to take some modest actions in that respect, for example, service his/her car, remain sober, and respect the speed limit. The moral judgment concerning the reprehensibility of the drunken driving concerns the character trait of recklessness that led the agent to behave in this way rather than the actual consequences of his/her action. For despite all his/her recklessness and the clear endangering of other people's welfare, our drunken driver could end up being lucky, that is, despite the high likelihood of him/her injuring someone, he/she could actually avoid this outcome. However, avoiding the consequences of one's recklessness does not make one any less responsible for it. That the driver was lucky and that the small chance of him/her getting home safely actualised does not make his/her risk taking any more acceptable.

One may respond here that we should not be concerned with actual consequences, but rather with expected consequences. For whatever the actual consequences of such reckless driving may be, the expected consequences of driving so recklessly are that someone is likely to be hurt and it is this aspect of the agent's action that we should hold him/her responsible for. However, estimating expected consequences in situations of risk can be problematic and even impossible in some cases (Hansson 1993). Furthermore, even if we were to set such problems of calculating expected outcomes aside, the impersonal calculation of consequences leaves no room for partial considerations, especially those that allocate greater weight to significant sacrifices by particular individuals (Hansson 2003), or those that differentiate between the bearers of different risks and benefits (Athanasoulis and Ross 2010). The first concern is that strict calculations of expected consequences do not do justice to the relative burdens born by different individuals. Consider the following example: suppose that as a result of an industrial accident at a nuclear power plant, there is a leakage of radioactive gasses. The leakage is relatively simple to stop in that it requires no particular expertise, anyone can enter the room to carry out the necessary operations; however, the concentration of radioactive gasses

in the room in question is so high that in stopping the leak, the person carrying out the repair will be exposed to high levels of radioactivity that have a 90% chance of killing him/her. Alternatively, the gases could be allowed to escape the building, rendering the room safe for the repair, but at the risk of exposing 1,000 people in the immediate vicinity to a risk of 0.001 of being killed by radioactive poisoning. Pure calculation of numbers suggests that the unfortunate security guard who happens to be in the vicinity of the leak should step into the room to carry out the repairs. However, this outcome, although it makes sense numerically, clashes with our sense of fairness with respect to the equitable distributions of the burdens of risk taking. Concentrating all the negative effects of the risk on one unfortunate individual seems a lot less fair than distributing a much smaller burden over larger numbers of people and some disadvantages for some people cannot be justified by the cumulative advantages conferred to a large number of other people.<sup>4</sup>

The second concern with consequentialist approaches to the moral evaluation of actions involving risk is a worry that the strict calculation of consequences does not allow room for differentiating between the bearers of risks and benefits. In some cases of risky action, the person or persons who run the risk of being harmed by the action may be different from the person or persons who run the risk of benefiting from the outcome and this feature makes these situations particularly problematic. Quite high risk of harm and even the risk of death may both be acceptable if one and the same individual stands to gain from the act. For example, a terminally ill patient may choose to take part in a Phase III trial of a promising, but untested, drug that also runs the risk of ending the patient's life prematurely. The background of the terminal illness for which all therapeutic options have been exhausted, coupled with the fact that the patient willingly risks only his/her *own* well being, make this a justifiable decision. However, the same cannot be said for actions which risk the welfare of others to benefit an individual. For example, an oil company may take significant risks by drilling in deep water with machinery which has been tested but not in the extreme conditions of the deep oceans. If the oil should spill during drilling, the impact upon the ocean and the inhabitants of nearby territories could be devastating (including possible death, illness, loss of livelihood, etc.). The oil company takes this risk in order to keep profit margins high and, if successful, stands to benefit by dominating the oil industry. Say that the risk of leakage is small and as it turns out, nothing bad happens. According to consequentialists, the small risk of leakage must be adjudged a case of acceptable risk taking. However, this does not seem to be quite right, the oil company is still unfairly putting people's lives and livelihoods at risk. Consequentialist approaches are not sensitive to these distinctions and leave much to be desired as they evaluate risk taking without accounting for the integrity of the persons making the decisions.

This sense of dissatisfaction with consequentialist approaches to risk is, however, useful because it points toward a different alternative. When we discussed recklessness above, we captured what was morally problematic about being indifferent to the risks to which one exposes people by referring to the *character trait* of recklessness. This notion of *character* gives us a different approach to the moral assessment of risk. Discussions of risk, strongly influenced by consequentialism, tend to focus on one-off, exceptional circumstances, dramatic choices that few individuals are ever unlucky enough to have to make. A character-based theory of risk would shift the focus from such high profile, but rare and therefore unrealistic, choices, to everyday concerns. If the focus is on one's character, then we have to examine the patterns in choices that people make, those choices that are reaffirmed over time, and those choices that express their deeply held values and beliefs which are hardly a matter for one-off exceptional

circumstances. The discussion of risk shifts from the exceptional to what is characteristic of individuals and this makes more sense of our common reactions to risk. The reckless person is not likely to be reckless in a one-off, extraordinary situation, but rather to exhibit this character trait of recklessness over time, consistently in different kinds of cases and with reliability. This is because recklessness is an attitude to risk, which is underpinned by a judgment about the relative unimportance of other people's well being. It is essentially characterized by a disregard for the welfare of others, an entrenched attitude that is displayed over time and in a variety of situations. A character-based theory of risk then would be more concerned with judgments of agents over time and over a variety of different situations, all of which illustrate the person's character, than with one-off, albeit spectacular, but extraordinary occurrences. A character-based theory of risk will be less about dramatic choices and more about the people involved in these decisions and how all their choices, over a variety of decisions, determine and illustrate who they are.

## Character: The Basics

---

The notion of "character" in virtue ethics refers to a specific and technical term. The word "character" comes from the Ancient Greek for carving, indicating a permanent and indestructible way of preserving something and this gives us a good indication of the use of the word nowadays. One's character is the set of stable, permanent, and well-entrenched dispositions to act in particular ways (Athanassoulis 2005, pp. 27–34). In the same way that a carving is a permanent and reliable mark, one's character is the collection of permanent and reliable dispositions, which characterize who one is. One's character leads one to act in a particular way, but these actions are also an expression of who one is, and one's behavior is explained by one's character. At the same time, when we speak of someone with no character, we tend to mean that that person has no strength of will, yields to the wishes of others easily, is overcome by temptation, and cannot be depended upon to act in a particular way consistently. So, the notion of character is essentially captured in the ideas of stability, reliability, predictability, and permanence (Kupperman 1991 esp. Part I).

Character dispositions are long-term features of agents, but they are not the *only* long-term features of agents, so it is important to provide a more substantial account of character, which can distinguish character from these other sorts of characteristics of agents. We cannot hope to offer a detailed comparison of character, identity, and personality here, but such an account can be found in Kupperman (1991, pp. 3–46). For our purposes, a preliminary narrowing of the definition of character can be made by specifying that it has to do with the ways we think and act, and that moral character concerns the way we think and act in moral situations. Moral character will be the focus of our discussion. Aristotle thinks of states of character (such as virtue or vice) as complex rather than simple states of mind. Virtue, for example, involves more than being in possession of a true or logically consistent belief about how one ought to act or being sentimentally generous to others. Indeed, what is required by Aristotle is a state in which the faculties of perception, motivation, thought, and reason seamlessly interact to bring about cogent appropriate action in individual cases and establish the long-term possession of a stable disposition to respond well to whatever situation is encountered. Consider his definition of virtue in the *Nicomachean Ethics*:

- ▶ Virtue, then, is a state of character concerned with choice, lying in a mean, i.e. the mean relative to us, this being determined by a rational principle, and by that principle by which the man of practical wisdom would determine it (NE 1107a).

For present purposes, what we are interested in extracting from this definition is what it tells us about character in general. What we can deduce from this definition is that states of character are intimately linked to action through choice. To possess character is to manifest it in the form of choices about how to act. In addition, this definition makes clear that choices and actions which manifest character are the product of the interaction of reaction, reason, and motivation. The way in which these relationships function is not something that is evident from choice or actions themselves, and it is for this reason that virtue or states of character are frequently described as dispositions; as here in the *Nicomachean Ethics*:

- ▶ There are three kinds of disposition [that can be constitutive of character], then, two of them vices, involving excess and deficiency respectively, and one a virtue, viz. the mean, and all are in a sense opposed to all; for the extreme states are contrary both to the intermediate state and to each other, and the intermediate to the extremes (NE 1108b).

So states of character are complex dispositions. Like all other dispositions, they will have the following characteristics:

- They are latent rather than manifest. We can only know of their existence through experience of the manifestations with which they are associated.
- They rely for their manifestation, although not for their existence, upon the obtaining of certain environmental conditions.

One's character is a state of being encompassing one's settled and stable dispositions that will, under normal circumstances, manifest themselves in action. That is, being kind will be the settled and stable disposition to display kindness in situations which call for a kind response. There is a clear connection then between one's character and the actions one chooses to perform, and conversely one's actions will manifest one's character.

We wish to illustrate this by returning to our time travel example from the beginning. Bob's choice of his young sister as one of the experiment participants who might be exposed to unknown and possibly serious risks, tells us something about his character, which, in turn, allows us to assess this decision to take risky action irrespective of the outcomes of the experiment. Bob's sister is both relatively young and therefore less likely to be able to weigh up correctly the serious risks involved in participating in such an experiment, and related to Bob with family bonds that may affect the voluntariness of her decision to participate. These concerns may lead one to worry about Bob's attempt to recruit his sister to the experiment and lead one to wonder whether Bob's judgment is clouded by any of the following:

- His devotion to and enthusiasm for the project of time travel
- His anxious state of mind
- A particular habitual pattern of interaction between him and his sister
- Pressure from his sponsor to "get on with it"

Bob's apparently reckless behavior toward his sister is indicative of his character, it appears to expose a simple disposition to endanger others for his own gain. We need to be careful however about inferring simple dispositions from this one instance of decision making. This

particular occasion may be a one-off, a situation of great temptation and difficulty, which has challenged Bob's otherwise sensible behavior. However, it may also be part of a pattern of such reckless actions that manifest itself over time. The real nature of this recklessness in Bob's character, cannot really be known without observing and understanding the behavior resulting from Bob's character over time. Observing Bob over time will help us determine whether he is habitually reckless – a vice – or prone to recklessness when faced with difficult or tempting situations – a case of weakness of will. In either case, the assessment of Bob's attitude to risk is not a matter of observing his one-off responses, one would need to get to know Bob's character over time before any such judgment could be made (Athanasoulis 2000).

Given this account of character, then, we would expect a character-based theory of risk to offer us not only a different answer to whether a risk should be taken in any one particular case, but also, more importantly, a different way of approaching the question. The focus of assessment turns from tangible consequences, probabilities, or individual intentions to produce consequences, toward the agent as a whole, toward her quality as a decision maker and therefore toward the quality of the way in which she lives. To illustrate the value of the “whole agent” approach to moral evaluation, let us consider an example, which is slightly less complex than Bob's. Consider the comparison of two mothers and their responses to the prospect of a potentially risky vaccination that is available for their children. Mother One informs herself by reading up on the disease, its prevalence, its side effects, possible treatments, efficacy of the vaccine, adverse effects of the vaccine, etc. Her research suggests that whilst the risk of the vaccination is small and unlikely compared with the risk of the disease, there is nevertheless reason to fear an adverse reaction. She considers her overall commitment to make decisions on behalf of her child based on the child's best interests and despite her natural fear for her child's well being, she reasons that not to vaccinate is to leave him vulnerable to horrible diseases, and that vaccinating also means contributing to public health. She decides that the risks involved in vaccination are worth taking in order to protect him from such vulnerability not purely because of the possible outcomes, but also because of the specific perspective she ought to adopt as the child's primary care giver. That is, being responsible for the welfare of another human being and having to make important healthcare decisions on their behalf, imposes an extra burden of caution. Risks and outcomes are then evaluated through the filter of this perspective of “deciding on behalf of a vulnerable other for whom I have special care responsibilities,” a perspective that changes the weight one allocates to possible dangers and benefits. Now lets say she vaccinates and her child has the rare and unlikely adverse reaction. Compare Mother One with Mother Two who makes an uninformed decision not to vaccinate, based primarily on the inconvenience of getting the vaccine. Fortunately, her child happens to experience little exposure to the disease concerned and benefits from herd immunity and so no harm results. Which mother in this example acts well? The answer has to be Mother One, but how can we explain this judgment in light of the negative consequences? Well, the virtue theorist would say that despite the bad consequences, despite her intentional risk of those bad consequences, Mother One acts responsibly, beneficially, and with some courage. Mother Two, by contrast, fails to respond appropriately to both her child and to the normative demand for responsible care which society makes on her, by basing her decision on her personal convenience. She also behaves as a free-rider, benefiting from the herd immunity maintained because other parents vaccinate their children. She is careless and callous independently of whether anyone is harmed by her choice and independently of her explicit intentions (she does not intend that her child be harmed, she is just

negligent) and therefore she is also reckless. In this case, it is fair to infer caring and carelessness/recklessness from one example because the situation has been set up as one in which there is no external pressure to act in a particular way and because the decision is the sort of routine decision that is part of the daily responsibilities of parents. As a result, these decisions can be justly seen as characteristic of the way in which the women approach risk taking on behalf of their children. It is worth noting, however, that the inference to character dispositions is only possible when we understand the process of practical reasoning that the decision makers undertake, the way in which they perceive, consider, and respond to facts of the situation, their attitudes, their values, etc. We can see from this the multi-dimensional nature of character, and this explains the comparative richness of the virtue ethicist's moral judgments when compared to those of consequentialists or deontologists.

## Habit, Education, and Moral Development

---

It seems, then, that having the right character is crucial in making the right decisions about risk. This, in turn, raises questions about the acquisition, development, and application of one's character. How does one come to have the right character and how does having the right character help with all sorts of tendencies we have toward risk?

A good place to start then is with whether a good character is a natural characteristic or one that is developed over time. At the beginning of Book II of the *Nicomachean Ethics*, Aristotle says the following:

- ▶ Virtue, then, being of two kinds, *intellectual* and *moral*, intellectual virtue in the main owes both its birth and its growth to teaching (for which reason it requires experience and time), while moral virtue comes about as a result of *habit*, whence also its name *ethike* is one that is formed by a slight variation from the word *ethos* (habit). From this it is also plain that none of the moral virtues arises in us by nature for nothing that exists by nature can form a habit contrary to its nature. For instance the stone which by nature moves downward cannot be habituated to move upwards, not even if one tries to train it by throwing it up ten thousand times; nor can fire be habituated to move downwards, nor can anything else that by nature behaves in one way be trained to behave in another. Neither by nature, then, nor contrary to nature do the virtues arise in us; rather we are adapted by nature to receive them, and made perfect by habit (NE1103a).

We are not born with good or bad or any other kind of character and it is not inevitable that we will develop one. Indeed, we do not even need one in order to produce actions (not all actions are actions from character; Butler 1988, pp 218–227). This is not to say that that we are not naturally born with certain tendencies, for example, a tendency to irascibility or a tendency to mildness of temperament, etc. Rather the claim is that natural tendencies differ from stable dispositions. Whatever our assigned lot from nature, we can become self aware of our natural tendencies, we can expose them to critical reflection, we can affirm the positive ones that guide toward virtue, and reject the negative ones that pull toward vice, and we can instil new tendencies in ourselves, until, over time, the correct ones become stable dispositions. A natural tendency toward kindness may or may not be present in particular individuals, but everyone has the option of developing the disposition to kindness, which is essential for the virtue of kindness. The tendencies with which we are born are part of what enables us to acquire

character, but they do not constitute it. Character has to be actively developed out of the raw materials with which we are born (Athanasoulis 2005).

So, moral virtue is not something we have by nature, but we are naturally possessed of the potential to become virtuous. How does the realization of that potential come about? Aristotle's answer is "through good education." Moral education, according to Aristotle, consists, in the main, in the inculcation of good habits. Often the need for habituation is taken as implying that morality is governed by the non-rational elements of the mind because it is these that need to be trained, being inaccessible to reason. However, a better way to think of the sort of habituation involved in the acquisition of good character would be to compare the process with what happens when a young person acquires a skill – playing the piano or speaking her mother tongue. The young learner learns by being required to produce simple performances of music or language and by watching others perform. In this way, she is exposed to the elements of language or piano playing and to the rules according to which these elements are usually combined (explicitly taught or inferred) and her mind sets to work analyzing these and experimenting with them. Her experiments are met with critical or approving responses by those from whom she learns as well as those affected by what she says and does. She adjusts her grasp of concepts, rules, and practices as a result. As she develops, she begins to be self-critical and takes an active role in habituating herself.

As with the acquisition of language or a skill, the acquisition of good character involves the coordination and development of a wide range of intrinsic abilities or potentialities, including reasoning, perception, emotion, desire, etc. All are capable of influencing and being influenced by each other and it simply takes good training to lay out the right tracks or set up the right relationships/patterns of interaction between them. The result is a sophisticated deliberator who can take into account relevant aspects of context and respond both intellectually and emotionally in an appropriate manner when faced with novel opportunities for choice and action. As the piano player becomes a composer and the language learner a poet, so the young agent becomes a *phronimos* – a practically wise exemplar of living well. This process of character development then involves the critical evaluation of one's natural tendencies, and the habitual work required to train one's desires to conform to the choices of one's reason, so that, when one's character is mature, the right action is chosen, chosen for its own sake, and chosen willingly and effortlessly.

Developing a good character and becoming a person of virtue is itself then a process with many built-in uncertainties, as many crucial elements in this process are subject to luck. Good moral education is crucial, but it is also rare and dependent upon contingencies of opportunity and resources. The long and difficult process of character development is vulnerable to circumstances, to the availability of good exemplars, and good influences. Furthermore, the process is as likely to be influenced by negative factors as it is by positive ones. Exposed to the wrong influences, the wrong peer group, the wrong examples, one's character may well be shaped toward vice with the same readiness that it could have, under other circumstances, been shaped toward virtue. Nussbaum points out that Aristotelian goodness of character is profoundly social and partly constituted by a capacity to interact unguardedly and generously with others (Nussbaum 1986, pp. 343ff). As a result, goodness opens the person of good character to the possibility of loss and betrayal, the experience of which is likely to be profoundly destabilizing to character. Character can be undermined even when it is fully developed and robust (Nussbaum uses the example of Euripides "Hecuba" to illustrate this claim, Nussbaum 1986, p. 397), however, like a growing plant, it is most vulnerable when it is still finding its

form. Formative experience of breaches of trust, injustice, and the loss or denial of social goods such as friendship and collective activity can all prevent character from developing well. The result may be bad or vicious character, but it might equally be weakness, confusion, and a state best described as “lack of character” (see Kupperman 1991, p. 7 for what lack of character amounts to). The process of moral development, then, is like the growth of a tender, young shoot; it will grow into a healthy, strong tree, capable of withstanding violent storms, but only if it is tended, nurtured, and exposed to the right conditions which encourage this growth. Risk and the conditions of vulnerability it creates for the development of the good character are not only acknowledged and accepted by virtue ethics, but also embraced and welcomed by it as a deep insight into the connection between vulnerability and the activity of valuing, upon which moral practice is founded.

## Decision Making

---

Thus far, we have claimed that choices to take risks ought to be morally assessed according to what those choices reveal about the character of the chooser rather than by appeal to the extent to which she respects her own and others rights or the extent to which that choice is likely to produce good consequences. We have pointed out that character is a complex multi-dimensional phenomenon, which is not only educable but also vulnerable to forces beyond the control of the agent. We have emphasized the fact that virtuous activity is activity in accordance with reason. In this section of the chapter, we will demonstrate that the role played by reason in the production of character-driven choice and action is much broader than the regulation of objective claims about what is an effective means to what. Virtue ethics recognizes that reason has a role to play in subjective valuing and emotional response. The virtue ethicist denies that personal values and feelings cannot be rationally criticized. As a result, virtue ethical analysis has the potential to penetrate aspects of risk-involving choice, upon which orthodox approaches to evaluating risk (such as those which rely upon expected utilities or stakeholder-determined priorities)<sup>5</sup> cannot even comment.

However, making decisions about risk is far from simple and unproblematic. People have natural tendencies toward risky or conservative behavior, but also toward particular, subjective interpretations of what counts as risky or conservative behavior. At the same time, reasoning about risk can become clouded with common fallacies relating to probabilities, individual variability in assessing the magnitude of risks and setting acceptability thresholds. In all this, there seems to be a conflict between an “idealized” approach to risk, involving an objective judgment based on transparent calculations of fact, and a subjective, personal interpretation of risk, which is shaped by the views, desires, and prejudices of individual risk takers. However, as we shall see, there need not be a conflict between the objective requirements of the situation and the subjective view point of the risk taker, and these two, apparently conflicting perspectives, may turn out to be far more compatible than at first thought.

Consider that in economic<sup>6</sup>, political<sup>7</sup> and even some legal/ethical (Sunstein 2002, pp. 28–53) literature about risk, which follows a broadly consequentialist approach to good risk taking, the attitude of the risk taker plays a significant but mysterious role. For example, a community that is inherently risk averse might “undervalue” a new technology (say a time machine) introduced into its environment and consequently, behave in a way that economists consider “irrational.” Economists, because they assume an essentially consequentialist theory

about risk acceptability, want to know not how something ought to be valued, but how it actually is or will be valued. To achieve this, they draw on work done in psychology concerning heuristics and how these structure thought and action. Sunstein too makes reference to psychological heuristics in his defense of expert risk decision makers. He develops the Tversky–Kaneheman heuristics to demonstrate the irrationality of risk perception and consequently of risk responses among “lay people” and uses this to argue that risk decision making ought to be left in the hands of the experts (Sunstein 2007, pp. 157–168).

So, it is widely accepted that “attitude” is one of the variables that has to be taken into account in determining the value or disvalue of outcomes, which, in turn, is necessary for deciding whether a particular risk is worthwhile. It is also widely acknowledged that “attitude” is a variable, which is difficult to track or predict. Heuristics act as correctives but, on the whole, theorists tend to simplify (reducing all subjective responses to degrees of risk aversion, thereby treating the whole of human life as if it were a gambling game) or generalize (attributing feelings like “selfishness” to all choosers and assuming that such feelings dominate in any given circumstances). When actual choosers choose differently from the ways that such theorist suggest are best, it is often claimed that these people are just bad at reasoning about risk. Because their subjective feelings and values fail to match those “arbitrarily” postulated by the theory, theorists conclude that ordinary reasoners somehow allow the irrational part of choice making to overwhelm the rational part. Subjectivity is seen as a source of error, a force that undermines reason (Lewens 2007, p. 15). Typically, those who think so take it that the subjective attitude to risk is something which is simply a psychological given which is not under much rational control and is fairly consistent across a variety of different types of risk (although it may vary according to the probability of bad results and the extent to which the consequence that is hoped for is valued). This seems to suggest a conception of risk decision making that is construes it as outside the agent’s control and open to subjective and subversive influences. Some authors think this can be overcome by removing the subjective element from risk decision making entirely and placing the responsibility for risk-involving choice in the hands of objective “experts” (Sunstein 2002, pp. 28–53). However, such claims rest upon the idea that good reasoning about risk at least approximates an exact science<sup>8</sup>, while at the same time human reasoners are at the mercy of fickle emotions and poor reasoning. This is the sort of picture of reasoning about risk that we wish to argue against.

In our view, good risk taking is the product of practically wise decision making and such decision making is not and cannot be “scientific” (for the full argument and explanation of Aristotelian “Non-Scientific Deliberation,” see Nussbaum 1986, pp. 290–317.). Aristotle argues that the right moral response is “a mean” between possible reactions. That mean is achieved as a result of sensitive perception, good practical reasoning, the well-sensitized emotional reactions, and an ability of all of these to impact upon a discerning capacity to formulate desires. The mean in each situation is different – for example, whilst rage and violent action might be thoroughly inappropriate in the case of a football fan whose team has lost, exactly the same reaction would be the appropriate response (i.e., in the mean) to someone torturing an innocent child. The variation in the Aristotelian mean has the consequence that little in the way of generalization can be made from one case to another and the correct answer will be a matter of considering the particulars of each situation. Decision making is not a matter of making or applying general, descriptive rules, rather it is intensely responsive to evaluative and normative aspects of particular situations. Specific features of the subjects involved and the circumstances in which they are involved have a crucial role to play in reasoning about what to

do and how to act well, as do features of the historical processes that brought the agent to the point of needing to make any specific risk-involving choice. It is also not “scientific” in the sense that emotional deliberation is part of the reasoning process and the emotions are compatible with and even constitutive of the agent’s reasoning. Decisions about risk that proceed from a good character involve emotional responses, which are integral to firm and stable dispositions to virtue. In what follows in this section, we will make the case for this interpretation of the Aristotelian approach and show how it enriches the explanation of moral judgments of risk taking.

Two features of Aristotelian decision making are worth discussing here: situational appreciation and practical wisdom, *phronesis*. Situational appreciation is a term coined by David Wiggins (1980) to capture the Aristotelian idea that the particular details of a case, which vary from one case to another, are crucial in ethical deliberation and it is the role of the agent to perceive these features and their ethical significance. Crucially, these particulars are situation specific, so they cannot be captured in a one-size-fits-all rule. At best, rules are rules of thumb (Nussbaum 1986; Roberts 1991; Dancy 2004), so the agent must always be sensitive to details of the particular case, which prove the exception to the rule. Situational appreciation then is the perception of the morally salient particulars of a case, which, in turn give rise to reasons to act, but these features can be difficult both to perceive and to gauge their importance relative to other features of the case. Such particulars might include the numbers of persons affected, the status and needs of stakeholders, the availability of alternatives, or features of the social context, etc, (Athanasoulis and Ross 2010). The emphasis upon attention to the particulars is in keeping with commonsense generalizations – the commonsense generalization that cases where an agent decides to expose another to risk are more problematic than cases where the agent decides to expose herself to risk is an example of different ethical significances being attributed to different cases because the “particulars of the case” (the first/third person nature of risk exposure) differ. Similarly, the reasonable claim that we have greater obligations when making any decision on behalf of a non-competent other such as a child, takes “competence” as ethically significant particular in the decision-making procedure and this seems correct. The above examples demonstrate how some sorts of particulars are relevant in a reasonably stable way, allowing the formulation of working “rules of thumb”; however, particular considerations such as “competence” and “first/third party exposure” do not occur in isolation and the Aristotelian must always allow that there are some particulars which ought to weigh differently in different situations, that “rules of thumb” are tentative and there will be contexts in which they do not apply or are even reversed leading to unconventional, but nevertheless appropriate, decisions.

A case in which context was very important in leading medical practitioners to take significant risks despite the general rule of risk avoidance was the ECMO case (Megone and Mason 2001). Clinicians were deciding to trial ECMO machines on neonates. ECMO machines provide cardiac and respiratory support to patients with severely compromised heart and lung function. In neonates, abstaining from treatment would run a very high risk of death, but the very first uses of ECMO machines also run the risk of an unconfirmed procedure, which, once initiated, could not be reversed in favor of another course of treatment. This placed clinicians deciding whether to use ECMO for the first time in a very difficult situation: not only were they making life and death decisions on behalf of incompetent others, but they had to do so under conditions of uncertainty as to the outcomes but with some evidence to suggest that the proposed treatment could avert death, their decisions were not reversible and there was no way the child could be substituted with an adult who would, at least, be able to decide for him/herself whether

the risk was worth running or not (Mason and Megone 2001). The ECMO decision is by no means clear, influenced on the one hand by the therapeutic promise to avoid a high probability of death, complicated by the lack of therapeutic alternatives once the decision is made, and constrained by the inability to substitute the child with an adult. Similar decisions may be made even more complicated because other factors of the environment turn out to be morally relevant. Similarly, they can be simplified because fewer contextual factors matter. Consider the following three slight variations of the ECMO case:

- Case 1: Medical practitioners need to decide whether to expose a pre-linguistic child to the risks of a mechanical treatment (e.g., respirator), which has not been well tested. No treatment will most likely result in death, but the treatment could result in severe brain/heart/lung damage producing severe disability. Treatment is not reversible. The case takes place in a modern hospital in London.
- Case 2: Medical practitioners need to decide whether to expose a pre-linguistic child to the risks of a chemical (drug) treatment, which has not been well tested. No treatment will most likely result in death, but the treatment could result in severe brain/heart/lung damage, producing severe disability. Treatment is not reversible. The case takes place in Somalia where many babies routinely die because there are no resources to provide them with good primary medical care.
- Case 3: Bob is deciding whether or not to put his new-born baby sister in his time machine, thereby exposing her to significant and uncertain risks.

In cases 1 and 2, it matters that the situation is bleak – the alternative to risk is death – and it matters that the relationship between the medical practitioners and the child is governed by the role and duty of doctors to their patients, which places significant weight upon saving lives. In case 3, a different kind of caring relationship is in place and thus different responsibilities arise, and there is no clear benefit to the child from participating in the experiment, in fact, there is no obvious reason why it should be a child who is exposed to the risk, an adult could have taken her place. Cases 1 and 2 are very difficult and we probably need to take further particulars into consideration before we could decide whether exposure of a child to a high degree of risk is morally required or acceptable or impermissible. Also, because the wider context of the decision and the future life of the child are also relevant considerations, it is likely that we would not arrive at the same sort of judgment in both cases. In case 3, however, things are clearer because there is an alternative that does not involve using the baby and there are reasons for Bob to be very protective of the particular child concerned. In this case, other particulars fade into the background of the case and do not play a role in decision making.

The comparison of these examples demonstrates the complexity of the particulars that can play a role in moral decision-making and the importance of becoming aware of these particulars before being able to come to a decision. The process of gradual habituation and education described in the previous section will eventually give rise to the ability to perceive morally salient features. Some features of a situation, for example, “that there is a child drowning in shallow water with no one else around to help,” are very easily perceived as morally relevant and as giving rise to obligations to act, in this case the obligation to wade into the water and pull the child out. However, many ethical situations will be far more complex than this, and agents will have to have become sensitized to perceiving and appreciating how the particulars of the case give rise to the need to act. Often, this process of sensitization will involve becoming familiar with scientific or technical aspects of a case,

which may require considerable professional expertise, but sometimes it will involve engaging one's emotional reactions and faculties of imagination. So, for example, making a decision on the time-traveling case may well involve developing a better understanding of the theoretical claims behind Bob's expectation that he can now travel through time and assessing their scientific validity at an abstract level before proceeding to a practical trial as well as the emotional attachment that he has to the project.

There is a tendency in modern choice theory to assume that self-interest is the only rational feeling and the only one whose influence upon choice deserves consideration. The Aristotelian approach to choice emphatically rejects this assumption (a contemporary argument for the rejection of this view can be found in Roeser 2010). For Aristotle, emotions are neither inimical to reason nor disruptive forces to be viewed with suspicion. The emotions can be trained and habituated to not only concur with reason but also play a role in reasoning. For example, arriving at the conclusion that one should help a homeless person find a bed on a very cold night is a process that involves both spontaneous feelings of kindness and empathic imaginings about the person's situation, which support the rational argument that help is appropriate here. Fear, sympathy, love, anger, generosity, etc., are an integral part of a proper human reaction to events. The person of practical wisdom is someone who has the appropriate emotions, to the right degree at the right time – and in doing so manifests the Aristotelian “mean.” Both habituation and reason have roles to play in ensuring that this occurs. When we decide that an emotion is “not in the mean,” then what we are detecting is a failure to balance a complex set of emotions in a way that fits the situation that one faces and recognizes the particularly morally salient features of it. Comparison, generalization, balancing, and modulating are all activities of reason assisted by emotion. This understood, it is easy to see why the subjective elements of decision making about risk are neither fundamentally irrational nor excess to requirements. In the time-machine case, it matters that when Bob makes his request of you, he is partly relying on your specific relation to him as a friend, which should lead you to view requests for assistance positively and to share in his enthusiasm about his concerns and projects. Because of this, the reasons that you have for or against exposing yourself to risk will and ought to be different to the reasons of someone who does not know him at all.

The other aspect of Aristotelian decision making we wish to highlight is *phronesis*, or practical wisdom, the state of being that underlies and underwrites all the virtues. Practical wisdom includes the ability to grasp how the different features of a situation relate to each other, which virtues relate to each case, and how the different virtues relate to each other. Practical wisdom allows the student of virtue to see not just what should be done as a matter of habit or following an example, but why it should be done, why it should be chosen, chosen knowingly, and for its own sake (Irwin 1980). This ability to reason morally allows the virtuous agent to determine the right action in a variety of different situations, as the right action will depend on the circumstances and differ according to them. The idea, that the right action will differ depending on the situation, is captured in Aristotle's doctrine of the mean. We know from the definition of virtue that Aristotle believes that the achievement of activity in accordance with “the mean” in some way requires the deployment of reason. However, it is difficult to clearly specify the precise role that reasoning plays here. One role that reasoning plays is instrumental, that is, the selection of means appropriate to ends (NE Book 7). It is now widely agreed amongst commentators that reason has *more* than an instrumental role to play in Aristotelian decision making. There has also been a great deal of

discussion about the role it plays in the selection of ends with some arguing that practical reasoning is involved in the reflective evaluation of ends (a book-length treatment of the subject can be found in Richardson 1997). John McDowell has emphasized that bringing about the integration and prioritization of morally salient particulars into decision making is very much part of the skill of the person of practical wisdom (McDowell 1998a, pp. 21–30; McDowell 1998b p. 53). Whatever the precise details, practical reason is, above all, the coordinator that enables complex psychological and active responses to match complex and demanding situations.

## To Time Travel or Not to Time Travel?

---

We began this chapter with a fictional example of risk taking, so it would seem reasonable to offer some kind of answer to that question. However, as noted earlier, Aristotle holds that we cannot expect more precision from the answer than the subject matter itself affords (NE1098a). If the subject matter is complex, diverse, and challenging, the answer has to be sensitive to these considerations and capture this complexity. If one answer does not fit all situations, it would be a mistake to demand one answer and if the answer for each situation turns out to be detailed and intricate, we should not seek to distil it to its bare essentials for the sake of simplicity. All this suggests that perhaps there is no simple, straightforward answer to whether one should participate in such an experiment. For one thing, we lack a lot of information that would be relevant in determining the salient particulars in this case. We lack information about the state of the scientific progress in terms of time travel, the details of this particular attempt, and their relative merits as compared to other scientific claims. We also lack the background information that may help us assess the participants' actions in this case. Knowing Bob will involve knowing his character and this would make it easier to judge whether, in this case, he is being reckless or cautious, appropriately ambitious or excessive, a bold ground-breaker, or a careless self-promoter. For example, you might think he is less reckless if you understand the close relationship Bob has with his sister and the huge respect he has for her decision-making capacity and technical skills despite her age. Similarly, you might judge him to be a moderate, humble, and considerate man in all other circumstances and therefore unlikely to be driven by overweening ambition. We would also need to find out about the background within which this project is taking place and whether there are any relevant checks and precautions that have been fulfilled prior to reaching this stage of experimentation. All these, as well as factors relating to your relationship with Bob and the obligations your friendship may bring to bear on this decision, are all crucially relevant details. Given the number, complexity, and depth of these details, it is not possible to give a conclusive answer to whether one should assist in this time-traveling experiment or not based on the limited information provided; however, we would like to continue making use of the case to illustrate how one might go about reasoning about it. The reasoning will be incomplete in terms of arriving at a definitive answer, but it may be helpful for illustrative purposes.

In what follows, we try to demonstrate how many of the considerations raised in this paper would go toward deliberating on whether one should risk time travel or not. We will not be able to consider all the possible different paths of reasoning that may be provoked, our aim is simply to provide a practical focus for what we have been saying about the process of virtuous choice

and action. The reasoning we consider will lay bare aspects of the reasoner's character and demonstrate ways in which that character may be flawed. It is worth emphasizing here that any moral judgment that is made is made on the basis of the whole character. Whilst we can point to flaws in the reasoning process which compromise character, there are so many possible ways in which character can be undermined that there is no possibility of reduction of the form: some immoral actions are associated with "x" flaw of reasoning and therefore to behave immorally is to include "x" in one's reasoning (or other way around, might be more straightforward but also mistaken).

The case starts with the invitation to participate in the experiment, which must produce an action-related response, for example, an intention to become involved or the opposite or no response at all. The virtuous person is likely, through a lifetime of training and development, to have the correct initial response, but for the rest of us, the struggle for virtue may mean that we have a number of different motives, which will need to be examined and endorsed or rejected as appropriate. Let us say for the moment that, in our example, you are inclined to participate in Bob's experiment. There are a variety of different reasons, which might underlie that inclination (different possible explanations of your response):

- Reason 1: Time travel might be your most cherished ambition, potentially the crown in your scientific achievements, and you simply jump at the chance to achieve it without consideration of the risks.
- Reason 2: You might be desperate to earn Bob's admiration, so keen to agree to anything he proposes
- Reason 3: You may be worried by the significant risks involved in time travel, but concerned to protect others from collaborators with less skill and understanding of the subject, so inclined to become involved so you can keep an eye on the project.
- Reason 4: You may be strongly attracted to the opportunity of helping a friend, although simultaneously unsure if the best expression of this friendship is to give Bob the assistance he asks for or to persuade him to reveal his plans to the academic community for further scrutiny before putting them into practice.
- Reason 5: You might hold the view that the risks involved are real, but worthwhile provided the time traveler is scrupulous in seeking not to alter the period to which they travel and be keen to ensure that this is the case by traveling yourself.<sup>9</sup>

Each of the above reasons for action involves the singling out of certain aspects of the available options as salient to your response, for example, the fact that it is Bob who has asked you rather than someone else, the fact that other potential participants are more vulnerable and less responsible than you, the fact that what you would be doing is time travel rather than something else equally risky but less "cutting edge," the vulnerability of "innocents" to harm as a result of your time travel, etc. In perceiving the morally salient features of a situation, you both evaluate these features and call your own responses and evaluations into question. In general, the way in which you represent the situation to yourself and the extent to which aspects of it will seem to you to be reasons for action will be the product of your educated dispositions. You are disposed to represent this complex situation to yourself in a simplified way, which emphasizes certain elements rather than others as requiring response (Butler 1988, pp. 221–227). So, in the case of Bob's request, you might see it primarily as an "opportunity for me" or as an instance of "a friend being in need of help," etc. (Butler 1988, pp. 220–221).

It is worth noting, however, that not all such representations are equally correct or equally good grounds for action. The accuracy or correctness of your own way of seeing the situation is not obvious “in the moment”, but it can be checked and changed on reflection. Reflection upon any of the above reasons for action might reveal the following sorts of “perceptual” error:

- Reasons 1 and 2: Initial considerations of personal gain, self-promotion, or scientific fervor seem to be preventing other aspects of the case such as the risks involved, the potential to harm innocents, the young and impressionable nature of Bob’s sister, etc., from being brought into the decision-making process. On reflection, one might conclude that although some concern for one’s own achievements and the regard of others are appropriate, an excess of this sentiment may cloud the judgment with respect to the risks involved.
- Reason 3: This response seems to attribute appropriate weight to the very significant risks involved and emphasizes the manipulative nature of the situation in which you find yourself. Reflection may be necessary in order to work out the extent to which one should allow oneself to be manipulated into taking risks and whether “manipulativeness” really is the most significant consideration here.
- Reason 4: This reason foregrounds the friendship between yourself and Bob, but further reflection seems to be required in order to clarify the way in which your choice is seen – in particular, your understanding of friendship, loyalty, and the requirements it places on friends are unknown, and therefore make the initial representation of the situation too vague to allow a decisive response. A second crucial feature of the situation here is the recognition of the role played by the scientific community in managing risk taking – the sort of management whose absence from Bob’s project is strikingly obvious to you, the reasoner. Recognition of this provides the reasoner with a way of making a conditional answer, which expresses enthusiasm for the project, but also takes seriously the risks involved.
- Reason 5: Here again, we have serious appraisal of the risk involved and, crucially, the recognition of the potential for managing the level of risk to which third parties are exposed and of you as better positioned than most to manage these risks. In this case, reflection might reveal that consistency requires that you be as concerned about Bob’s sister as you are about third parties and so your initial confidence in your ability to manage all the significant risks might have been overblown.

In addition to being sensitive to the particulars, reasons 1–5 above cite emotions experienced by the reasoner as a rationally relevant part of his/her response. The real prospect of time travel is likely to stimulate feelings of fear, concern for others, and excitement. In addition, you will probably have feelings that arise because of the relationship between time travel and your personal ends – you might experience joy that a long cherished and seemingly impossible scientific advance is close to realization, or you might be delighted to have the opportunity to demonstrate your loyalty and usefulness to Bob, etc. Finally, added to all of the above, will be emotions appropriate to the relationships between you (the potential risk chooser), Bob, and Bob’s sister – emotions like love, loyalty, and respect. The appropriateness of the content and intensity of particular emotions will be dependent upon your representation of the situation, your stake in the outcome, etc. We said above that emotional response

must manifest the Aristotelian “mean” and reason has a role to play in ensuring that it does. We can see from this example that being “in the mean” is not a simple matter – because it requires the balancing of different emotions as well as the modulation of individual emotions. The virtuous person will be disposed to respond with appropriately balanced and modulated emotions in a way that is similar to the disposition of the excellent language speaker to respond to a communication in the appropriate tone, with an appropriate degree of seriousness, etc. The language speaker responds in a way that is at once intuitive and underwritten by a sophisticated process of comparison and adjustment, etc., and similarly, the virtuous agent’s emotional reaction to the prospect of this time-travel adventure would be “automatic,” but nevertheless fine-tuned.

Of course, this process can go wrong – the emotions in play can get out of balance and the individual emotions may have more or less influence over the overall response than they should. Good examples of the latter are reasons 1 and 2 above. Most of us would be tempted to say that response 1 and 2 exhibit a little too much self-promotion and admiration of others, respectively, and this is cause for concern because these feelings render the agent improperly responsive to some significant risks and insufficiently careful and respectful of the needs and entitlements of others. Difficulty in balancing different emotions can be seen in reason 3 above where appropriate fear finds itself in the company of strong protective feelings toward Bob’s sister and (at least some of) the third parties who could be affected. In the scenario we are considering, protectiveness out-balances fear, but it is far from obvious that this is the right response. Similarly, in reason 5, the reasoner exhibits appropriate self-confidence but we might worry that too much weight is placed upon that feeling in the overall emotional response. Of the reasons we have been considering, reason 4 seems to be the closest to a well-balanced and appropriate emotional response blending as it does enthusiasm for the project, caution, concern for others as well as care for a friend.

Finally, it is worth noting that all of the potential reasons for participating listed above make some sort of reference to the thing, which action would be an attempt to achieve, and its purpose. The ends toward which an agent strives will range from objectives that are the products of reflection and with which she identifies, to things for which she simply has a non-rational taste. There is a very general sense in which all reasons are attempts to achieve “the best thing.” What is obvious from 1 to 5 above is that there are a lot of different conceptions of what “the best thing” is. Some have greater objective validity than others; for example, self-aggrandizement and the eternal admiration of Bob, are ends whose importance is objectively questionable. Whilst some concern for one’s own achievements is appropriate, it is hard to see why personal achievement should outweigh the value of the achievements of others that may be prevented or delayed by what you do. Similarly, the approval of others one admires is not itself an unworthy goal, but valued to an excess it will probably compromise your ability to achieve other goods that are arguably (objectively) of greater value, for example, autonomy and the well-being of others (if the person you admire is not virtuous)<sup>10</sup>. In the case of reason 3, the goal of personal safety is potentially sacrificed for the purpose of achieving a different goal – preservation of the well-being of others. Personal safety is a sensible objective and benevolent desires are noble, so here the difficulty comes in working out whether one can and should be sacrificed for the other. This is a very difficult task because good ends are not commensurable on a single scale (Nussbaum 1986; Richardson 1997). There are no infallible rules, which can help with this sort of discriminative task. Instead, skill acquired

though practice and good teaching, is necessary here. Reason 4 includes one of the ends that Aristotle thinks is constitutive of a good human life, that is, the aim to be a good friend, and combines it with something that Aristotle thinks is equally important – the goal of “good citizenship” which includes the desire for justice. Reason 5 takes as key the technological value of the project although it seeks to balance this value against the genuine disvalue of potential harm. Probably, none of the reasons we have considered give appropriate weight to all the genuinely valuable ends that ought to be in play (friendship, citizenship, technological value, the healthy and autonomous future potential of Bob’s sister, etc.); however, this examination of the sorts of ends that inform decision making and the ways in which they might be questioned is intended only to illustrate the sort of discursive process that we think a virtue ethics approach can bring to a moral debate rather than to give a complete and definitive answer.

## Conclusion

---

In this chapter, we have tried to give a brief account of the main features of virtue ethics and to illustrate how these offer a unique perspective on thinking about risk. Due to the nature of this project, the account is far from fully fleshed out and only partly defended, but hopefully it offers an insight into the theory and its contribution to making decisions about risk.

Prominent in our analysis has been the claim that the ethical life is a complex and diverse enterprise, which requires an equally detailed, flexible and situation-specific approach. One answer does not fit all, and discovering these challenging and varied answers may well be a lifelong project. This lifelong project is understood in terms of gradual, long-term, and vulnerable character development. In terms of risk, this means that we should shift the focus from the consequences of one-off, and often extreme, cases, to a broader view. We should consider the nature of the decision to take a risk, the type of character this decision reveals, and the life within which this character is displayed. The evaluation of the decision to risk must reflect the morally salient particulars of the situation and how these are ordered by the person who exhibits *phronesis*. If this approach results in a less prescriptive and less direct answer, this is no cause for complaint. For, it is the nature of ethical judgments that they are difficult to arrive at and require thought and effort. We shouldn’t expect anything less of ethical judgments involving risk.

## Further Research

---

In this paper, we have examined the essential role of character in good decision making about risk. In a previous paper, we have considered the way in which aspects of context influence decision-making about risk (Athanassoulis and Ross 2010). These two papers set up a framework for a virtue approach to risk taking. There is much work to be done to fill out this framework. In particular, we have emphasized that a virtue approach would need to consider particular issues on a case-by-case basis and there is work to be done looking at individual risk problems in particular disciplines. For example, questions about the circumstances in which it is acceptable to expose research subjects to risk or questions concerning what sort of risk taking in business is

ethical, etc. In addition, this paper has emphasized the role of education for virtue and more work is needed to fill out an account of what it takes to educate virtuous risk takers and to look at how such education can be incorporated into the professions.

## Notes

---

<sup>1</sup>We have chosen time travel as our example of risk decision making because it has the advantage of being unfamiliar and challenging to readers from all disciplines and yet embodies many of the dilemmas that will arise when making decisions concerning the use of any risky technology.

<sup>2</sup>Deontologists differ over what defines moral rights and duties. Some think they are determined by divine command (Quinn 1999, p. 53), and others by political consensus (Hobbes 1660, Chap. 13; Rawls 1971, Book I). The most influential of the deontological theories has been Kant's – he argues that we can work out what our rights and duties are by appeal to "the categorical imperative" which is the logical consequence of seeing ourselves as valuable because we are agents and, as a matter of consistency, seeing all other agents as equally valuable (Kant 1785).

<sup>3</sup>Of course, not all situations involving risk are instigated by an agent, for example, many are the result of natural forces over which we exercise no control, but in this chapter, we are interested in moral judgments and responsibility for one's decisions so we have limited 'the discussion to these kinds of cases of risk. For more on this, see Athanassoulis and Ross 2010.

<sup>4</sup>This example is adapted from Hansson 2003, p. 295. The reason for the changes is that the individual in Hansson's original example is a repairman with the skills to effect the repair. It seems to us that selecting this person in particular raises questions about one's obligation to expose oneself to danger when the risk of doing so is part of one's employment obligations, which were freely entered upon. Such considerations, as well as more general questions regarding the selection of the individual who runs the risk, for example, whether he/she is a volunteer, whether he/she has any role obligations in this respect, etc., make a difference to the moral evaluation of the decision.

<sup>5</sup>In these views, "the passions" which include both desire and emotion are the product of causal processes that are little or are of no interest to philosophers. They take it that these elements can best be catered to by studying the patterns of reactions that people actually have and using these as a measure of value.

<sup>6</sup><http://homepage.newschool.edu/het/essays/uncert/aversion.htm>; <http://hadm.sph.sc.edu/courses/econ/Risk/Risk.html>; <http://moneyterms.co.uk/risk-aversion/>

<sup>7</sup>Rawls, for example, feels the need to stipulate a level of risk aversion, which he considers to be reasonable in arguing for the MAXIMIN strategy (Rawls 1971, pp. 123–133)

<sup>8</sup>The basic idea is the consequentialist one that reasoning about risk is a matter of marrying probabilities and value/disvalue of potential outcomes and then selecting the combination that comes out with the best score.

<sup>9</sup> This list is not intended to be exhaustive, merely illustrative.

<sup>10</sup>Aristotle thinks that what is valuable for its own sake is an objective matter – that the good life for a rational being has a substantive nature, which requires the pursuit of particular ends – ends such as friendship, political participation, justice, contemplation, creative achievement,

etc. So, reason enters into “end-adoption” as a criterion –  $x$  is only a good end if its pursuit in some way contributes to our living the lives of rational beings; if it is an end whose pursuit will exercise and develop our rational (as opposed to arational) natures.

**Abstract:** Philosophical conceptions of the relationship between risk and trust may be divided into three main families. The first conception, taking its cue from Hobbes, sees trust as a kind of risk assessment involving the expected behavior of another person, for the sake of achieving the likely benefits of cooperation. The second conception of trust sees it as an alternative to calculative risk assessment, in which instead of calculating the risks of relying on another person, one willingly relies on them for other reasons, e.g., habitual, social, or moral reasons. The third conception sees trust as a morally loaded attitude, in which one has a moral expectation that one takes it to be the responsibility of the trusted person to fulfill. In the context of interpersonal relationships this attributed moral responsibility creates spheres perceived to be free of interpersonal risk, in which one can pursue cooperative aims. In this chapter, we examine how these three views account for two *prima facie* relationships between risk and trust, and we look at some empirical research on risk and trust that employs these different conceptions of what trust is. We then suggest some future areas of philosophical research on the relationship between trust and risk.

## Introduction

---

This chapter describes some prominent philosophical connections between trust and risk. Section **● History** briefly describes historical thought about these connections. In section **● Current Research**, we describe current philosophical research on trust, including relevant empirical work on trust, attempting to understand how trust helps people pursue welfare cooperatively under conditions of risk. We conclude by indicating, in the final section, areas of future philosophical research on trust and risk.

## History

---

There are only a few significant references to trust in ancient Western philosophical sources, such as a work by the “anonymous Iamblichus” (Gagarin and Woodruff 1995, cited in Hardin 1998). Trust thought of as a practical solution to situations of risk has its modern theoretical origins in Hobbes. Humans outside of civil society, Hobbes argues, are vulnerable to risks both from the harsh natural environment and to risks from other people. It is rational to protect one’s own life, Hobbes argued, but for this very reason rational cooperation is not generally possible, because in many situations it will be rational to exploit others’ willingness to cooperate, and to expect similar exploitation from others. Therefore, outside of social and political structures it is rational to treat all other persons in a warlike way, cooperating with them only if it is possible to guarantee that they will not do harm to oneself. Many cooperative goods will then be impossible to obtain (Hobbes 1968 [1651], p. I.13). For this reason, Hobbes thinks it is practically necessary to establish a powerful political authority that will coercively enforce the terms of promises and ensure the possibility of mutual cooperation (Hobbes 1968, p. I.14). Hobbes calls *trust* the attitude of rational confidence in the reciprocal cooperation of others that is safeguarded by such a powerful authority (Hobbes 1968, p. I.15).

The particular way that trust figures in Hobbes’ political philosophy was not addressed explicitly by his many contemporary detractors (they focused more on his conception of the rational person and the natural law). Indeed, the notion of trust was relatively unimportant in moral, political, and social philosophy throughout the modern period, except for a minor role in

the political philosophy of John Locke (Laslett 1988; Dunn 1984). When trust reemerged as a philosophical topic in the twentieth century, it did so in three main areas. Some scholars picked up where Hobbes left off, seeking to understand how cooperative relations going against immediate self-interest but beneficial for social well-being are strategically and motivationally enabled under conditions of risk (Held 1968; Coleman 1990). A second group sought a more wide-ranging understanding of trust as an explanatory concept in social theory and social science, thinking of trust as an emergent property of societies in modernity (Luhmann 1979). Finally, a third group, beginning with the work of Annette Baier, sought a moral-philosophical account of trust. Baier criticizes the other traditions for failing to give a satisfactory normative ethical account of trust outside of contractual or quasi-contractual relations. She points out that trust relationships are characteristic, perhaps especially so, of relationships that cannot easily be thought of as contractual or exchange based, e.g., parent–child relationships and other relationships among intimates, and that here and elsewhere the question of whether trust is good or bad is not merely strategic (Baier 1986). Since all three of these conceptions of trust are still actively relevant to the relationship between trust and risk, they will be discussed in the next section on current research.

## Current Research

---

### Philosophical Conceptions of Trust and Risk

---

In the first subsection below, we give some initial definitions of risk and trust, and then set out two apparent conceptual relationships between risk and trust. This will provide an impression of the relationships to risk that should be explained by a philosophical theory of trust. We then proceed to discuss how three families of philosophical conceptions of trust explain and interpret these relationships.

### Two Relationships Between Trust and Risk

Compared to the concepts of risk and risk perception, the concept of trust is relatively problematic and unsettled. Following Hansson, we define risk as a possible but not certain future harm, or the probability of such a harm, or the expected disutility of such a harm (Hansson 2004). Risk perception is the mental representation of a risk, as realized in emotions such as fear and in cognitive states such as prediction.

It is sometimes useful to draw a distinction between risk and epistemic uncertainty. On this understanding, risk is one kind of uncertainty: a quantified or well-characterized uncertainty. Other kinds of uncertainty are less well quantified or characterized. For example, in a poker game, the likelihood that a given poker hand will lose is a well-characterized possibility, given a fair game. It can be assigned a numerical value. The likelihood that the hand will lose because the game is not fair, however, might not be easy to characterize or quantify. We sometimes want to distinguish these two factors by calling the former a risk and the latter an uncertainty. In risk perception, these two factors are sometimes difficult to separate.

Trust is a concept used variously by research in psychology, sociology, management studies, philosophy, economics, and political science. There are many conflicting accounts of what it is, how it arises, and what kind of explanatory work it might perform in an account of

interpersonal relations. Even within these fields there is disagreement about how to define and investigate trust (McLeod 2002; Hardin 2006). Because of these disagreements, we will settle on as neutral an initial definition of trust as possible. Trust is *a disposition willingly to rely on another person or entity to perform actions that benefit or protect oneself or one's interests in a given domain*. This definition departs from some prevalent accounts of trust in several ways. First, it leaves out the distinctively moral character that the attitude of trust is often conceived to have by philosophers. (This view will be discussed in the section [Trust as a Moral Attitude](#)). Second, it fixes two objects of trust: the agent and the actions-within-a-domain that are to be performed by the agent. This notion of trust, containing a trustor, a trustee, and a domain or an action, is referred to in the literature as “three-place trust” (Baier 1986) and is already implicit in one of the earliest contemporary philosophical treatments of trust (Horsburgh 1961). The three-place account is more concrete than accounts of trust that view the object of trust as a measure of general confidence in the good intentions of other persons or institutions. The third point relates to the *willingness* of trust. When one's disposition to rely on another is only due to coercion or a lack of alternatives, it is not a trusting disposition. In cases where one trusts, one has some independent reason for doing so, relating to the qualities of the trusted entity.

The definition, however, leaves open what characteristic reasons support trust. Most accounts of trust specify this in some way or other, e.g., by saying that it is characteristically based on social information, such as group membership, relationship, reputation, and power. This point about the reasons for trust is important for our understanding of the relationship of trust and risk. It is important for understanding the first of two main conceptual relations we use to see how theories of trust address the issue of risk. Suppose we are thinking of hiring WDC Dredging Company to conduct a small dredging project. The *Handbook of Dredging Engineering* states that “Characterizing the environmental risk posed by dredged material requires information on the likelihood that organisms will be exposed to contaminants and the probability that such exposure will produce adverse effects in the environmental receptors (organisms) of concern. The uncertainty associated with these estimated risks has been high” (McNair 2000, p. 22.39). Special techniques have been developed to reduce these risks under different conditions. In order rationally to rely on WDC to carry out the project, however, we need not quantify these risks and uncertainties ourselves, reaching a conclusion about how they should be addressed. We could instead confidently count on WDC to know and apply appropriate methods, and to abide by relevant laws and industry practices – in a word, we could trust them. Our reasons for this would have to do with WDC's reputation, with the existence of regulatory bodies, and with the knowledge that WDC wishes to protect its future reputation. They would not normally depend on specific information about probable dangers due to this particular dredging job.

This suggests that the question whether it is a good or bad idea to rely on another person or entity to perform a given action can be answered in two ways. One way is by evaluating the risks associated with that action. The other is by determining whether the other person or entity is trustworthy. For example, whether it makes sense to rely on WDC to dredge a harbor safely and without environmental damage partly depends on the quantifiable risks that are associated with this agent performing this activity. But, it also depends on the trustworthiness of WDC relative to other companies. Therefore, in a situation like this, risk evaluation and determination of trust are in some sense *different answers to the same question*: whether to rely on the company to perform a given action. Whereas risk evaluation focuses on the probabilities

associated with the underlying activity, determination of trust focuses on the qualities of the entity (in this case, the company) such as its competence and motives, as influenced by its social and normative standing. In case one of the answers is incomplete or inadequate, it may be possible to answer the question in the other way: where risks cannot be easily quantified under the circumstances, one can ask whether the company is trustworthy; where the company is unknown, one can attempt to quantify the risks independently. This is echoed in a recent survey article by a group of psychologists: “There are two general ways [that individuals predict cooperation in others]. One, *trust*, is defined as the willingness, in expectation of beneficial outcomes, to make oneself vulnerable to another based on a judgement of similarity of intentions or values; the other, *confidence*, is defined as the belief, based on experience or evidence, that certain future events will occur as expected” (Earle et al. 2007, p. 30; see also Luhmann 1979; Seligman 1997; and Deutsch 1977 for other versions of this distinction).

A corollary is that actively controlling risks tends to reduce trust rather than increasing it. To the extent that we attempt to quantify and control the risks and uncertainties of this dredging job and choose the proper methods ourselves, this reduces the scope of our trust in WDC by reducing the extent of our reliance and vulnerability, even though the action that we essentially rely on them to do – dredging the harbor – remains the same. If we attempt to reduce our risk by taking out insurance, this reduces the extent to which our well-being depends on WDC’s fully adequate performance. Or suppose we want to be as sure as possible that WDC will perform safely, and to this end we do a detailed investigation into this company’s entire history of activity and the safety of the methods they use, and moreover formulate a plan to monitor the stages of their dredging operation. This would reduce our epistemic reliance on WDC. In such cases, where we take active steps to control or reduce our risks, epistemically and practically, it might be appropriate to remark that we *do not fully trust* WDC, or at any rate that after going through these steps we do not need to trust them as much. It seems, then, that as our own knowledge and control of the risks associated with reliance on another entity increase, our independence increases, our reliance and vulnerability decrease, and our (need for) trust in the other entity decreases. Hence in this way, too, the characteristic reasons for risk taking and for trusting are different from one another. This, then, is the first main conceptual point about risk to be explained by theories of trust: the characteristic reasons for risk evaluation and for trust are different, and to some extent mutually exclusive.

The second main apparent conceptual relationship to be explained by a theory of trust is that high background risk makes trust more salient, but also more difficult to justify. Suppose Q is the organizer of a protest group under a repressive government. Q faces the risk that if the group is discovered, she will go to prison. In order to expand membership in the group and coordinate group actions, she must tell others about the group and count on them to carry out activities on the group’s behalf in strict confidence. In such a situation, Q must rely on other people to protect her interests and those of the group. Her willingness to do this goes along with her trust. It seems that in cases like this where risks are high, but where reliance on others is essential to a valued activity, well-grounded trust is of great importance (Boon and Holmes 1991, cited in Das and Teng 2004, p. 87). Trust often coexists with risk and is made more salient by it, because the need for trust increases as the risks associated with a valuable act of cooperation increase. On the other hand, in trusting one wants to minimize risk as much as possible by finding the most competent, cooperative people available and the most conducive background conditions. In our example, Q would be rational to trust those individuals least likely to compromise her interests while helping fulfill her goals and those of the group.

It might be rational, e.g., to collaborate with family members or close associates of people already in the group, because these persons have more to lose if they defect. Because the stakes are high for Q, she must be very careful about whom she trusts and under what circumstances. Thus, the risks associated with a cooperative act make trust more important, but also more difficult to adopt on careful, stringent grounds.

One way of justifying this point is to draw on intuitions from recent epistemology about the relation between knowledge ascription and practical stakes. The intuition is that the greater the practical stakes that hang on the truth of some claim P, the more difficult it is to have knowledge or sufficient justification for believing P. Here is a version of a standard example used to motivate this intuition:

- ▶ It's late on Friday afternoon, and raining hard. Lo and her next-door neighbor Hi are [separately] thinking about going out to the bank, but wondering whether the trip could be postponed until tomorrow. Both of them can remember a recent Saturday visit to the bank, but neither of them has any further information relevant to the question of whether the bank will be open tomorrow. Nothing much is at stake for Lo—her banking errand could be done any time in the next week—but for Hi the question has burning practical importance. Hi knows he must deposit his paycheck before Monday, or he will default on his mortgage and lose his home (Nagel 2008, p. 279; the original example is found in DeRose 1992).

Among epistemologists, a widely adduced intuition about this case is that whereas Lo knows (or is justified in believing) that the bank is open on Saturday, Hi does not know this, even though Hi and Lo have the same evidence. The only difference between Hi and Lo is what they have at stake concerning the question whether the bank is open, hence this is taken as the key difference that explains why one of them has sufficient justification for knowledge and the other not. High-stakes practical reasons raise the bar of sufficient justification. Assuming we can extrapolate from this type of high-stakes case to other cases, such as Q's question whether a given person will keep secrets about the protest group from the authorities, it appears that sufficient justification for trust is difficult to come by partly because the epistemic standards for knowledge or justified belief are higher in Q's high-stakes situation, although the data supporting this intuition and the interpretation of the alleged intuition are disputed (Buckwalter 2010; Nagel 2008).

There is also the more mundane principle that where more is at stake, there is often more reason for any given individual relied upon not to perform as expected, and consequently more reason not to trust them. People in Q's country take a much greater personal risk by participating in a protest group than those in countries without an oppressive government, so they need to have special motives or qualities such as courage in order to perform as Q expects of them. What is needed for trustworthiness in this high-stakes context may therefore be more demanding. Since the characteristics underlying trustworthiness are more rare, it will be more difficult for Q to justify trust. It is also distinctive of this example that those who are trustworthy for Q may have special reason to conceal the very characteristics that would indicate this to others. There also may be government agents who pretend to have such characteristics in order to infiltrate and undermine the protest group. Thus Q's epistemic task is difficult indeed.

These, then, are two main apparent conceptual relationships between risk and trust that one hopes a theory of trust will elucidate: on the one hand, extensive risk evaluation makes trust less relevant; on the other hand, when the risks are greater, trust is more difficult to justify. In the remainder of this section, we will set out three prevalent approaches to the theory of trust and see how well they explain and justify these apparent relationships.

## Trust as Interpersonal Staking

The first approach under consideration sees trust as a special instance of rational risk taking. As Sztompka writes, “Trust is a bet about the future contingent actions of others” (1999, p. 25; see also Gambetta 1988). Suppose Q considers inviting Ron to join her protest group. If Ron is trustworthy, his membership in the group will bring a significant added benefit to Q. If Ron is not trustworthy, inviting him could be very detrimental to Q. Thus, in considering whether to invite Ron, Q must weigh the likely benefits of inviting him against the possible risk that if she does so, Ron will betray her and the group. This can be regarded as a calculated choice, or a kind of bet Q is in a position to make on Ron’s future behavior. Some have regarded the willingness to make such an interpersonal bet as the essence of trust. There are important methodological reasons for considering trust in this way, such as its ability to help predict and explain macro-level social effects as a function of the cooperative behavior of individuals with limited options and interests, where the values of different options for individuals (including the option of reliance on others) can be thought of as preference rankings or subjective expected utilities (Coleman 1990, Ch. 1).

This type of view does an excellent job explaining the second of the conceptual points set out above, why the difficulty of justifying trust increases with the risks. This is due to the obvious fact that on such a view one’s dispositions to trust are based on expected utilities, which take into account both the likelihood of performance, and the stakes to be gained through performance and lost through nonperformance. The increasing benefits of performance can increase the willing disposition to rely on another; similarly, the increasing harms of nonperformance can decrease this willing disposition. This means that the willing disposition is not exclusively dependent on the *belief that another person will perform* (is likely to perform). It is just as dependent on the *stakes* that are attached to performance and nonperformance, where the expected utility of reliance given these stakes is compared with a situation in which one relies on somebody else, or does not rely on anybody. Such a view is therefore quite different from a doxastic (belief based) view of trust according to which the willing disposition is based on a *belief* that the entity relied upon will perform in a certain way. One need only believe it is likely enough that the entity will perform to make it worthwhile, given the utilities of performance and nonperformance, to rely on him (Nickel 2009). In cases where there is little to lose given nonperformance, one need not believe strongly that a person will perform in order to feel comfortable relying on him. But that is not Q’s situation. She has a lot to lose through Ron’s nonperformance, so before she can willingly rely on Ron she needs information that more fully ensures that Ron will perform, and this increases the justificatory burden for a belief in his trustworthiness.

However, this view does not do much to explain the first of the conceptual points set out above, the mutual exclusivity between reasons for trusting and detailed risk assessment. To emphasize this, consider a thought experiment involving the dredging job again. Suppose I have conducted detailed research on the history of all dredging jobs in my region, including those of WDC. I also come to learn almost perfectly the scientific appraisal of the methods used by WDC. I come to have as much knowledge about these topics as anybody ever has before. Suppose, too, that I have taken out a large insurance policy to protect me in case WDC does something wrong for which I am liable. I also form a detailed plan for monitoring WDC. Now on the “staking” view of trust that we have been considering, this gives me perfect grounds for the attitude of trust: the more I can guarantee performance and safeguard against

nonperformance, the more purely I can trust. But this is exactly the opposite of the first intuitive link discussed above, according to which these are not the characteristic reasons for trust.

Some advocates of this type of approach have specified that trust relates only to reliance undertaken on the basis of certain sorts of reasons. One prominent view in particular adopts the condition that Q's trust is characteristically based on Q's belief that the one to be relied upon (Ron, in this case) cares about Q's interests as part of Ron's own interests: Q believes that her interests are *encapsulated* in Ron's (Hardin 2006). This moves some way toward explaining the distinctively interpersonal nature of reasons for trust. According to this encapsulated interest view of trust, possible reasons for thinking one's own interests are encapsulated in another person's interests include the thought that it is for their own strategic future benefit to perform as expected, that they are subject to sanctions if they do not perform as expected, or that they are fair and law abiding. The risks involved in trusting are interpersonal risks: they therefore depend on, among other things, the motives of the trusted person.

However, Hardin does not hold that efforts to quantify risks objectively or control them result in a reduction of trust. Indeed, on his view they would seem to enhance trust, since trust is for him still calculative. Reacting against this view, the sociologist Eric Uslaner distinguishes between strategic trust and moralistic trust (1992). Strategic trust is based on rational assessment and verification; in moralistic trust, one relies on others without detailed risk assessment and without expecting anything else in return, as in Uslaner's example of a fruit stand owner who leaves the stand unoccupied, expecting others (mostly people he does not know and will never meet) to pay on the honor system for what they take (Eric Uslaner 1992, pp. 14–15). There are many situations in which we seem to trust unknown others by default, without frequent disappointment (Verbeek 2002, pp. 140–141). Decisions to trust have been shown not to be based on risk information in some studies (Eckel and Wilson 2004). Indeed, some have even argued that we are under some kind of weak moral obligation to regard others in this way, until they are proven unreliable (see Thomas 1978). The question then is what, if anything, could make it epistemically rational to adopt a trust attitude on these grounds. So as not to lose a connection with a quantitative behavioral theory, Das and Teng suggest that this appearance of non-calculative, default trust is an illusion: estimates of the likelihood of a trusted person's performance can be posited below the surface as "unconscious calculations" about the good-will and competence of others, based on estimates of risk (2004, p. 99).

## Trust Beyond Rational Calculation

The second approach sees trust as an interpersonal belief that is essentially nonrational or non-calculative, involving to some extent a leap of faith. Such a view can originally be traced to Luhmann (1979), who held that trust is primarily a means of reducing complexity by relying on others instead of making an independent assessment of risk. As Guido Möllering sets out the idea, many philosophers of a rational choice orientation are led a certain distance in this direction by the need to acknowledge the occasional therapeutic or future oriented, rather than evidential, nature of trust. Placing trust is sometimes used as a means of cultivating reciprocal engagement and cooperation; in many cases it can actually help produce the effect of performance, even though there was no specific prior evidence this would occur. In this way trust is

“reflexive” (Möllerling 2006, pp. 80–84). But according to Möllerling, this does not go far enough, because this still assimilates trust to a calculation based on past performance and future consequences, now taken in a slightly broader sense. Möllerling advocates a more radical account that instead views trust as more fundamentally nonrational, according to which it is truly a “leap of faith” in which one suspends calculations about benefits and risks to some degree. On this view, trust does not just reduplicate an explanation that could already be provided by the rational choice paradigm, but can instead be usefully applied to empirical phenomena of cooperation that do not easily fit that paradigm, such as patients’ suspension of rational considerations when electing a surgery (Möllerling 2006, pp. 188–189). Another expression of this idea is that trust involves *optimism* about the performance of others (Jones 1996), an attitude in which despite the presence of risk a good outcome will be achieved (Nooitboom 2002).

If we are reluctant to postulate such a motivation for cooperation beyond a subjectively rational basis, then we can explicate the view more prosaically by claiming that the essential reasons of trust are substantially interpersonal, social, and/or moral instead of calculative. It is important not to conflate this non-calculative view of trust with the view that trust is emotive. On the one hand some emotions, e.g., fear, can be regarded as affective “calculations” of risk, and on the other hand some socially based judgments have none of the affect characteristic of emotional states. Thus, trust is properly based on the following kinds of considerations:

- The desire of the trusted to engage in future interaction with the trustor
- The desire of the trusted to protect their future reputation (Pettit 1995)
- The security of the institutional context in which the trusted person operates
- The moral qualities of the trusted person (see section ➤ [Trust as a Moral Attitude](#) below)
- General confidence that things will work out no matter what happens
- The ethical desirability of trust itself

That some of these are reasons for trust is already acknowledged by advocates of the staking model. But their acknowledgement is subject to the understanding that such elements can be converted into calculative factors in one’s judgment of the benefit and likelihood of different outcomes. Taking the reasons in this way disregards one of the principal motivations of the view under discussion, which is that trust is “a functional *alternative to rational prediction* for the reduction of complexity. Indeed, trust is to live as if certain rationally possible futures will not occur” (Lewis and Weigert 1985, p. 976, italics added; cited in Möllerling 2006, p. 83). Certain risks are therefore excluded from consideration at the moment of deciding to trust. On such a conception perfectly central, normal cases of trust would include situations in which no good calculative basis for trust is available, nor is employed (in terms of a concrete track record or an estimation of general reliability in similar situations), but willing reliance on another nonetheless occurs.

Such a view does a good job explaining the first of our earlier intuitive claims about the relationship between trust and risk, that trust formation and risk evaluation seem like quite different processes, and that risk evaluation and control tend to make trust irrelevant or out of place, rather than increasing it. Since trust is non-calculative, risk evaluation and control tend to push it aside. As for the second of our earlier claims about risk and trust, the non-calculative view of trust takes a paradoxical stance. On the one hand, it grants the normative claim that from a restricted rational choice point of view, justifying trust becomes more difficult as the

stakes increase. But it holds that trust can proceed without this type of justification, either on the basis of sheer optimism, or on the basis of interpersonal, social, or moral reasons. In order to have an interesting field of application in the real world, such a conception of trust invites the corresponding empirical hypothesis that the occurrence of willing reliance on others is not directly inversely proportional to the magnitude of risks perceived to be associated with this reliance. Evidence on this point is ambivalent. Empirical studies of the prisoner's dilemma and other similar game situations seem to indicate that people sometimes willingly rely on others even in the absence of calculative reasons to do so (Möllering 2006, p. 38; Hardin 2006, pp. 50–51). This suggests that such a non-calculative conception of trust may well have an interesting domain of application.

However, there are still philosophical worries about such a view. For example, Pamela Hieronymi has argued that the attitude of trust is conceptually constrained by the fact that it inherently answers the question “Is the other person trustworthy?” (Hieronymi 2008). In much the same way as belief in P answers the question “Is it the case that P?” and an intention to φ answers the question “Is φ to be done?” and the attitude of trust toward some person R answers the question “Is R trustworthy?” Although Hieronymi leaves open what kinds of considerations close the question of whether R is trustworthy, her account implies that in really adopting the attitude of trust, one is always committed to having sufficient reason for thinking that the other person is trustworthy. To the extent that her argument is plausible, it tethers the notion of trust to the reasons for thinking another person trustworthy. Genuine trust is not compatible with the presence of severe, realistic risks associated with reliance that are known to the truster and have not been ruled out, controlled, or hedged.

## Trust as a Moral Attitude

The third approach to the concept of trust sees it primarily as a moral attitude among intimates and community members, defining social spheres within which cooperative actions are safely pursued. A good example of this approach can be seen in the work of Caroline McLeod, who thinks that any notion of trust should first accommodate “prototypes” or central examples such as “child-parent relationships, intimate . . . relationships, and professional-client relationships” (2002, p. 16), and then address theoretically useful but more peripheral examples such as self-trust and trust between strangers. According to McLeod, the prototypical examples of trust are best seen as involving an ascription of certain moral and relationship-regarding qualities to the trusted person, such as moral integrity, and a shared perception of the relationship itself. These qualities ensure that the person will have *goodwill* toward us, a characteristic belief of trust first emphasized by Annette Baier (1986). The focus on trust as connected with the quality of intimate relationships can be traced back to the developmental psychologist Erik Erikson (1950), who held that the quality of the mother–child bond determines trust dispositions that are crucial for normal social development.

Baier holds that trust essentially involves remaining vulnerable to the actions of another person, partly due to the discretion given to that person within a domain of activity (Baier 1986). This vulnerability is especially present in intimate relationships for several reasons: because the domain of shared activity is large; because the discretion given is considerable; and because the relationship itself is often valued intrinsically, so that something extra is at stake should a failure or breakdown occur. This is sometimes manifested in a disposition to *feelings* of vulnerability

as well, something noted by empirical studies of partner trust (Kramer and Carnevale 2001). On Baier's view, we willingly increase our vulnerability to another because we are confident of the *competence* and the *goodwill* of the other person, although we often do not consider these factors consciously. Vulnerability provides a link with risk on Baier's account. Correspondingly, feelings of vulnerability or security provide a link with risk perception.

In addition, the *state* (as opposed to the feeling) of vulnerability is conceptually related to risk. In talking about the causal components of risk, it is common in technical literature on risk management to distinguish between vulnerability, exposure, and hazard (Renn 2008, p. 69). Vulnerability is a (relational) property of a thing that makes it potentially susceptible to damage or harm, should exposure to a hazard source occur. Baier does not draw this distinction between vulnerability and exposure, but it is instructive to do so. We might even restate Baier's view by saying that trust involves, not increasing one's inherent vulnerability, but instead increasing one's *exposure* to a potential hazard source – in this case another person – by giving them discretion over something important. This, in turn, creates a feeling of vulnerability.

The reason philosophers often claim that the attitude of trust has an essential moral dimension is that trust seems intuitively to commit one to certain characteristic morally tinged responses in cases where another person fails to perform as they were trusted to do. Moral philosophers are careful to distinguish two fundamentally different kinds of expectation that we can take toward other people when we rely on them (Holton 1994; Faulkner 2007). *Predictive* expectations are simple beliefs that the future will go one way or another. They do not inherently involve a personal or emotional commitment to its going one way or another. When one relies on the future being a certain way in this predictive sense, one is at most disappointed if one's expectation is not met. *Normative* expectations, on the other hand, involve a prescriptive judgment or assumption that the future *should* go a particular way. If the future does not go this way – if a person does not do what she has agreed to do, for example – then moral disapprobation and other richly evaluative or moral judgments are appropriate. In cases where one willingly relies on another person, but is not disposed toward any moral judgment such as blame or betrayal toward them if they do not perform, intuitively this does not seem like a central case of trust. It is *mere reliance*, a simple prediction that a person will behave a certain way, not trust.

In its refined form, then, trust seems to have a moral dimension. Philosophers have differed in how they describe this moral component, however. Some philosophers have characterized it as a requirement that there should be mutually shared values between the trusting person and the trusted person (McLeod 2002). Others have suggested a weaker condition than that of shared moral values, since it seems that I can trust somebody even when I know them to have rather different values and standards than myself. It has been variously suggested that in trusting I commit myself to blaming a trusted person if he or she does not perform (Holton 1994), holding them responsible for performing (Walker 2006), or taking a moral expectation toward them (Nickel 2007). None of these suggestions require that the trusted person share the values of the trusting person, only that they be sufficiently responsive to moral requirements and situational expectations that they are suited to be the objects of moral attitudes.

If we think of trust as a morally loaded attitude, what does this mean for the relationship between trust and risk? On this view, trust presupposes an awareness of moral expectations and responsibilities in the trusted person, making that person more trustworthy and reducing the

human risks in interpersonal reliance. If Q, from our earlier example, has as part of her trust a moral expectation of Ron, the content of which is that he keeps information about the group confidential, this presupposes a view of Ron on which he is capable of responding to the morally salient features of the situation, including the vulnerable situation of Q and her group. Thus, if Q is right in her moral expectations, this minimizes the purely interpersonal, strategic risk in relying on Ron, allowing them jointly to focus their attention on their other goals within their cooperative activity, including the avoidance of other risks.

On such a view, one would often expect to see extensive risk evaluation of a person during the process in which trust is established, but once it has been established this activity would largely cease, allowing one to turn one's attention elsewhere. (However, in some relationships, e.g., parent-child relationships, trust will simply be presupposed rather than established.) Continuing surveillance is therefore a sign that trust has not yet been achieved or that it has failed (Baier 1986). This partially captures the first intuitive point discussed earlier in section ➤ [Two Relationships Between Trust and Risk](#), according to which extensive scrutiny of risks is incompatible with trust. However, it also leaves room for relationships in which full trust has yet to be established or is never reached, so that risk evaluation is still ongoing or there are persistent feelings of vulnerability and associated anxiety.

Our second intuition above was that when the risks are greater, trust is more difficult to justify. On moral conceptions of trust, the attitude of trust is partly justified by one's reasons for thinking that the trusted person has certain moral qualities, or is capable of responding to moral expectations. We could therefore look to this feature to explain why trust is more difficult to justify under conditions of risk. Social psychology has shown that people's tendency to do the virtuous or morally required thing *toward a person unknown to them* is highly susceptible to background conditions such as time pressure (Darley and Batson 1973). This suggests that under adverse conditions, moral responsibility is not usually sufficient to generate altruistic or cooperative behavior. Highly risky situations may also create circumstances in which people's moral characteristics are less reliable toward unfamiliar persons. Thus trust in strangers would be difficult to justify on the basis of attributions of moral responsibility. On the other hand, trust toward intimates or people within one's community might be much better justified under such conditions. The moral dispositions of close associates might be expected to "kick in" especially under conditions of risk and adversity, making them even more trustworthy under those conditions. Thus, here too, the moral view of trust only partly supports our earlier intuitive association between risk and trust. (It is important to note here that there are striking instances in which trust in strangers under highly adverse conditions also turns out to be justified, e.g., those discussed in Monroe 1996.)

## Scientific Approaches to Trust and Risk

---

The three conceptual approaches to trust discerned above (trust as interpersonal staking, trust as nonrational, and trust as moral attitude) are also useful for characterizing and subdividing the scientific discussion concerning the development and evolution of trust. In what follows, we reconsider these three approaches, looking at the scientific research carried out within each paradigm. The consistency and explanatory interest of this scientific research may help to settle which approach is correct, or it may imply that we should take a pluralistic view of the nature of trust for empirical purposes.

## The Science of Trust as Rational Risk Taking

Trust as risk taking under uncertainty is at the heart of many game-theoretic approaches to trust: one tries to determine the factors inhibiting and enabling the evolution of trust, given *calculative self-interested agents*. For instance, many scholars have used prisoner's dilemmas as a way of studying trust. In the classic prisoner's dilemma, two players can choose between two moves, either "cooperate" or "defect". Each player gains when both cooperate. But if only one of them cooperates, the other one, the defector, will gain *more*. If both defect, both lose, but not as much as when an agent's cooperative act is defected by the other. Since there is a risk of greater expected loss in case of cooperation (namely, when the other player defects), the best strategy for securing one's own safety is to defect – but this is a suboptimal strategy in terms of collective benefit. In this game, it is in the interest of the individual to forego cooperation, and to defect. The aim, then, is to identify the conditions under which the payoffs of cooperation start to outweigh the payoffs of individual action. If cooperation does emerge, the implication from cooperation to trust seems straightforward: one can expect an agent to cooperate only when she trusts the other to reciprocate her cooperative act.

Morton Deutsch was one of the first to study these ideas empirically and systematically (Deutsch 1960). He looked at how individual trust orientations (cooperative, individualistic, or competitive) affected the likelihood of individuals cooperating, and found that individuals with a cooperative general trust orientation were also more likely to make cooperative choices in prisoners dilemma situations. Deutsch used standard two-player nonzero-sum games, in which players were requested to imagine they were oriented either cooperatively (before playing, players were asked to consider themselves to be partners), individualistically (players were asked to play just to make as much money as possible for themselves), or competitively (players were asked to play just to make as much money as possible for themselves and also to do better than the other). Deutsch found that cooperation was most likely to develop when both players' trust orientations were cooperative.

The main problem with Deutsch's approach (and that of his followers) is that it does not say much about the conditions under which trust develops, unless one takes the cooperative behavior of a person as an indication of that person's disposition to trust, as Deutsch did. Under that condition, however, the exercise becomes circular, since the measure of trust (cooperative behavior) is exactly the feature that trust was said to cause (Cook and Cooper 2003). In other words, when an agent makes a choice in a prisoner's dilemma, she does two things: she decides whether or not to trust the other, and simultaneously, whether to honor the possible trust placed in her. Consequently, her decision to cooperate does not need to reflect her trust, for it might just as well indicate her willingness to reciprocate the other's possible act of trust.

For these reasons, scholars started to look for new game-theoretic protocols in which trust and reciprocity could be dissociated. One such protocol, currently widely used in economics and psychology, is the so-called trust-honor game (see, e.g., Snijders and Keren 1999). Basically it is a sequential prisoner's dilemma, with players no longer making decisions simultaneously, but consecutively. First, player 1 has to decide whether or not to trust player 2, without knowing what the latter will decide; second, player 2, with knowledge of the first player's decision, decides whether to honor the trust by reciprocating.

To get an idea of how trust-honor games work, consider the so-called investment game, developed by Berg et al. (1995). Two players get \$10 each. The game consists of two stages: the trust *placing* and the trust *honoring* stage. In the first stage, player 1 needs to decide how much

money to pass to an anonymous player 2. All the money which is passed is increased by a factor greater than 1, say, 3. So if player 1 passes \$10, player 2 will receive \$30, resulting in the allocation (\$0, \$40). In the second stage, player 2 needs to decide whether or not to honor the trust placed in her: she gets the opportunity either to keep all the money or to send an amount  $x$  back to player 1. For all  $x$ 's smaller than 30 but greater than 10, both players will be better off than in the original allocation (\$10, \$10). For an increase in payoff for either player to occur at all, however, the first stage of the game is crucial: player 1 needs to be willing to take a risk on player 2.

In the study of Berg et al. (1995), players were not only anonymous, their interaction was one shot (taking away the possible effects of reputation building), and there was no opportunity for them to punish dishonored trust. Notwithstanding these conditions, the researchers found that their subjects did both place trust (by sending money) and honor trust (by sending money back). Trust is calculated with the likelihood of reciprocity in mind, and since reciprocity is assumed by the trustor “as a basic element of human behavior” this results in his extending trust even to an anonymous counterpart (p. 122). The reciprocity of an anonymous partner is interesting because one cannot use similarity or other identifying characteristics to gauge her likely future performance. The trustor's reason for positing reciprocation depends on the mere idea of the game situation or of an agent in that situation. Follow-up studies changed the incentive structure of the investment game, added mechanisms of reputation building and punishment, made the encounters between players non-anonymous, looked at cultural background effects, and so on, but one premise remained constant: trust is measured by looking at the *risk* a player is willing to take on the other. In the setup above, player 1's behavior would indicate a high level of trust in case she passed \$10 to player 2, a low level in case she did not pass any money. Thus, Cook and Cooper (2003) write, “First, I decide whether or not to ‘trust’ you (or take a risk on you) and cooperate on the first play of the game, then you must decide whether or not to ‘honor’ that trust by cooperating in turn. Clearly, this behavior can be viewed as risk taking by the first player” (p. 217).

So in these studies, an explanation of trust simply *is* an explanation of the conditions under which subjects decide in favor of social risk taking. Social risk taking, in turn, is calculative, as argued in section [Trust as Interpersonal Staking](#): one takes a risk (i.e., one trusts) in the hope of benefiting afterward (receiving more than the \$10 one started with). If trust is a strategy of generating higher payoffs for individuals, and if these individuals are calculative utility maximizers, trust games would offer a reasonable explanation indeed for why in such essentially self-interested agents as humans, an (apparent) prosocial trait such as trust (or cooperation, more generally) could have evolved.

It is worth briefly discussing the selective pressure commonly invoked here – something which will prove useful for understanding section [The Science of Trust as a Moral Attitude](#). The prehistorical background against which the evolution of cooperation is usually set is a world that was becoming increasingly harsh. In particular, early humans started to cooperate to cope with (1) increased climatic and seasonal variability (Potts 1998; Ash and Gallup 2007); (2) the colonization of new environments, requiring new, cooperative modes of foraging (Kaplan et al. 2000); and/or (3) increased intraspecies competition, given the expansion of hominin populations (Humphrey 1976; Alexander 1989; Dunbar 1998). In these challenging environments, an individual's self-interest was best served by the individual's contributing toward the interest of the group. From a selective point of view, cooperation succeeded where individual efforts began to fail.

The prime cooperative interaction to be explained in these evolutionary scenarios is between genetically *unrelated* agents, namely, how unrelated agents began to form bonds to settle down and defend new environments, or how some 1.5 million years ago hunter *Q* started to trust hunter *R* not to comprise *Q*'s life by dropping out of the hunting coalition early, and to do his fair share of stone throwing and clubbing. In other words, it is assumed that genetically *related* individuals have a natural incentive to cooperate, and that therefore, non-kin cooperation has explanatory prevalence over cooperation among kin. Although this methodological choice has yielded neat models and explanations of why trust and other prosocial behaviors *might* have developed in humans, it has obscured some of the non-calculative aspects of trust, which are discussed in the next two subsections.

In summary, in models that assume utility maximizing agents, it is common to treat trust simply as the willingness of an agent to take a risk on another agent. The aim, then, is to establish the conditions under which these calculative agents may develop such calculative form of trust. The prime explanandum of these models is economic cooperation between unrelated agents, while neglecting cooperation among kin.

## The Science of Trust as Non-Calculative

There are two strands of empirical research which question the strong link between trust and risk taking as pictured in staking accounts. The first relates to a remark made in our conceptual discussion of trust as interpersonal staking (section [Trust as Interpersonal Staking](#)), namely that, contrary to what staking accounts would predict, extensive risk reduction (e.g., through extensive risk assessment) should decrease rather than increase levels of trust. Empirical evidence, now, indeed suggests that if one takes away the risk of defection, one takes away the substrate for trust.

In empirical research, risk reduction is usually introduced by letting agents make formal binding agreements about the transaction in which they are about to engage (see, e.g., Molm et al. [2000, 2009](#)). These are often called *negotiated* exchanges: one negotiates the conditions of the transaction, and secures them through some binding agreement (as is the case in most contemporary market exchanges). Both partners know in advance what each will give and get; the agreement ensures that both partners live up to their promise. These exchanges contrast with so-called *reciprocal* exchanges. The latter are riskier in that partners, at the moment of performing an altruistic act, do not know whether the act will be reciprocated in the future. The altruistic act, one hopes, will elicit altruism in the other, although there is no guarantee to that effect.

Molm and colleagues did not use a behavioral measure of trust (e.g., cooperative behavior), but rather an attitudinal one. That is, they asked subjects about their general commitment and trust toward their exchange partner. They found that trust is more likely to develop in reciprocal than negotiated exchange. In negotiated exchange, one might be *confident* that the other will do as promised, yet remain skeptical about the other's trustworthiness. In reciprocal exchange, by contrast, trustworthiness is tested through real interaction; one gets the opportunity to infer the other's trustworthiness from her behavior rather than from the promises she makes. While interacting, partners typically come to trust each other more, evaluate them more positively, and feel more committed to the relationship. To be sure, both negotiated and reciprocal exchange may yield a fair reallocation of goods. Nonetheless, they have different extra payoffs: increased levels of certainty versus increased levels of trust.

Often the contrast is framed somewhat differently, namely, by drawing on the distinction between cognition-based and affect-based trust (see McAllister 1995). On this account, both negotiated and reciprocal exchanges may yield trust, but of different kinds. Negotiated exchange involves cognition-based trust, which is based on beliefs and estimations of a partner's reliability, and which is abandoned in case the partner behaves differently from how she was expected to behave. Conversely, reciprocal exchange results in affect-based trust. Here beliefs about the other's reliability are complemented with affective states of care and personal regard, and often in addition with a sense of forgiveness for occasional instances in which the partner dishonors the trust placed in her.

The second line of empirical research that undermines the idea of trust being merely calculative suggests that risk taking and trust placing rely on two different psychological mechanisms. Note what we should expect if they did not: risk-aversive people should exhibit a lower propensity to engage in relations of trust, and conversely, risk-minded people should be more trust prone (Ben-Ner and Putterman 2001). Several studies have tried to establish this link, but mostly without success (see, e.g., Eckel and Wilson 2004; Ashraf et al. 2007; Fehr 2009; Ben-Ner and Halldorsson 2010). For instance, in the most comprehensive study, Ben-Ner and Halldorsson (2010) looked for correlations between several measures of trust and several measures of risk orientation. Measures of trust included both behavioral measures (i.e., how subjects behaved in an investment game) and so-called survey measures (determined by means of a questionnaire), indicating a subject's general sense of trust in other people. Also with respect to risk attitudes, both behavioral and survey measures were used. Ben-Ner and Halldorsson found that no measure of risk attitude correlated with any of the measures of trust used. (In contrast, gender and personality – extroversion, openness, agreeableness, conscientiousness, and neuroticism – did predict trusting behavior.)

That risk taking and trust building depend on different psychological mechanisms is also suggested by recent studies on the psychological and behavioral effects of certain hormones. Testosterone, e.g., has been shown to increase risk taking (Apicella et al. 2008), but to decrease trust (Bos et al. 2010). Oxytocin has precisely the opposite effect: it decreases risk taking, but increases trust (Kosfeld et al. 2005).

In sum, both strands of empirical research point to a shortcoming in attempts to characterize trust in terms of risk taking: staking accounts largely ignore the profoundly interpersonal and social aspects of trust. There might be good methodological reasons to do so (e.g., to keep models tractable), but it is important to bear in mind that one might miss out on some salient characteristics of trust. Yet, the research described here shares with staking accounts the concern of explaining trust primarily among strangers (or non-kin). That is what sets them apart from the approach considered next.

## The Science of Trust as a Moral Attitude

As we remarked at the end of subsection [The Science of Trust as Rational Risk Taking](#), it is common to argue that human hypersociality evolved to cope with environments that became ever more challenging. On this account, trust is basically a strategy to safeguard one's own fitness indirectly. By enabling cooperation among non-kin, trust increases the fitness of the collective.

Recently, this dominant view has come under attack. Sarah Hrdy (2009), e.g., argues that human cooperative behavior did not evolve in a context of competition (with other groups of

humans), but rather in a context of cooperative childcare among kin and as-if kin. The idea is that the delayed maturity characteristic of humans requires childcare that cannot be provided by mothers alone. A large fraction of the 13 million calories that are needed to rear a modern human from birth to maturity (approx. age 15–16), for instance, is provided not by the mother, but by other caregivers. In contrast to the great apes, human fathers and older siblings invest fairly extensively in their offspring and younger siblings. Even more crucial is the role of grandmothers: they take over when the mother is too busy, when the mother dies early, or when the mother is simply giving birth to the next infant. According to Hawkes, O’Connell, Blurton Jones, and colleagues, this explains the unusual trait of humans to live actively many years after the birth of their final child (Hawkes et al. 1999). Menopause is an adaptation enabling longer childhoods, and in virtue thereof, increased braininess.

Cooperative childcare (or cooperative breeding, as it is often called) is dependent on three factors. First, the child must be able to elicit attention. It must display its vulnerability, and try to solicit the care not only of its mother, but also of more remote caregivers. Second, the mother must be able to delegate some of her work. She must be willing to put her baby’s fate in the hands of others. In other words, she must trust her helpers, and assume their moral qualities, namely, good intentions and selfless motives. In fact, human mothers are unique in this respect. Unlike the other great apes, human mothers do not hold jealously onto their infants, but willingly allow others to hold them. A human mother has a default sense of trust: she assumes – in the absence of counterevidence – that others will not harm her helpless child. If these strangers did harm the baby nonetheless, there would be a clear sense of wrongdoing, backed up by moral or proto-moral attitudes. Third, both the mother and her helpers (grandparents, fathers, siblings, and other as-if kin) must sense and be responsive to the vulnerability and to the particular needs of the infant. Mothers are particularly well-adapted on this score, as they tend to be attuned to the slightest perturbations in the conditions of their young, and to perceive all neonates as attractive (Hrdy 2009). Arguably, such a positive attitude toward babies applies to the human species in general, since it is also commonly found (in varying degrees) in male adults, teens, adolescents, and so forth.

In the view of authors such as Hrdy, the prosocial behavior exhibited in cooperative breeding forms the cornerstone of our morality. In the context of cooperative breeding, early humans developed their capacity to form relations of trust with kin and as-if kin, a capacity which was extended to non-kin only later. In conclusion, from a scientific perspective it seems to make good sense to view trust as an attitude that originates in our dealings with intimates and community members – as expressed by Carolyn McLeod in Section 4.A. It implies a sphere in which even the most valued things, such as one’s child, can be safely entrusted to others. Trust in cooperative breeding is the prototypical form of trust, from which other more peripheral examples of trust derive.

## Further Research

---

In this final section, we set out a few areas for future philosophical research. As suggested in the previous section, there is still empirical research to be done within the conceptual paradigms of trust. “Empirical philosophy” could contribute to this project. Recent philosophical “experiments” have provided us with additional information about people’s intuitive conceptions of intentionality (e.g., Knobe 2003), weakness of will (Mele 2010), causation (Livengood and

Machery 2007), and consciousness (Knobe and Prinz 2008), so there is no principled reason why similar methods could not yield novel insights regarding (folk) conceptions of trust. Such research may eventually suggest that one of the conceptions of trust is more theoretically interesting or useful than the others, or that there is a way of reconciling them. Such work should take up the relationship of trust and risk as an important challenge.

Second, greater philosophical development of some of the underlying conceptual paradigms would be useful to the understanding of human responses to risk. The non-calculative conception of trust stands in need of greater philosophical conceptualization, a point that Möllering also makes (2006, p. 126). Much of the conceptual work on this theory of trust has been carried out by sociologists. Philosophers may also have something to contribute to such an account of trust. It may also be useful to ask whether the moral account can be reconciled with either the calculative or the non-calculative account of trust, explaining how moral considerations make trust more strategically rational, or how they help people to bypass the need for strategic rationality. Perhaps, too, if one distinguished risk and uncertainty from one another more sharply, or drew distinctions between different kinds of risks and uncertainties, the conceptual relation between risk, uncertainty, and trust would become more evident. Another strategy might be to distinguish more sharply between descriptive or conceptual accounts of trust (i.e., concerning when something *is* trust) and normative accounts (i.e., concerning when one *should* trust).

Finally, an area of particular interest in future philosophical work is understanding how trust is related to technological risk. For several reasons, trust in technology has become a key issue in recent years. First of all, as Meijboom (2008, p. 31) points out, food production and other means of satisfying basic welfare have become increasingly large scale, decentralized, and socially and technologically complex. In this context, perception of technological risk is prevalent as a background fear. Ulrich Beck (1992) famously argues that the imposition of technological risks has reached a critical juncture, at which we must reconsider our practices of justifying and imposing such risks. Horror and science fiction films in which technology gives rise to bad consequences are evidence that this fear resonates with the public. Risk is increasingly impersonal. As Renn puts it, “personal experience of risk has been increasingly replaced by information about risks, and individual control over risk by institutional risk management. As a consequence, people rely more than ever on the credibility and sincerity of those from whom they receive information about risk” (2008, p. 222). However, Onora O’Neill suggests that the solution to fears of technological risks does not lie in making more data available to the public. Paradoxically, she points out, greater openness has not created greater trust in the UK health care system, for example (2002a, pp. 72–73; 2002b, pp. 134–135). After all, the public has a difficult time processing information about risks, and does not have time to assess all the data with respect to every technology they could rely upon. These remarks suggest that trust is crucial to understanding public attitudes toward technological risks. It could be that a philosophical approach emphasizing the centrality of trust to the use of technology would help reconcile technocratic and public attitudes about technological risks.

In this chapter, we have shown that although the relationship of trust and risk is still unsettled, and is grounded in underlying disagreement about the nature of trust, that disagreements about this relationship can be given a clear characterization. This may lead to such disagreements eventually being settled by further methodological reflection and empirical study, or it may just mean that different paradigms of trust can be used for different purposes in thinking about risk. In that case, a sketch of the available paradigms for thinking about this relationship, such as we have given here, will be of some value.

**Abstract:** When a risk materializes, it is common to ask the question: who is responsible for the risk being taken? Despite this intimate connection between risk and responsibility, remarkably little has been written on the exact relation between the notions of risk and responsibility. This contribution sets out to explore the relation between risk and responsibility on basis of the somewhat dispersed literature on the topic and it sketches directions for future research. It deals with three more specific topics. First we explore the conceptual connections between risk and responsibility by discussing different conceptions of risk and responsibility and their relationships. Second, we discuss responsibility for risk, paying attention to four more specific activities with respect to risks: risk reduction, risk assessment, risk management, and risk communication. Finally, we explore the problem of many hands (PMH), that is, the problem of attributing responsibility when large numbers of people are involved in an activity. We argue that the PMH has especially become prominent today due to the increased collective nature of actions and due to the fact that our actions often do not involve direct harm but rather risks, that is, the possibility of harm. We illustrate the PMH for climate change and discuss three possible ways of dealing with it: (1) responsibility-as-virtue, (2) a procedure for distributing responsibility, and (3) institutional design.

## Introduction

---

Risk and responsibility are central notions in today's society. When the Deepwater Horizon oil rig exploded in April 2010 killing 11 people and causing a major oil spill in the Gulf of Mexico, questions were asked whether no unacceptable risks had been taken and who was responsible. The popular image in cases like this appears to be that if such severe consequences occur, someone must have, deliberately or not, taken an unacceptable risk and for that reason that person is also responsible for the outcome. One reason why the materialization of risks immediately raises questions about responsibility is our increased control over the environment. Even in cases of what are called natural risks, that is, risks with primarily natural rather than human causes, questions about responsibility seem often appropriate nowadays. When an earthquake strikes a densely populated area and kills thousands of people, it may be improper to hold someone responsible for the mere fact that the earthquake occurred, but it might well be appropriate to hold certain people responsible for the fact that no proper warning system for earthquakes was in place or for the fact that the buildings were not or insufficiently earthquake resistant. In as far as both factors mentioned contributed to the magnitude of the disaster, it might even be appropriate to hold certain people responsible for the fatalities.

The earthquake example shows that the idea that it is by definition impossible to attribute responsibility for natural risks and that such risks are morally less unacceptable is increasingly hard to maintain, especially due to technological developments. This may be considered a positive development in as far it has enabled mankind to drastically reduce the number of fatalities, and other negative consequences, as a result of natural risks. At the same time, technological development and the increasing complexity of society have introduced new risks; the Deepwater Horizon oil rig is just one example. Especially in the industrialized countries, these new risks now seem to be a greater worry than the traditional so-called natural risks. Although these new risks are clearly man-made, they are in practice not always easy to control. It is also often quite difficult to attribute responsibility for them due to the larger number of people involved; this is sometimes referred to as the "problem of many hands" (PMH), which we will describe and analyze in more detail in section ➤ [Further Research: Organizing Responsibility for Risks](#). Before we do

so, we will first discuss the relation between risk and responsibility on a more abstract, conceptual level by discussing different conceptions of risk and responsibility and their relation, in section [Conceptions of Risk and Responsibility](#). Section [Responsibility for Risks](#) focuses on the responsibility for dealing with risk; it primarily focuses on so-called forward-looking moral responsibility and on technological risks.

While risk and responsibility are central notions in today's society and a lot has been written about both, remarkably few authors have explicitly discussed the relation between the two. Moreover, the available literature is somewhat dispersed over various disciplines, like philosophy, sociology, and psychology. As a consequence, it is impossible to make a neat distinction between the established state of the art and future research in this contribution. Rather the contribution as a whole has a somewhat explorative character. Nevertheless, sections [Conceptions of Risk and Responsibility](#) and [Responsibility for Risks](#) mainly discuss the existing literature, although they make some connections that cannot be found in the current literature. Section [Further Research: Organizing Responsibility for Risks](#) explores the so-called problem of many hands and the need to organize responsibility, which is rather recent and requires future research, although some work has already been done and possible directions for future research can be indicated.

## Conceptions of Risk and Responsibility

---

Both risk and responsibility are complex concepts that are used in a multiplicity of meanings or conceptions as we will call them. Moreover, as we will see below, while some of these conceptions are merely descriptive, others are clearly normative. Before we delve deeper into the relation between risk and responsibility, it is therefore useful to be more precise about both concepts. We will do so by first discussing different conceptions of risk (section [Conceptions of Risk](#)) and of responsibility (section [Conceptions of Responsibility](#)). We use the term “conception” here to refer to the specific way a certain concept like risk or responsibility is understood. The idea is that while different authors, approaches, or theories may roughly refer to the same concept, the way they understand the concept and the conceptual relations they construe with other concepts is different. After discussing some of the conceptions of risk and responsibility, section [Conceptual Relations Between Risk and Responsibility](#) discusses conceptual relations between risk and responsibility.

### Conceptions of Risk

---

The concept of risk is used in different ways (see [Chap. 3, The Concepts of Risk and Safety](#), in this handbook). Hansson (2009, pp. 1069–1071), for example, mentions the following conceptions:

1. Risk = an *unwanted event* that may or may not occur
2. Risk = the *cause* of an unwanted event that may or may not occur
3. Risk = the *probability* of an unwanted event that may or may not occur
4. Risk = the statistical expectation value of an unwanted event that may or may not occur
5. Risk = the fact that a decision is made under conditions of *known probabilities* (“decision under risk”)

The fourth conception has by now become the most common technical conception of risk and this conception is used usually in engineering and in risk assessment. The fifth conception is common in decision theory. In this field, it is common to distinguish decisions under risk from decisions under certainty and decisions under uncertainty. Certainty refers to the situation in which the outcomes (or consequences) of possible actions are certain. Risk refers to the situation in which possible outcomes are known and the probabilities (between 0 and 1) of occurrence of these outcomes are known. Uncertainty refers to situations in which possible outcomes are known but no probabilities can be attached to these outcomes. A situation in which even possible outcomes are unknown may be referred to as ignorance.

The fifth, decision-theoretical conception of risk is congruent with the fourth conception in the sense that both require knowledge of possible outcomes and of the probability of such outcomes to speak meaningfully about a risk. One difference is that whereas the fifth conception does not distinguish between wanted and unwanted outcomes, the fourth explicitly refers to unwanted outcomes. Both the fourth and the fifth conception are different from the way the term “risk” is often used in daily language. In daily language, we commonly refer to an undesirable event as a risk, even if the probability is unknown or the exact consequences are unknown. One way to deal with this ambiguity is to distinguish between hazards (or dangers) and risks. Hazard refers to the mere possibility of an unwanted event (conception 1 above), without necessarily knowing either the consequences or the probability of such an unwanted event. Risk may then be seen as a specification of the notion of hazard. The most common definition of risk in engineering and risk assessment, and more generally in techno-scientific contexts, is that of statistical expectation value, or the product of the consequences of an unwanted event and the probability of the unwanted event occurring (meaning 4 above). But even in techno-scientific contexts other definitions of risk can be found. The International Program on Chemical Safety, for example, in an attempt to harmonize the different meanings of terms used in risk assessment defines risk as: “The probability of an adverse effect in an organism, system, or (sub)population caused under specified circumstances by exposure to an agent” (International Program on Chemical Safety 2004, p. 13). This is closer to the third than the fourth conception mentioned by Hansson. Nevertheless, the International Program on Chemical Safety appears to see risk as a further specification of hazard, which they define as: “Inherent property of an agent or situation having the potential to cause adverse effects when an organism, system, or (sub)population is exposed to that agent” (International Program on Chemical Safety 2004, p. 12).

Conceptions of risk cannot only be found in techno-scientific contexts and in decision theory, but also in social science, in literature on risk perception (psychology), and more recently in moral theory (for a discussion of different conceptions of risk in different academic fields, see Bradbury 1989; Thompson and Dean 1996; Renn 1992; Shrader-Frechette 1991a). We will below discuss some of the main conceptions of risk found in these bodies of literature. The technical conception of risk assumes, at least implicitly, that the only relevant aspects of risk are the magnitude of certain unwanted consequences and the probability of these consequences occurring. The conception nevertheless contains a normative element because it refers to *unwanted* consequences (or events). However, apart from this normative element, the conception is meant to be descriptive rather than normative. Moreover, it is intended to be context free, in the sense that it assumes that the only relevant information about a risky activity is the probability and magnitude of consequences (Thompson and Dean 1996). Typically, conceptions of risk in psychology, social science, and moral theory are more

contextual. They may refer to such contextual information as by whom the risk is run, whether the risk is imposed or voluntary, whether it is a natural or man-made risk, and so on. What contextual elements are included, and the reason for which contextual elements are included is, however, different for different contextual conceptions of risk.

The psychological literature on risk perception has established that lay people include contextual elements in how they perceive and understand risks (e.g., Slovic 2000). These include, for example, dread, familiarity, exposure, controllability, catastrophic potential, perceived benefits, time delay (future generations), and voluntariness. Sometimes the fact that lay people have a different notion of risk than experts, and therefore estimate the magnitude of risks differently, is seen as a sign of their irrationality. This interpretation assumes that the technical conception of risk is the right one and that lay people should be educated to comply with it. Several authors have, however, pointed out that the contextual elements included by lay people are relevant for the acceptability of risks and for risk management and that in that sense the public's conception of risk is "richer" and in a sense more adequate than that of scientific experts (e.g., Slovic 2000; Roeser 2006, 2007). In the literature on the ethics of risk it is now commonly accepted that the moral acceptability of risks depends on more concerns than just the probability and magnitude of possible negative consequences (see [Chap. 30, Ethics and Risk](#), in this handbook). Moral concerns that are often mentioned include voluntariness, the balance and distribution of benefits and risks (over different groups and over generations), and the availability of alternatives (Asveld and Roeser 2009; Shrader-Frechette 1991b; Hansson 2009; Harris et al. 2008; Van de Poel and Royakkers 2011).

In the social sciences, a rich variety of conceptions of risk have been proposed (Renn 1992) (see [Chap. 40, Sociology of Risk](#), in this handbook). We will not try to discuss or classify all these conceptions, but will briefly outline two influential social theories of risk, that is, cultural theory (Douglas and Wildavsky 1982) and risk society (Beck 1992). Cultural theory conceives of risks as collective, cultural constructs (see [Chap. 28, Cultural Cognition as a Conception of the Cultural Theory of Risk](#), in this handbook). Douglas and Wildavsky (1982) distinguish three cultural biases that correspond to and are maintained by three types of social organization: hierarchical, market individualistic, and sectarian. They claim that each bias corresponds to a particular selection of dangers as risks. Danger here refers to what we above called a hazard: the (objective) possibility of something going wrong. According to Douglas and Wildavsky, dangers cannot be known directly. Instead they are culturally constructed as risks. Depending on the cultural bias, certain dangers are preeminently focused on. Hierarchists focus on risks of human violence (war, terrorism, and crime), market individualists on risks of economic collapse, and sectarians on risks of technology (Douglas and Wildavsky 1982, pp. 187–188).

Like Douglas and Wildavsky, Ulrich Beck in his theory of risk society sees risk as a social construct. But whereas Douglas and Wildavsky focus on the cultural construction of risks and believe that various constructions may exist side by side, Beck places the social construction of risk in historical perspective. Beck defines risk as "*a systematic way of dealing with hazards and insecurities induced and introduced by modernization itself*" (Beck 1992, p. 21, emphasis in the original). Speaking in terms of risks, Beck claims, is historically a recent phenomenon and it is closely tied to the idea that risks depend on decisions (Beck 1992, p. 183). Typically for what Beck calls the "risk society" is that it has become impossible to attribute hazards to external causes. Rather, all hazards are seen as depending on human choice and, hence, are, according to Beck's definition of these notions, conceived as risks. Consequently, in risk society the

central issue is the allocation of risk rather than the allocation of wealth as it was in industrial society.

Some authors have explicitly proposed to extend the technical conception of risk to include some of the mentioned contextual elements. We will briefly outline two examples. Rayner (1992) has proposed the following adaption to the conventional conception of risk:

$$R = (P \times M) + (T \times L \times C)$$

with

R = Risk

P = Probability of occurrence of the adverse event

M = Magnitude of the adverse consequences

T = Trustworthiness of the institutions regulating the technology

L = Acceptability of the principle used to apportion liabilities for undesired consequences

C = Acceptability of the procedure by which collective consent is obtained to those who must run the consequences

Although this conception has a number of technical difficulties, it brings to the fore some of the additional dimensions that are important not just for the perception or cultural construction of risks but also for their regulation and moral acceptability.

More recently, Wolff (2006) has proposed to add cause as a primary variable in addition to probability and magnitude to the conception of risk. The rationale for this proposal is that cause is also relevant for the acceptability of risks. Not only may there be a difference between natural and man-made risks, but also different man-made risks may be different in acceptability depending on whether the human cause is based on culpable or non-culpable behavior and the type of culpable behavior (e.g., malice, recklessness, negligence, or incompetence). We might have good moral reasons to consider risks based on malice (e.g., a terrorist attack) less acceptable than risks based on incompetence even when they are roughly the same in terms of probability and consequences. In addition to cause, Wolff proposes to add such factors as fear (dread), blame, and shame as secondary variables that might affect each of the primary variables. Like in the case of Rayner's conception, the technicalities of the new conception are somewhat unclear, but it is definitively an attempt to broaden the conception of risk to include contextual elements that are important for the (moral) acceptability of risks.

Rayner's and Wolff's proposals raise the question whether all factors which are relevant for decisions about acceptable risk or risk management should be included in a conceptualization of risk. Even if it is reasonable to include moral concerns in our decisions about risks, it may be doubted whether the best way to deal with such additional concerns is to build them into a (formal) conception of risk.

## Conceptions of Responsibility

Like the notion of risk, the concept of responsibility can be conceptualized in different ways. One of the first authors to distinguish different conceptions of responsibility was Hart (1968, pp. 210–237) who mentions four main conceptions of responsibility: role responsibility, causal responsibility, liability responsibility, and capacity responsibility. Later authors have

distinguished additional conceptions, and the following gives a good impression of the various conceptions that might be distinguished (Van de Poel 2011):

1. Responsibility-as-cause. As in: the earthquake caused the death of 100 people.
2. Responsibility-as-role. As in: the train driver is responsible for driving the train.
3. Responsibility-as-authority. As in: he is responsible for the project, meaning he is in charge of the project. This may also be called responsibility-as-office or responsibility-as-jurisdiction. It refers to a realm in which one has the authority to make decisions or is in charge and for which one can be held accountable.
4. Responsibility-as-capacity. As in: the ability to act in a responsible way. This includes, for example, the ability to reflect on the consequences of one's actions, to form intentions, to deliberately choose an action and act upon it.
5. Responsibility-as-virtue, as the disposition (character trait) to act responsibly. As in: he is a responsible person. (The difference between responsibility-as-capacity and responsibility-as-virtue is that whereas the former only refers to ability, the second refers to a disposition that is also surfacing in actions. So someone who has the capacity for responsibility may be an irresponsible person in the virtue sense).
6. Responsibility-as-obligation to see to it that something is the case. As in: he is responsible for the safety of the passengers, meaning he is responsible to see to it that the passengers are transported safely.
7. Responsibility-as-accountability. As in: the (moral obligation) to account for what you did or what happened (and your role in it happening).
8. Responsibility-as-blameworthiness. As in: he is responsible for the car accident, meaning he can be properly blamed for the car accident happening.
9. Responsibility-as-liability. As in: he is liable to pay damages.

The first four conceptions are more or less descriptive: responsibility-as-cause, role, authority, or capacity describes something that is the case or not. The other five are more normative. The first two normative conceptions – responsibility-as-virtue and responsibility-as-obligation – are primarily forward-looking (prospective) in nature. Responsibility-as-accountability, blameworthiness, and liability are backward-looking (retrospective) in the sense that they usually apply to something that has occurred. Both the forward-looking and the backward-looking normative conception of responsibility are relevant in relation to risks. Backward-looking responsibility is mainly at stake when a risk has materialized and then relates to such questions like: Who is accountable for the occurrence of the risk? Who can be properly blamed for the risk? Who is liable to pay the damage resulting from the risk materializing? Forward-looking responsibility is mainly relevant with respect to the prevention and management of risks. It may refer to different tasks that are relevant for preventing and managing risk like risk assessment, risk reduction, risk management, and risk communication. We will discuss the responsibility for these tasks in section [● Responsibility for Risks](#).

Cross-cutting the distinction between the different conceptions of responsibility is a distinction between what might be called different “sorts” of responsibility like organizational responsibility, legal responsibility, and moral responsibility. The main distinction between these sorts is the grounds on which it is determined whether someone is responsible (in one of the senses distinguished above). Organizational responsibility is mainly determined by the rules and roles that exist in an organization, legal responsibility by the law (including

jurisprudence), and moral responsibility is based on moral considerations. The two types of distinctions are, however, not completely independent of each other. Organizational responsibility, for example, often refers to responsibility-as-task or responsibility-as-authority and seems unrelated to responsibility-as-cause and responsibility-as-capacity. It might also refer to responsibility-as-accountability, just like legal and moral responsibility. We might thus distinguish between organizational, legal, and moral accountability, where the first is dependent on an organization's rules and roles, the second on the law, and the third on moral considerations.

In this contribution we mainly focus on moral responsibility. Most of the general philosophical literature on responsibility has focused on backward-looking moral responsibility, in particular on blameworthiness. In this literature also, a number of general conditions have been articulated which should be met in order for someone to be held properly or fairly responsible (e.g., Wallace 1994; Fischer and Ravizza 1998). Some of these conditions, especially the freedom and knowledge condition, go back to Aristotle (*The Nicomachean Ethics*, book III, Chaps. 1–5). These conditions include:

1. Moral agency. The agent A is a moral agent, that is, has the capacity to act responsibly (responsibility-as-capacity).
2. Causality. The agent A is somehow causally involved in the action or outcome for which A is held responsible (responsibility-as-cause).
3. Wrongdoing. The agent A did something wrong.
4. Freedom. The agent A was not compelled to act in a certain way or to bring about a certain outcome.
5. Knowledge. The agent A knew, or at least could reasonably have known that a certain action would occur or a certain outcome would result and that this was undesirable.

Although these general conditions can be found in many accounts, there is much debate about at least two issues. One is the exact content and formulation of each of the conditions. For example, does the freedom condition imply that the agent could have acted otherwise (e.g., Frankfurt 1969)? The other is whether these conditions are individually necessary and jointly sufficient in order for an agent to be blameworthy. One way to deal with the latter issue is to conceive of the mentioned conditions as arguments or reasons for holding someone responsible (blameworthy) for something rather than as a strict set of conditions (Davis *forthcoming*).

Whereas the general philosophical literature on responsibility has typically focused on backward-looking responsibility, the more specific analyses of moral responsibility in technoscientific contexts, and more specifically as applied to (technological) risks, often focus on forward-looking responsibility. They, for example, discuss the forward-looking responsibility of engineers for preventing or reducing risks (e.g., Davis 1998; Harris et al. 2008; Martin and Schinzingher 2005; Van de Poel and Royakkers 2011). One explanation for this focus may be that in these contexts the main aim is to prevent and manage risks rather than to attribute blame and liability. This is, of course, not to deny that in other contexts, backward-looking responsibility for risks is very relevant. It surfaces, for example, in court cases about who is (legally) liable for certain damage resulting from the materialization of technological risks. It is also very relevant in more general social and political discussions about how the costs of risks should be borne: by the victim, by the one creating the risks, or collectively by society, for example, through social insurance.

## Conceptual Relations Between Risk and Responsibility

The conceptual connections between risk and responsibility depend on which conception of risk and which conception of responsibility one adopts. The technical conception of risk, which understands risks as the product of probability and magnitude of certain undesirable consequences, is largely descriptive, but it contains a normative element because it refers to undesirable outcomes. Typically, responsibility also is often used in reference to undesirable outcomes, especially if responsibility is understood as blameworthiness. Yet if the undesirable consequences, to which the technical conception of risk refers, materialize this does not necessarily imply that someone is blameworthy for these consequences. As we have seen, a number of conditions have to be met in order for someone to fairly be held responsible for such consequences. In cases of risks the knowledge condition will usually be fulfilled because if a risk has been established it is known that certain consequences might occur. It will often be less clear whether the wrongdoing condition is met. Risks normally refer to unintended, but not necessarily unforeseen, consequences of action. Nevertheless, under at least two circumstances, the introduction of a risk amounts to wrongdoing. One is if the actor is reckless, that is, if he knows that a risk is (morally) unacceptable but still exposes others to it. The other is negligence. In the latter case, the actor is unaware of the risk he is taking but should and could have known the risk and exposing others to the risk is unacceptable.

If we focus on forward-looking responsibility rather than backward-looking responsibility, the technical conception of risk might be thought to imply an obligation to avoid risks since most conceptions of risk refer to something undesirable. Again, however, the relation is not straightforward. Some risks, like certain natural risks, may be unavoidable. Other risks may not be unavoidable but worth taking given the advantages of certain risky activities. Nevertheless, there seems to be a forward-looking responsibility to properly deal with risks. In section [❸ Responsibility for Risks](#), we will further break down that responsibility and discuss some of its main components.

In the psychological literature on risk perception, no direct link is made between risk and responsibility. Nevertheless, some of the factors that this literature has shown to influence the perception of risk may be linked to the concept of responsibility. One such factor is controllability (e.g., Slovic 2000). Control is often seen as a precondition for responsibility; it is linked to the conditions of freedom and knowledge we mentioned above. Also voluntariness, another important factor in the perception of risk (e.g., Slovic 2000), is linked to those responsibility conditions. This suggests that risks for which one is not responsible (or cannot take responsibility) but to which one is exposed beyond one's will and/or control are perceived as larger and less acceptable.

In the sociological literature on risk that we discussed in section [❸ Conceptions of Risk](#), a much more direct connection between risk and responsibility is supposed. Mary Douglas (1985) argues that the same institutionally embedded cultural biases that shape the social construction of risks also shape the attribution of responsibility, especially of blameworthiness. Institutions are, according to Douglas, typically characterized by certain recurring patterns of attributing blame, like blaming the victim, or blaming outsiders, or just accepting the materialization of risks as fate or the price to be paid for progress. According to the theory of risk society, both risk and responsibility are connected to control and decisions. This implies a rather direct conceptual connection between risk and responsibility. As Anthony Giddens expresses it: "The relation between risk and responsibility can be easily stated, at least on an

abstract level. Risks only exist when there are decisions to be taken . . . The idea of responsibility also presumes decisions. What brings into play the notion of responsibility is that someone takes a decision having discernable consequences” (Giddens 1999, p. 8). The socio-logical literature seems to refer primarily to organizational responsibility, in the sense that attribution of responsibility primarily depends on social conventions. Nevertheless, as we have seen the idea of control, which is central to risk in the theory of risk society, is also central for moral responsibility.

The redefinitions of risk proposed by Rayner and Wolff, finally, both refer to responsibility as an ingredient in the conception of risk. Rayner includes liability as an aspect of risk. While liability is usually primarily understood as a legal notion, his reference to the *acceptability* of liability procedures also has clear moral connotations. In Wolff’s conception of risk, responsibility affects the variable “cause” that he proposes as additional primary variable for risk. As Wolff points out, it matters for the acceptability of risk whether it is caused by malice, recklessness, or negligence. These distinctions also have a direct bearing on the moral responsibility of the agent causing the undesirable consequences; they represent different degrees of wrongdoing. So, on Wolff’s conceptualization, whether and to what degree anyone is responsible for a risk has a bearing on the acceptability of that risk.

Although the relation between risk and responsibility depends on the exact conceptualization of both terms and one might discuss how to best conceptualize both terms, the above discussion leads to a number of general conclusions. First, if an undesired outcome is the result of someone taking a risk or exposing others to a risk, it appears natural to talk about responsibility in the backward-looking sense (accountability, blameworthiness, liability) for those consequences and for the risk taken. Second, both risk and responsibility are connected to control and decisions. Even if one does not accept the tight conceptual connection between risk and control that the theory of risk society supposes, it seems clear that risks often are related to decisions and control. As pointed out in the introduction, even so-called natural risks increasingly come under human control. This implies that we can not only hold people responsible for risks in a backward-looking way, but that people can also take or assume forward-looking responsibility (responsibility-as-virtue or as obligation) for risks. Third, the acceptability of risks appears to depend, at least partly, on whether someone can fairly be held responsible for the risk occurring or materializing.

## **Responsibility for Risks**

---

In the literature on risk some general frameworks have been developed for thinking about the responsibility for risks and some general tentative answers have been formulated to the question who is responsible for certain risks. In this section, we present a number of these positions and the debates to which they have given rise. We focus on human-induced risks, that is, nonnatural risks, with a prime focus on technological risks. Our focus is also primarily on forward-looking responsibility rather than on backward-looking responsibility (accountability, blameworthiness, and liability) for risks.

Forward-looking responsibility for risks can be subdivided in the following main responsibilities:

1. Responsibility for risk reduction.
2. Responsibility for risk assessment, that is, establishing risks and their magnitude.

3. Responsibility for risk management. Risk management includes decisions about what risks are acceptable and the devising of regulations, procedures, and the like to ensure that risks remain within the limits of what is acceptable.
4. Responsibility for risk communication, that is, the communication of certain risks, in particular to the public.

Section ② [The Responsibility of Engineers](#) will discuss the responsibility for risk reduction. In the case of technological risks, this responsibility is often attributed to engineers. Section ② [Risk Assessment Versus Risk Management](#) will focus on the responsibility for risk assessment versus risk management. The former is often attributed to scientists, while governments and company managers are often held responsible for the latter. It will be examined whether this division of responsibilities is justified. Section ② [Individual Versus Collective Responsibility for Risks](#) will focus on an important issue with respect to risk management: whether decisions concerning acceptable risk are primarily the responsibility of individuals who take and potentially suffer the risk or whether it is a collective responsibility that should be dealt with through regulation by the government. Section ② [Risk Communication](#) will discuss some of the responsibilities of risk communicators and related dilemmas that have been discussed in the literature on risk communication.

## The Responsibility of Engineers

---

Engineers play a key role in the development and design of new technologies. In this role they also influence the creation of technological risks. In the engineering ethics literature, it is commonly argued that engineers have a responsibility for safety (Davis 1998; Harris et al. 2008; Martin and Schinzinger 2005; Van de Poel and Royakkers 2011). In this section, we will consider these arguments and discuss how safety and risk are related and what the engineers' responsibility for safety implies for their responsibility for technological risks.

Most engineering codes of ethics state that engineers have a responsibility for the safety of the public. Thus, the code of the National Society of Professional Engineers in the USA states that: "Engineers, in the fulfillment of their professional duties, shall: . . . Hold paramount the safety, health, and welfare of the public" (NSPE 2007). Safety is not only stressed as the engineer's responsibility in codes of ethics but also in technical codes and standards. Technical codes are legal requirements that are enforced by a governmental body to protect safety, health, and other relevant values (Hunter 1997). Technical standards are usually recommendations rather than legal requirements that are written by engineering experts in standardization committees. Standards are usually more detailed than technical codes and may contain detailed provisions about how to design for safety.

Does the fact that safety is a prime concern in engineering codes of ethics and technical codes and standards entail that engineers have a moral responsibility for safety? One can take different stances here. Some authors have argued that codes of ethics entail an implicit contract either between a profession and society or among professionals themselves. Michael Davis, for example, defines a profession as "a number of individuals in the same occupation voluntarily organized to earn a living by openly serving a certain moral ideal in a morally permissible way beyond what law, market, and morality would otherwise require" (Davis 1998, p. 417). This moral idea is laid down in codes of ethics and thus implies, as we have seen, a responsibility for

safety. According to Davis, codes are binding because they are an implicit contract between professionals, to which engineers subscribe by joining the engineering profession.

One could also argue that codes of ethics or technical codes and standards as such do not entail responsibilities for engineers but that they *express* responsibilities that are grounded otherwise. In that case, the engineers' responsibility for safety may, for example, be grounded in one of the general ethical theories like consequentialism, deontology, or virtue ethics. But if we believe that engineers have a moral responsibility for safety, does this also entail a responsibility for risks? To answer this question, we need to look a bit deeper into the conceptual relation between safety and risk (see ➤ [Chap. 3, The Concepts of Risk and Safety](#), in this handbook). In engineering, safety has been understood in different ways. One understanding is that safety means absolute safety and, hence, implies the absence of risk. In most contexts, this understanding is not very useful (Hansson 2009, p. 1074). Absolute safety is usually impossible and even if it would be possible it would in most cases be undesirable because eliminating risks usually comes at a cost, not only in monetary terms but also in terms of other design criteria like sustainability or ease of use. It is therefore better to understand safety in terms of "acceptable risk." One might then say that a technological device is safe if its associated risks are acceptable. What is acceptable will depend on what is feasible and what is reasonable. The notion of reasonableness refers here to the fact that reducing risks comes at a cost and that hence not all risk reductions are desirable.

So conceived, engineers may be said to be responsible for reducing risks to an acceptable level. What is acceptable, however, requires a normative judgment. This raises the question whether the engineer's responsibility for reducing risks to an acceptable level includes the responsibility to make a normative judgment on which risks are acceptable and which ones are not or that it is limited to meeting an acceptable risk level that is set in another way, for example, by a governmental regulator. The answer to this question may well depend on whether the engineers are designing a well-established technology for which safety standards have been set that are generally and publicly recognized as legitimate or that they are designing a radically new technology, like nanotechnology, for which existing safety standards cannot be applied straightforwardly and of which the hazards and risks are more uncertain anyway (for this distinction, see Van de Poel and Van Gorp 2006). In the former case, engineers can rely on established safety standards. In the latter case, such standards are absent. Therefore in the second case engineers and scientists also have some responsibility for judging what risks are acceptable, although they are certainly not the only party that is or should be involved in such judgments.

## Risk Assessment Versus Risk Management

---

In the previous section we have seen that a distinction needs to be made between responsibility for risk reduction and responsibility for decisions about acceptable risks. Engineers have a responsibility for risk reduction but not necessarily or at least to a lesser degree a responsibility for deciding about acceptable risk. In this section we will discuss a somewhat similar issue in the division of responsibility for risk, namely, the responsibility for establishing the magnitude of risks (risk assessment) and decisions about the acceptability and management of risks (risk management). Traditionally risk assessment is seen as a responsibility of scientists, and risk management as a responsibility of governments and (company) managers (National Research Council 1983) (see ➤ [Chap. 46, Risk Management in Technocracy](#), in this

handbook). In this section, we will discuss whether this division of labor and responsibility is tenable or not. In particular, we will focus on the question whether adequate risk assessment can be completely value free, as is often supposed, or, as has been argued by a number of authors, that it needs to rely on at least some value judgments.

One reason why risk assessment cannot be entirely value free is that in order to do a risk assessment a decision needs to be made on what risks to focus. Since, on the conventional technical conception of risk (see section [Conceptions of Risk](#)), risks are by definition undesirable, classifying something as a risk already involves a value judgment. It might be argued, nevertheless, that decisions about what is undesirable are to be made by risk managers and that risk assessors, as scientists, should then investigate all potential risks. In practice, however, a risk assessment cannot investigate all possible risks; a selection will have to be made and selecting certain risks rather than others implies a value judgment. Again, it can be argued that this judgment is to be made by risk managers. A particular problem here might be that some risks are harder to investigate or establish scientifically than others. Some risks may even be statistically undetectable (Hansson 2009, pp. 1084–1086). From the fact that a risk is hard or even impossible to detect scientifically, of course it does not follow that it is also socially or morally unimportant or irrelevant, as it might have important consequences for society if it manifests itself after all. This already points to a possible tension between selecting risks for investigation from a scientific point of view and from a social or moral point of view.

The science of risk assessment also involves value judgments with respect to a number of methodological decisions that are to be made during risk assessment. Such methodological decisions influence the risk of error. A risk assessment might, due to error, wrongly estimate a certain risk or it might establish a risk where actually none exists. Heather Douglas (2009) argues that scientists in general have a responsibility to consider the consequences of error, just like anybody else. While this may seem common sense, it has important consequences once one takes into account the social ends for which risk assessments are used. Risk assessment is not primarily used to increase the stock of knowledge, but rather as an input for risk management. If a risk assessment wrongly declares something not to be a risk while it actually is a serious risk, or vice versa, this may lead to huge social costs, both in terms of fatalities and economic costs.

Various authors have therefore suggested that, unlike traditional science, risk assessment should primarily avoid what are called type 2 errors rather than type 1 errors (Cranor 1993; Shrader-Frechette 1991b; Hansson 2008; see also Hansson's [Chap. 2, A Panorama of the Philosophy of Risk](#), in this handbook). A type 1 error or false positive occurs if one establishes an effect (risk) where there is actually none; a type 2 error or false negative occurs if one does not establish an effect (risk) while there is actually an effect. Science traditionally focuses on avoiding type 1 errors to avoid assuming too easily that a certain proposition or hypothesis is true. This methodological choice seems perfectly sound as long as the goal of science is to add to the stock of knowledge, but in contexts in which science is used for practical purposes, as in the case of risk assessment, the choice may be problematic. From a practical or moral point of view it may be worse not to establish a risk while there is one than to wrongly assume a risk. As Cranor (1993) has pointed out the 95% rule for accepting statistical evidence in science is also based on the assumption that type 1 errors are worse than type 2 errors. Rather than simply applying the 95% rule, risk assessors might better try to reduce type 2 errors or balance type 1 against type 2 errors (Cranor 1993, pp. 32–29; Douglas 2009, pp. 104–106).

There are also other methodological decisions and assumptions that impact on the outcomes of risk assessment and the possibilities of error. One example is the extrapolation of

empirically found dose–effect relations of potentially harmful substances to low doses. Often, no empirical data are available for low doses; therefore the found empirical data has to be extrapolated to the low dose region on the basis of certain assumptions. It might, for example, be assumed that the relation between dose and response is linear in the low dose region, but it is also sometimes supposed that substances have a no effect level, that is, that below a certain threshold dose there is no effect. Such methodological decisions can have a huge impact on what risks are considered acceptable. An example concerns the risks of dioxin. On basis of the same empirical data, but employing different assumptions about the relation between dose and response in the low dose region, Canadian and US authorities came to norms for acceptable levels of dioxin exposure to humans that are different by a factor of 1,000 (Covello and Merkhofer 1993, pp. 177–178).

While it is clear that in risk assessment, a number of value judgments and morally relevant methodological judgments need to be made, the implications for the responsibility of risk assessors, as scientists, are less obvious. One possibility would be to consider such choices to be entirely the responsibility of the risk assessors. This, however, does not seem like a very desirable option; although risk assessors without doubt bear some responsibility, it might be better to involve other groups as well, especially those responsible for risk management, in the value judgments to be made. The other extreme would be to restore the value-free science idea as much as possible. Risk assessors might, for example, pass on the scientific results including assumptions they made and related uncertainties. They might even present different results given different assumptions or different scenarios. While it might be a good idea to allow for different interpretations of scientific results, simply passing on all evidence to risk managers, who then can make up their mind does not seem desirable. Such evidence would probably be quite hard if not impossible to understand for risk managers. Scientists have a proper role to play in the interpretation of scientific data, albeit to avoid that data is deliberately wrongly interpreted for political reasons. Hence, rather than endorsing one of those two extremes, one should opt for a joint responsibility of risk assessors and risk managers for making the relevant value judgments while at the same recognizing their specific and different responsibilities. Among others, this would imply recognizing that risk assessment is a process that involves scientific analysis and deliberation (Stern and Feinberg 1996; Douglas 2009).

## Individual Versus Collective Responsibility for Risks

When you get into your car in order to transport your children to school and yourself to an important work meeting, you expose a number of people to the risk of being injured or even killed in an accident. First, you expose yourself to that risk. Second, you expose your children to that risk. Third, you expose other drivers, passengers, pedestrians, and cyclists to that risk. Furthermore, someone made decisions that affected your driving: decisions about driving licenses, street lighting, traffic lights and signs, intersections, roundabouts, and so forth. Who is responsible for these different forms of risk exposure? There is an individual and a collective level at which to answer this question. The underlying philosophical question is that of individual and collective responsibility – to what extent and for which risks is an individual responsible and to what extent and for which risks is society collectively responsible? In the following, we will explain how these issues relate to each other. The analysis of road traffic

serves as an example of how aspects of individual and collective responsibility reoccur in most areas of risk management and policy today.

The fact that you expose yourself to the risks associated with driving a car appears to be a primarily individual responsibility. As a driver with a license you are supposed to know what the relevant risks are. Unless you acted under compulsion or ignorance you are held responsible for your actions, in road traffic as elsewhere. As discussed in section [● Conceptions of Responsibility](#), the condition of voluntariness has been discussed by philosophers since Aristotle. When you voluntarily enter your car and know that you risk yours and others' health and life by driving your car, even if those risks are considered fairly small in probability terms, you are responsible in case something bad happens because you accepted the risks associated with driving. This assessment is, of course, complicated by the behavior of other road users. Perhaps someone else made a mistake or even did something intentionally wrong, thereby causing an accident. In that case, you are often considered responsible to some extent, because you were aware of the risks associated with driving and these risks include being exposed to other people's intentional and unintentional bad behavior. However, other road users may bear the greatest share of responsibility in case their part in the causal chain is greater and their wrongdoing is considered more serious. The point is that the individual perspective distributes responsibility between the individuals involved in the causal chain. The key elements are (1) individuals, (2) causation, and (3) wrongdoing. The one/s that caused the accident by doing something wrong is/are responsible for it. (In section [● Conceptions of Responsibility](#), we mentioned two further conditions for responsibility, i.e., freedom and knowledge. These are usually met in traffic accidents and therefore we do not mention them separately here, but they may be relevant in specific cases.) When attributing responsibility according to this approach the road transport system is taken for granted the way it is. However, as we noted, someone made decisions concerning the road transport system and the way you and your fellow road users are affected by those decisions.

The collective or systemic perspective, instead, focuses on the road transport system. Were the roads of a reasonable standard, was there enough street lighting, and was the speed limit reasonable in relation to the condition and circumstances of the road? The default is to look at what the individuals did and did not do and to take the road transport system as a given and this is often reflected in law. However, in some countries the policy is changing and moving toward a collective or systemic perspective. In 1997, the Swedish government made a decision which has influenced discussions and policies in other European countries. The so-called Vision Zero was adopted, according to which the ultimate goal of traffic safety policy is that no one is killed or seriously injured in road traffic (Nihlén Fahlquist 2006). This may be seen as obvious to many people, but can be contrasted to the cost-benefit approach according to which the benefit of a certain method should always be seen in relation to its cost. Instead of accepting a certain number of fatalities, it was now stated that it is not ethically justifiable to say that 300 or 200 are acceptable numbers of fatalities. In addition to this idea, a new view of responsibility was introduced. According to that approach, individuals are responsible for their road behavior, but the system designers are *ultimately* responsible for traffic safety. This policy decision reflected a change in perspective moving from individual responsibility to collective responsibility. Road traffic should no longer be seen purely as a matter of individual responsibility, but instead the designers of the system (road managers, maintainers, and the automotive industry) have a great role to play and a great share of responsibility for making the roads safer and saving lives in traffic. Instead of merely focusing on individuals, causation, and

wrongdoing, the focus should be on (1) collective actors with the (2) resources and abilities to affect the situation in a positive direction. The example of road traffic illustrates how an activity often has a collective as well as an individual dimension. The adoption of Vision Zero shows that our views on who is responsible for a risky activity, with individual and collective dimensions, can be changed.

Furthermore, this example illuminates the difference between (1) backward-looking and (2) forward-looking responsibility. Sometimes when discussing responsibility, we may refer to the need for someone to give an account for what happened or we blame someone for what happened. In other situations we refer to the aim to appoint someone to solve a problem, the need for someone to act responsibly or to see to it that certain results are achieved. There are several distinctions to be made within these two broad categories, but it could be useful to make this broad distinction between backward-looking and forward-looking notions of responsibility (see also section [❸ Conceptions of Responsibility](#)).

The issue of collective responsibility is a much discussed topic in contemporary philosophy. Some scholars argue that there is no such thing and that only individuals can rightly be considered responsible. This position was taken, for example, by H.D. Lewis (1948) some years after World War II and it is understandable that many people were skeptical to the idea of collective actors and collective guilt at that point in time. The world has changed a lot since then and 65 years after World War II the ideas of collective actors and holding collectives responsible are not as terrifying. On the contrary, against the background of multinational corporations, for example, banks and oil producers, behaving badly and causing harm to individuals it appears more and more crucial to find a way of holding such actors accountable for harm caused by them. Philosophers like Peter French have therefore defended the idea that collective agents, such as corporations or governments, can be morally responsible (e.g., French 1984). Some authors claim that collective responsibility is sometimes irreducible to individual responsibility, that is, a collective can be responsible without any of its members being responsible (French 1984; Gilbert 1989; Pettit 2007; Copp 2007). Others claim that collective responsibility is, in the end, analyzable only in terms of individual responsibility (Miller 2010). The collective responsibility of the government might, for example, be understood as the joint responsibility of the prime minister (as prime minister), other members of the government, members of the Parliament, and maybe civil servants. In section [❸ Further Research: Organizing Responsibility for Risks](#), we will explore possible tensions between individual and collective responsibility, and the so-called problem of many hands.

Scholars are likely to continue discussing whether the notion of collective responsibility makes philosophical sense and if so how it should be conceived. What cannot be denied is that in society we treat some risks as an individual responsibility and others as a collective responsibility. Whereas the risks associated with mountaineering are usually seen as individual responsibility, the risks stemming from nuclear power are seen as collective. However, it is arguably not always that simple to decide whether an individual or a collective is responsible for a certain risk. It is often the case that there is an individual as well as a collective dimension to risks. Climate risks arising from the emissions of carbon dioxide are good examples of this. Arguably, individuals have a responsibility to do what they can to contribute to the reduction of emissions, but governmental and international action is also crucial. Furthermore, it is also a matter of which notion of responsibility we apply to a specific context. While we sometimes blame individuals for having smoked for 40 years thereby causing their own lung cancer, we may make it a collective responsibility to give them proper care.

There are two general perspectives on the balance between individual and collective responsibility for health risks. First, the libertarian approach views lifestyle risks, for example, smoking, as an individual matter and relates causation to blame and responsibility for the cost of damage. A liberal welfare approach considers causation as one thing and paying for the consequences as another thing so that even if an individual is seen as having caused her own lung cancer, she should perhaps not have to pay for the health care she now needs. Furthermore, according to liberal welfare theories, individuals are always situated in a socioeconomic context and, consequently, the fact that a particular individual smokes may not entirely be a matter of free choice. Instead, it may be partly due to the situation she is in, her socioeconomic context, education, and so forth, which entails a different perspective on causation, and hence also on the distribution of responsibility between the individual and the collective. The liberal welfare approach does not pay as much attention to free choice as the libertarian approach, or alternatively does not see choices as free in the same sense as libertarians do. This is because the two perspectives assume different conceptions of liberty. Libertarians focus on so-called negative freedom, that is, being free to do whatever one wants to do as long as one does not infringe on another person's rights. Liberal welfare proponents focus on positive liberty, that is, freedom to act in certain ways and having possibilities to act. The former requires legislation to protect individuals' rights and the latter requires a more expansive institutional setting and taxation to create the circumstances and capabilities (see [Chap. 39, The Capability Approach in Risk Analysis](#), in this handbook) needed for people to make use of those possibilities. Different conceptions of liberty entail different conceptions of responsibility. Those emphasizing negative liberty attribute a greater share of responsibility to individuals and those who prefer positive liberty make governments and societies collectively responsible to a greater extent. (For a classic explanation of the concepts of negative and positive liberty see Isaiah Berlin [1958](#).)

The decision to view a certain risk as an individual or a collective matter entails different strategies for dealing with risk reduction and different strategies for deciding about the acceptability of a risk. If the risk is seen as an individual matter the strategy is likely to emphasize information campaigns at the most. If, for example, road safety is seen as an individual responsibility risk managers who want to reduce the number of fatalities and injuries will inform the public about risky behavior and how to avoid such behavior. "Don't drink and drive" campaigns is an example of that strategy. Some libertarians would probably argue that even this kind of campaign is unacceptable use of taxpayers' money and that an information campaign should only objectively inform about the risks of drunk driving and not give any advice because individuals should be considered competent enough to make their own decisions about driving. However, a "Don't drink and drive" campaign could also be seen as a way of making sure individuals do not harm each other, that is, do not infringe on other individuals' rights not to be harmed, and for this reason it would probably be acceptable to a moderate libertarian. Surely, libertarians would not agree to anything more intrusive than this, for example, surveillance cameras.

If, instead, road safety is seen as a collective responsibility, risk managers may try to find other ways of reducing the risks of driving. In the case of drunk driving, one such example could be alcohol interlocks, that is, a new technology which makes it impossible to drive under the influence of alcohol. This device measures the driver's blood alcohol concentration (BAC) before the car starts, for example, through an exhalation sample, and because it is connected to the car's ignition it will not start if the measured concentration is above the maximum set. Alcohol interlocks are currently used in some vehicles and some contexts in Sweden and elsewhere. It is

possible that the device will be a natural part of all motor vehicles in the future and this would indeed be a way of making drunk driving a collective responsibility, although individuals would still be responsible for not misleading or otherwise circumventing the system.

The collective approach to responsibility for risks is sometimes criticized for being paternalistic. The argument is that people should be free to make their own decisions about which risks are worth taking. One way to assure freedom of choice is to apply the principle of informed consent to decisions about acceptable risk. Informed consent is a principle commonly used in medical experiments and the idea is that those who take part in the experiments are informed about the risks and then decide whether to consent through signing a document. Similarly, individuals are to decide what technological risks they want to take. To this end, they should be informed about the risks of different technologies, and they should be free to decide whether to take a certain risk or not. The approach of informed consent clearly fits in a libertarian approach to risk taking. However, when people make decisions about risks, their choices can be affected through the way information is presented. Thaler and Sunstein (2008) argue that a decision is always made in a context and that “choice architects” design this context. Since choices are always framed in one way or another, you might as well opt for “nudging” people in the “better,” healthier for instance, direction. One example of this is a school cafeteria in which different food products are arranged in one way or another and without removing the less healthy options, a “choice architect” could nudge children in the direction of the healthier options. Even a very anti-paternalistic libertarian, they argue, could accept this since no options are removed and the food has to be arranged in one way or another (Thaler and Sunstein 2008).

There are, however, several problems with applying the principle of informed consent to risk taking. One problem is that it might be hard, if not impossible, to present risks in a neutral and objective way (see also section [Risk Communication](#)). Second, risks are sometimes uncertain. Imagine there is research on how radiation from mobile phones affects grown-ups in the time frame of 10 years after you start using the phone, but not how it affects children or how it affects grown-ups in the long-term perspective of say 20–30 years. When you use your mobile phone or you let your child use one and you have been informed about the known risks, have you consented to all risks of radiation stemming from mobile phones? Third, it might be doubted whether all risks are or can be taken voluntarily, take for example, the risks associated with driving in an area lacking public transport. Fourth, in many cases the decision whether to accept or take a certain risk is or cannot be an individual decision because it affects other people. Take for example, the decision whether a certain area of the Netherlands should be additionally protected against the sea given expectations of rising sea levels due to the greenhouse effect. Such measures are likely to be very costly and whereas some individuals will judge that an increased risk should be accepted rather than spending large amounts of public funds on higher dikes, others are likely to make the opposite assessment.

Decisions about which risks of flooding should be accepted are by their very nature collective decisions. Since such collective decisions are usually based on majority decision making, individual informed consent is not guaranteed. An alternative would be to require consensus, to safeguard informed consent, but that would very likely result in a stalemate and in a perseverance of the status quo. That would in turn lead to the ethical issue of how the status quo is to be understood. For example, in the case of increased likelihood of flooding the question is whether the status quo should be understood in terms of the current risk of flooding, so that maintaining the status quo would mean heightening the dikes, or whether it should be understood in terms of the current height of the dikes and accepting a higher risk of flooding.

Many acts of seemingly individual risk taking have a collective element. Even committing suicide by driving or jumping in front of a train is not an individual act since other road users may come in the way and get hurt and there is probably psychological damage to the train driver and others who see it happen. By driving your car you inevitably risk the lives of others when you risk your own life. Your own risk taking is then intertwined with the risk exposure of others.

The upshot of the above discussion is not that all decisions about risk are or should be, at least partially, collective decisions, but rather that we should distinguish different kinds of risks, some more individual and others more collective. Consider, for example, the alleged health risks of radiation from mobile phones. The risk that is generated by using a mobile phone, and thereby exposing oneself to radiation, is an individual risk; the radiation only affects the user of the phone. Radiation from base stations, on the other hand, is a collective risk. This is why it has been suggested that the former is managed through informed consent whereas the latter should be subject to public participation and democratic decision making (IEGMP 2000).

However, even if we decide that the risks associated with using a mobile phone is sometimes an individual responsibility, it should be noted that a seemingly individual risk carries with it aspects of collective decision making and responsibility since the government and international agencies may have to set a minimal risk level (MRL) stating what is acceptable radiation and what is not. Many contemporary risks are complex and collective. As democratic societies we have to make choices about what risks to allow. There is a procedural dimension to this, but also a normative dimension. As noted by Ferretti (2010), scholars have been discussing how to make sure that the procedure by which decisions about risks are made become more democratic and fair, but that we also have to discuss the normative and substantive issues of what risks are acceptable and what the decisions are about.

## Risk Communication

As we have seen the tasks of risk assessment, risk management and risk reduction involve different groups, such as engineers, scientists, the government, company managers, and the public, with different responsibilities. Since each group has its specific expertise and fulfilling one's specific responsibility often requires information from others, communication between the groups is of essential importance. Risk communication is therefore crucial for the entire system of dealing with risks in order to work.

In the literature, risk communication is often understood as communication between the government and the public (e.g., Covello et al. 1989) (see [Chap. 29, Tools for Risk Communication](#) and [Chap. 27, Emotion, Warnings, and the Ethics of Risk Communication](#), in this handbook). Although as indicated it might be advisable to understand the notion of risk communication broader, we will here follow this convention and understand risk communication as the communication between the government (or a company) and the public. The goals of such risk communication depend to an important extent on whether one conceives of risk management as an individual or collective responsibility as discussed in the previous section. As we saw there, whether risk management is seen as an individual or collective responsibility partly depends on one's philosophical or political stance. However, it also depends on the kind of risks focused on. Moreover, as we argued, risks are often both an individual and collective responsibility. Therefore, the distinction between individual and

collective responsibility does not exactly match comparable distinctions between consequentialist and deontological approaches or between liberal and paternalistic approaches.

If one conceives of risk management, and especially of decisions about acceptable risk, as the individual responsibility of the one taking or undergoing the risk, the responsibility of the government as risk communicator is to inform the public as completely and as accurately as possible. However, it seems that the government should refrain from attempts to convince the public of the seriousness or acceptability of risks. In this frame, the goal of risk communication is to enable informed consent and the responsibility of the risk communicator is basically to provide reliable and relevant information to enable informed consent.

However, if one conceives of decisions about acceptable risk and risk management as a collective responsibility, trying to convince the public of the acceptability or seriousness of certain risks or trying to get their cooperation for certain risk management measures is not necessarily or always morally problematic, especially if the risk communicator is open about his or her goals (cf. Morgan and Lave 1990; Johnson 1999; Thaler and Sunstein 2008). In a liberal society, it might in general be improper for the government to deliberately misinform the public or to enforce certain risk measures, but convincing the public is not necessarily morally problematic. Moreover, in some extreme situations even misinformation and enforcement might be considered acceptable. It is, for example, generally accepted that violence may sometimes be used by the police to reduce the risks of criminality and terrorism. With respect to risk communication, one might wonder whether it would be acceptable to be silent about the risk of burglary if people have to leave their homes as quickly as possible because of the safety risk as a result of a coming hurricane. Misinformation about risks may in some cases be deemed acceptable if the consequences, or risks, of proper information are larger than the risks communicated. In such cases, consequentialist considerations may be considered more relevant than deontological considerations. In general, if one conceives of risk management as collective rather than as a purely individual responsibility, the consequences of risk communication may be relevant to the responsibilities of the risk communicator and these responsibilities can thus extend beyond informing in the public as well as possible. However, it seems that if one accepts that some risk management decisions are a collective responsibility, one can still either take a more consequentialist or a more deontological view on risk communication.

It might seem that the question concerning what information to provide to the public only arises if risk management is (partly) seen as a collective responsibility. If risk management is an individual responsibility and the aim of risk communication is to enable informed consent, the risk communicator should simply pass on all information to the public. However, not all information is equally relevant for informed consent, and so a certain choice of filtering of information seems appropriate. In addition to the question of what information should be provided, ethical questions may arise in relation to the question of how the information is to be framed (Jungermann 1996).

Tversky and Kahneman (1981) have famously shown that the same statistical information framed differently leads to contradictory decisions about what risks are accepted, for example, depending on whether risk information is framed in terms of survival or death. There are many other factors that are relevant for how risks are presented. One issue is the risk measure used. It makes a difference whether you express the maximum dosage of dioxin per day in picograms, milligrams, or kilograms. The latter presentation – maybe unintentionally – gives the impression that the risk is far smaller than in the first case. Another important issue in risk

communication is how uncertainty should be dealt with. Should the risk communicator just communicate the outcome of a risk assessment or also include uncertainty margins? Should the risk communicator explain how the risk assessment was carried out, so that people can check how reliable it is? Should the methodological assumptions and choices made in the risk assessment (section [Conceptions of Responsibility](#)) be explained to the public?

## Further Research: Organizing Responsibility for Risks

---

A major philosophical challenge today is to conceptualize responsibility in relation to collective agency. While the increased control over the environment seems to increase the total amount of responsibility, this responsibility is also increasingly dispersed over many different individuals and organizations. The somewhat paradoxical result is that it sometimes appears to be increasingly difficult to hold someone responsible for certain collective effects like climate change. Partly this may result from the fact that today's society is so obsessed with holding people responsible (blameworthy) that many individuals and organizations try to avoid responsibility rather than to assume it. Ulrich Beck (1992) has described this phenomenon as "organized irresponsibility."

We have identified five important topics for further research that we will discuss in the following subsections. In subsection [The Problem of Many Hands \(PMH\)](#), we discuss what has been called the problem of many hands (PMH).

In subsection [Climate Change as an Example](#), we will discuss the risk of climate change as an example of the PMH. We are all contributing to climate change. However, if and how this observation of (marginal) causal responsibility has implications for moral responsibility is not at all clear and this issue needs considerable attention.

Subsection [Responsibility as a Virtue](#) will discuss the idea that rather than understanding responsibility in a formal way, we should appeal to individuals who should take up responsibility proactively. To that purpose, we suggest to turn to virtue ethics and care ethics. We explore the possibilities of an account of responsibility as the virtue of care, as a way to deal with the PMH.

Another example is the discussion in section [Responsibility for Risks](#) about the related responsibilities for risk assessment, risk management, risk reduction, and risk communication. We have seen that there are some problems with the traditional allocation of responsibilities in which, for example, scientists are only responsible for risk assessment and have no role to play in risk management. These examples illustrate the need to discuss the distribution of responsibility (subsection [The Procedure of Responsibility Distribution](#)) among the actors involved as well as the question of who is responsible for the entire system, which involves the notion of institutional design (subsection [Institutional Design](#)).

### The Problem of Many Hands (PMH)

---

Although Dennis Thompson (1980) already coined the term "problem of many hands" in 1980, relatively little research has been done in this area. For this reason, we will summarize briefly what already has been done, but large parts of the discussion relate to directions and suggestions for further research.

Thompson describes the PMH as “the difficulty even in principle to identify who is responsible for . . . outcomes” (Thompson 1980, p. 905). Many different individuals act in different ways and the joint effect of those actions is an undesired state-of-affairs X, but none of the individuals (1) directly caused X or (2) wanted or intended X. In such cases, it is either difficult to discern how each actor contributed to X or it is unclear what implications the joint causal responsibility should have for the moral responsibility of the individuals whose combined actions caused X. As we have seen, there is backward-looking and forward-looking responsibility. The PMH can be seen as a problem of forward-looking responsibility, but it has primarily been discussed as a problem of backward-looking responsibility. Typically, the PMH occurs when something has happened and although there may not have been any wrongdoing legally speaking, the public may have a feeling that something has been done for which someone is morally responsible. The question is just who should be considered responsible, since the traditional conditions of responsibility are extremely hard to apply.

Two features of contemporary society make the PMH salient today. First, human activities are to an increasing extent carried out by groups of people instead of by individuals. Second, we are increasingly able to control risks and hazards, which also seem to increase our responsibilities. We will briefly discuss these features in turn.

Traditionally, philosophers theorize about morality in relation to individuals and how they act. However, in contemporary societies, a substantial part of the daily lives of individuals are intertwined with collective entities like the state, multinational corporations, nongovernmental organizations, and voluntary associations. Collective agency has become frequent. We talk about nations going to war, companies drilling for oil, governments deciding to build a new hospital, a local Lions club organizing a book fair. As discussed in section ➤ [Individual Versus Collective Responsibility for Risks](#), the concept of collective moral responsibility is a much debated topic in philosophy. A risky activity can be seen as an individual or a collective responsibility, but most risks have aspects of both.

Collectively caused harm complicates ethical analysis. This is so partly for epistemic reasons, that is, because we do not know how the actions of different individuals combine to cause bad things. Furthermore, did each and every individual in that particular collective know what they took part in? However, it is not merely for epistemic reasons that we have problems ascribing responsibility in such cases. Collective harm may also arise due to a tragedy of the commons (Hardin 1968). In a tragedy of the commons, the commons – a shared resource – are exhausted because for each individual it is rational to use the commons as much as possible without limitation. The aggregate result of these individual rational actions, the exhaustion of the common resource so that no individual can continue to use it, is undesirable and in a sense irrational. Many environmental problems can be understood as a tragedy of the commons. Baylor Johnson (2003) has argued that in a tragedy of the commons individuals are not morally required to restrict their use of the common resource as long as no collective agreement has been reached, hence no individual can properly be held responsible for the exhaustion of the commons (for a contra argument, see Braham and van Hees 2010).

Similarly, Philip Pettit (2007) has argued that sometimes no individual can properly be held morally responsible for undesirable collective outcomes (for support of Pettit’s argument see, e.g., Copp (2007), for criticism, see Braham and van Hees (2010), Hindriks (2009), and Miller (2007)). The type of situations he refers to are known as voting paradoxes or discursive dilemmas. Pettit gives the following example. Suppose that three employees (A, B, and C) of a company need to decide together whether a certain safety device should be installed and

suppose that they agree that this should only be done if (1) there is a serious danger ( $p$ ), (2) the device is effective with respect to the danger ( $q$ ), and (3) the costs are bearable ( $r$ ). If and only if all three conditions are met ( $p \wedge q \wedge r$ ) the device is to be installed implying a pay sacrifice ( $s$ ) for all three employees. Now suppose that the judgments of the three individuals on  $p$ ,  $q$ ,  $r$ , and  $s$  are as indicated in the table below. Also suppose that the collective decision is made by majority decision on the individual issues  $p$ ,  $q$ , and  $r$  and then deducing  $s$  from ( $p \wedge q \wedge r$ ). The result would be that the device is installed and that they all have to accept a pay sacrifice. But who is responsible for this outcome? According to Pettit neither A, B, or C can be properly be held responsible for the decision because each of them believed that the safety device was not worth the pay sacrifice and voted accordingly as can be seen from the table (based on the matrix in Pettit 2007, p. 197). Pettit believes that in cases like this the collective can be held responsible even if no individual can properly be held responsible. Like in the case of the tragedy of the commons, this suggests that the collective agency may make it impossible to hold individuals responsible for collective harmful effects.

In addition to the salience of collective agency today, in today's society negative consequences often result from risk rather than being certain beforehand. Whereas moral theories traditionally deal with situations in which the outcome is knowable and well determined, societies today spend a considerable amount of time and money managing risks, that is, situations in which there is a probability of harm. If it is difficult to decide whether killing is always wrong when done by and to individuals, it is even more difficult to decide whether it is acceptable to expose another human being to the risk of, say 1 in 18,000, of being killed in a road crash. Or, on the societal level, are the risks associated with nuclear power ethically acceptable? Would a difference in probabilities matter to the ethical acceptability and if so, where should the line be drawn between acceptable and unacceptable probability? It is difficult to know how to begin to answer these questions within the traditional ethical frameworks (Hansson 2009). The questions concerning the ethical acceptability of risks clearly have implications for responsibility. If A kills B, A is reasonably held responsible for it and the consequences of that vary according to norms and context. If A exposes B to the risk of 1 in 18,000 of being killed in a road crash, in what way is A responsible for that risk exposure? Interestingly, while it appears more intricate to decide how someone is responsible for exposing another person to the risk of dying than it is to decide whether someone is responsible for killing that person, the very concept of risk appears to imply some sense of responsibility. A risk is often seen as something we can or ought to be able to manage and control (cf. section ② Conceptual Relations Between Risk and Responsibility).

**Table 35.1**

The discursive dilemma (based on Pettit 1997)

	Serious danger? ( $p$ )	Effective measure? ( $q$ )	Bearable costs? ( $r$ )	Pay sacrifice $s$ ( $p \wedge q \wedge r$ )
A	No	Yes	Yes	No
B	Yes	No	Yes	No
C	Yes	Yes	No	No
Majority	Yes	Yes	Yes	[Yes] no

Thus, contemporary society is confronted by more collective agency and possibly more risks. These two features put the so-called problem of many hands (PMH) to the fore. A lot may be at stake: people's lives, the environment, and public health. Furthermore, in addition to cases where the probability is relatively well known, technological research and development entail substantial uncertainty about future hazards about which we do not have any knowledge today.

## Climate Change as an Example

---

Climate change is an illustrative example of a substantial risk (or cluster of risks) for which it is extremely difficult to ascribe and distribute responsibility and which is caused by more or less all human beings, private companies, and governments. It is therefore a possible example of the PMH.

In debates about climate change, various notions of responsibility are at play (cf. section [Conceptions of Responsibility](#)) as is reflected in the different principles of responsibility that have been proposed. First, there is the polluter pays principle (PPP) stating that the polluting actor, that is, the one who caused the pollution, is the actor who ought to pay the cost (United Nations 1992; Caney 2005; Shue 1999). This principle applies a backward-looking notion of responsibility since it focuses on the causal link, but it also associates backward- and forward-looking responsibility in the claim that the one who caused the damage is also the one who should rectify the situation.

Second, there is a principle referred to as common, but differentiated responsibilities (CDR), which states that although all countries share responsibility for climate change, the developed nations have a greater share of responsibility to do something about it (forward-looking responsibility) because their past and current causal contribution is greater (backward-looking responsibility) (United Nations 1998). Thus, both the PPP and the CDR assume that the agent who caused climate change is also the one who is responsible to improve the situation. We often think about responsibility in these terms, but it is possible to conceive of responsibility for climate change differently. The ability to pay principle represents a different approach (Caney 2010). Originally, this principle is associated with a progressive tax system to justify why wealthy people should pay a greater share of their incomes in taxes than poor people in order to maintain a social welfare system. It is possible to design a principle of responsibility for climate change in a similar vein. A central principle in ethics is “ought” implies “can,” essentially meaning that it does not make sense to demand that people do X if they are unable to do X. It has also been argued that sometimes “can” implies “ought” (Garvey 2008). This means that it may be reasonable to attribute a greater share of responsibility for climate change to developed nations not only because they contributed more to the causal chain, but because they simply have more resources to do something about it. This would of course not be reasonable for all risks, but considering the scope and potentially devastating consequences of this particular cluster of risks, it may be a reasonable principle in this case.

We have seen that there are different ways of approaching the distribution of responsibility for climate change between collective actors. In addition, there is the question about how to distribute responsibility between individuals versus collective agents, for example, governments and private companies. To what extent are individuals responsible? Furthermore, in what ways and for which parts are they responsible? Some philosophers argue that individuals are responsible, in the sense of accountability and blameworthiness (backward-looking

responsibility) (e.g., Braham and van Hees 2010). Others argue that individuals are not responsible, but that governments are (e.g., Sinnott-Armstrong 2005), and still others argue that individuals are responsible in a forward-looking way, but that they are not to blame for how climate change and environmental problems came about (e.g., Nihlén Fahlquist 2009).

By talking about risks instead of direct harm, we have changed the perspective of time. A risk that something negative could happen is something for which someone can *take responsibility* and do something about. This is different from cases in which harm has already been done. When the risk has materialized, we want to find someone to blame or give an account of what happened. We need a backward-looking notion since harm will be done and we will want to blame someone to compensate victims. However we also need responsible engineering, research, and risk management, that is, people who act responsibly in order to minimize the risks to society, people, and the environment.

The typical PMH situation occurs when something undesirable has happened as a consequence of collective acting. The PMH can be described by the question: “Who did that?” which is the epistemic problem of knowing who actually did something to cause the undesired event, but the PMH can also point to the normative problem that we cannot find anyone whom it would be fair to hold responsible for the undesired event. The responsibility notion assumed in this question appears to be individualistic and backward looking. Although this notion of responsibility is common and in some ways necessary, there are other notions which may complement it. After all, if we are interested in solving the PMH we probably have to look not only for ways to attribute blame when a risk has materialized, but also for ways in which risks can be reduced or managed in a responsible way to prevent them from materializing. Presumably, what we want is to prevent the PMH from occurring. In the following subsections, we will look into three ways to, if not replace, supplement the “Who did that?”-approach to responsibility: responsibility as a virtue (☞ [Responsibility as a Virtue](#)), responsibility distributions (☞ [The Procedure of Responsibility Distribution](#)), and institutional design (☞ [Institutional Design](#)).

## Responsibility as a Virtue

---

Responsibility is an unusually rich concept. Whereas many notions of responsibility focus on attributing blame for undesired events, there is also a notion that focuses on character traits and personality. To be responsible can be more than having caused X, being blameworthy for causing X, or even having particular obligations to do something about X. Responsibility can also be a virtue and a responsible person can be seen as a virtuous person, that is, having the character traits of a responsible person (see section ☞ [Conceptions of Responsibility](#)). We will now take a closer look at this virtue-ethical notion of responsibility.

By researching, developing, and using technology, opportunities are created. In this process, risks are created as well. In essence, technology creates opportunities and threats. It is, in this sense, a double-edged sword. For example, we want oil for energy, which means that we have to deal with risk of leakage as well as the actual leakage when it happens. Although we live with risks every day, it becomes clear to most people only when the risk actually materializes. Intuitively many people probably think that activities providing us with opportunities, but also risks, imply an increased sense of responsibility and that such activities should be carried out responsibly.

To associate the concept of responsibility with character traits and a “sense of responsibility” means having a closer look at virtue ethics (see ☞ [Chap. 33, Risk and Virtue Ethics](#), in

this handbook). Virtue ethics is often mentioned as the third main branch of ethical theories (next to consequentialism and deontology). Virtue ethicists attempt to find answers to questions of what an agent should do by considering the agent's character and the morally relevant features of the situation (Van Hooft 2006, p. 21). Seeing responsibility as a virtue would entail a focus on how to develop and cultivate people's character with the aim to establish a willingness to actively take responsibility. A willingness to take responsibility involves emotions such as feeling personal involvement, commitment, and not leaving it to others, a feeling that it is up to me and a willingness to sacrifice something (Van Hooft 2006, p. 144, see [Chap. 32, Moral Emotions as Guide to Acceptable Risk](#), in this handbook). It is not the same as a willingness to accept blame for things an agent has done wrong (backward looking) although that may be one part (Van Hooft 2006, p. 141). The main focus is on forward-looking responsibility.

One important aspect of responsibility as a virtue is the recognition that being a responsible person is about carefully balancing different moral demands (Williams 2008, p. 459). Against the background of the different kinds of moral demands human beings face today, it may be difficult to point to one action which is the only right one. Instead a virtuous-responsible person uses her judgment and finds a way to respond and optimize, perhaps, the various demands. Against this background, it could be argued that in order to avoid PMH, we need virtuous-responsible people who use their judgment to form a balanced response to conflicting demands. This could be one way of counteracting the organized irresponsibility of contemporary society. The question is of course how such a society or organization can be achieved. Virtue ethicists discuss upbringing, education, and training as ways of making people more virtuous (Hursthause 2000; Aristotle 2000).

As mentioned in section [The Problem of Many Hands \(PMH\)](#), there are two features of contemporary society which combine to put the PMH to the fore. First, collective agency is increasing. Second, the number of risks has increased, or at least our desire to control risks has grown stronger. A virtue approach to responsibility may counteract the problem of many hands in two ways, both related to the second feature. First, focusing on responsible people may prevent risks from materializing instead of distributing responsibility when it has already materialized (see [Chap. 33, Risk and Virtue Ethics](#)). Responsible people are concerned about risks to human health and the environment because they care and they use their judgment to prevent such risks from materializing. Second, when risks do materialize responsible people will not do everything to avoid being blamed, but will take ownership of what happened and make sure the negative consequences are minimized. Whether the virtue notion of responsibility could also meet the challenge of increasing collective agency is less straightforward. It could be argued that the very tendency to have more collective agency counteracts responsibility as a virtue since people can hide behind collective agents. However, the collectivization could also be seen as making it ever more important to develop a sense of responsibility. Such a development would probably start with moral education and training of young children, something which virtue ethicists often suggest as a way to cultivate virtue. It would also require organizations that foster virtues and a sense of responsibility (see also [Institutional Design](#)).

## The Procedure of Responsibility Distribution

As mentioned earlier, the concept of responsibility is extraordinarily rich and refers to not one but many different notions. In addition to the difference between legal and moral

responsibility, there are many different notions of moral responsibility. It is not surprising that people have different notions in mind and what may appear as conflicts about who is responsible for a certain state-of-affairs may sometimes primarily be misunderstandings due to lack of conceptual clarity. However, it is not merely conceptual lack of clarity which causes differences. People disagree about the normative issues involved, that is, how responsibility *should* be understood and distributed. This is true for people in general and surely holds for professionals as well. According to Doorn (2010, 2011), the prevalence of differences in views on responsibility may cause the PMH. One way of attempting to resolve these differences may be to focus on the procedural setting instead of the substantive conception of responsibility. In order to do this, it is important that we agree that there are disagreements. The solution is not to find and apply the right one, but rather to achieve respect for differences, consensus concerning the procedural setting (this may of course be hard to achieve), and possibly agreement on concrete cases of responsibility distributions.

In political philosophy, John Rawls famously showed that what is needed in pluralist societies is a consensus on the basic structure of society among different religious, moral, and other “comprehensive doctrines” (Rawls 1999 [1971]; Rawls 1993). He argues that we cannot expect that all citizens in a pluralist society agree on politics, but there are some basic principles to which most reasonable people regardless of which doctrine they adhere to would agree, not the least because those very principles would grant them the right to hold those different doctrines. In order for people with different comprehensive doctrines to agree to a basic structure as being fair they justify it through working back and forth between different layers of considerations, that is, their (1) considered moral judgments about particular cases, (2) moral principles, and (3) descriptive and normative background theories. When coherence is achieved between these different layers, we have achieved a wide reflective equilibrium (WRE). In spite of differing judgments on particular cases, different moral principles, and background theories, people can justify the basic structure of society. When many people agree on the basic principles of fairness through different WRE we have an overlapping consensus. Therefore, even if the ways in which we justify it may differ substantially everyone agrees on something, that is, the basic structure of society.

Doorn applies Rawls’ theory to the setting of R&D networks (see also Van de Poel and Zwart 2010). The aim is to develop a model which shows how engineers do not have to agree on a specific conception of responsibility as long as they agree on fair terms of cooperation. R&D networks are non-hierarchical and often lack a clear task distribution, which leaves the question of responsibility open. Doorn shows how a focus on the procedure for responsibility distribution instead of a substantive conception of responsibility makes it possible for engineers to agree on a specific distribution of responsibility. They can agree to it because the procedure was morally justified and fair, even if they disagree about a specific notion of responsibility. This way responsibility is distributed, that is, the PMH is avoided, but the professionals do not have to compromise their different views on responsibility. Without reaching a consensus on a responsibility notion or a responsibility distribution, consensus is reached on a procedure yielding legitimate responsibility distributions. In addition to Rawls’ procedural theory there are others theories, for example, based on deliberative democracy that are set out by authors like Habermas, Cohen, and Elster which can be used in order to help focus on the procedure of distributing responsibility instead of the substantive notions (see, e.g., Habermas 1990; Bohman and Rehg 1997; Elster 1998).

## Institutional Design

---

We have discussed responsibility as a virtue ([❶ Responsibility as a Virtue](#)) and the procedure by which responsibility may be distributed ([❷ The Procedure of Responsibility Distribution](#)) as two ways of counteracting the problem of many hands. We will now look at the importance of institutions. In particular, we will look at what has been called institutional design, the purposeful design of institutions (see, e.g., Weimer 1995). Since institutions generally already exist and cannot be designed from scratch, institutional design usually amounts to modulating or changing existing institutions. Institutional design may contribute to solving the PMH in two different ways: (1) it might create the appropriate institutional environment for people to exercise responsibility-as-virtue and (2) it might help to avoid unintended collective consequences of individual actions. We will discuss both possibilities briefly below.

Institutions may facilitate virtuous or vicious behavior. As argued by Hanna Arendt (1965), Eichmann was an ordinary person who, when he found himself in the context of Nazi-Germany, started to behave like an evil person. Institutions may socialize people into evil doing. Although most cases are not as dramatic and tragic as Eichmann's case, the institutions within and through which we act affect to what extent we act as responsible people. Larry May (1996) has developed a theory of responsibility that connects ideas about responsibility as a virtue to institutions. Institutions can facilitate and encourage or obstruct virtuous behavior. May discusses the ways in which our individual beliefs may change at the group level. The community has an important role in shaping the beliefs of individuals. Relationships between people require a certain collective consciousness with common beliefs. The important point about May's theory is that to foster a sense of responsibility-as-virtue among individuals in a group or organization requires an appropriate institutional environment. As we have argued before ([❶ Responsibility as a Virtue](#)) fostering responsibility-as-virtue may contribute to solving the PMH. The additional point is that doing so not only requires attention for individuals and their education but also for their institutional environment.

The other way that institutional design can contribute to solving the PMH is by devising institutions that minimize unintended collective consequences of individual actions. As we have seen in [❷ The Problem of Many Hands \(PMH\)](#), the PMH partly arises because the actions of individuals may in the aggregate result in consequences that were not intended by any of the individuals. The tragedy of the commons and the discursive dilemma were given as examples of such situations. The phenomenon of unintended consequences is, however, much more general. The sociologist Raymond Boudon (1981) has distinguished between two types of systems of interaction. In what he calls functional systems, the behavior of individuals is constrained by roles. A role is defined by "the group of norms to which the holder of the role is supposed to subscribe" (Boudon 1981, p. 40). In interdependent systems, roles are absent but the actors are dependent on each other for the achievement of their goals. An ideal-typical example of an interdependent system is the free economic market. The tragedy of the commons in its classical form also supposes an interdependent system of interaction and the absence of roles, since the actors are not bound by any institutional norms.

According to Boudon, emergent, that is, collective, aggregate effects are much more common in interdependent systems than in functional systems. Reducing emergent effects can therefore often be achieved by organizing an interdependent system into a functional system. This can be done, for example, by the creation of special roles. The "invention" of the role of the government is one example. In cases of technological risks, one may also think of

such roles as a safety officer or safety department within a company or directorate, or an inspectorate for safety within the government. Another approach might be to introduce more general norms as constraints on action. This is in fact often seen as the appropriate way to avoid a tragedy of the commons. In both cases new role responsibilities are created. Such role responsibilities are obviously organizational in origin, but they may entail genuine moral responsibilities under specific conditions, like, for example, that the role obligations are morally allowed and they contribute to morally relevant issues (see also Miller 2010).

## Conclusion

---

There are many different conceptions of risk and psychologists and philosophers have pointed out the need to include more aspects than probabilities and consequences, or costs and benefits when making decisions about the moral acceptability of risks. It remains to be seen whether these additional considerations also need to be built into the very concept of risk.

In addition there are many different notions of responsibility, and the exact relation between risk and responsibility depends on how exactly both notions are understood. Still in general, both risk and responsibility often refer to undesirable consequences and both seem to presuppose the possibility of some degree of control and of making decisions that make a difference.

We started this chapter by mentioning the Deepwater Horizon oil spill in 2010. People were outraged when it occurred and, it seems, rightly so. It raised the issue of responsibility-as-blameworthiness because it appeared as though there had been wrongdoing involved. However, it also raised the issue of responsibility-as-virtue since a lot of people joined the work to relieve the negative consequences of the oil spill and to demand political action to counteract companies from exploiting nature and human beings.

As this example shows, there is not only backward-looking responsibility for risk but also forward-looking responsibility. We discussed in some details relevant forward-looking responsibilities that might be attributed to engineers, risk assessors, risk communicators, and risk managers. We also discussed that risks may be more or less seen as individual or collective responsibility.

We ended with discussing the problem of many hands (PMH), which seems a possible obstacle to taking responsibility for the risks in our modern society. We also suggested three possible ways for dealing with the PMH: responsibility-as-virtue, a procedural approach to responsibility, and institutional design. What is needed is probably a combination of these three approaches, but the discussion suggests that there is also hope in that people are able to unite and release a collective sense of responsibility.

**Abstract:** What is a fair distribution of risk? This chapter will look into three separate, but related, aspects of fairness in risk distributions. Firstly, I will locate the object of fairness when it comes to risk distribution. In contrast to distributions of goods, which we want to both increase and distribute fairly, risks are something we want to decrease and distribute fairly. The question of fairness in risk distributions is the question of how to combine these two partially conflicting claims; to fairness on the one hand and to risk reduction on the other. Secondly, I will take a closer look at what an equal distribution of chances for harm might be. I will point to the problem that the very idea of distributing probabilities entails. Thirdly, I address the question of when deviations from equal distributions of risks may be justified and how such inequalities can be addressed in a fair way. It will be suggested that the locus of fairness of risk should be sought in two steps: (1) the justification of particular risky activities, where the level of risk and the spread of that risk is taken into account, and (2) that any resulting higher risk for certain groups or individuals should be addressed through a combination of consent, precaution, and compensation, seeking to even out unfair exposure.

## Introduction

---

What is a fair distribution of risk? In political philosophy we have since Rawls' *A Theory of Justice* been accustomed to think of equal distributions as fair distributions, unless competing reasons, such as efficiency, calls for some less than equal distribution to be balanced with the claims of equality. In Rawls' theory this balance is struck in the *difference principle* where all deviations from equal distributions need to be justifiable and beneficial also to the least advantaged (Rawls 2003). What is of importance for the present chapter is the underlying idea that equality is the initial starting point for thinking about justice and fairness. The question is when any deviations from equality can be considered fair. According to Rawls, such deviations are only just if they are to everyone's advantage (Rawls 2003, 54ff).

Does this approach to fairness about goods also apply to the topic of risk? Can we adopt the model of balancing equality with risk mitigation, such that *ceteris paribus* equal distribution is to be preferred but may be deviated from in order to reduce the total level of risk? Can we think of risks in the same way being distributed equally so that no one faces more risk than anyone else (unless there is strong risk reducing reasons to distribute them less equally in the interest of all including those at higher risk)? This chapter will investigate the idea of an equal distribution of risk and the justification for when deviations from this ideal of equality may be legitimate. I will argue that the idea of equal distribution of uncertain harm is more problematic than in the case of distribution of goods. Or rather the ideal of equality cannot be properly applied to estimates of probabilities but ought to focus instead on outcomes and sources of risk.

I shall assume that the moral permissibility of imposing a risk upon a person depends, at least to some degree, *upon how much risk others are subjected to*. If one person is subjected to all the risks but no one else is, we would spontaneously think that this would be unfair (Broome 1990, p. 95). Intuitively, an equal distribution seems the most fair. But it is not clear what this would mean: Equal distribution of outcomes or of chances for outcomes? Equal probability for harm given the same exposure or equal exposure for all?

But how much can the spread of a particular distribution tell us about the fairness of that distribution? Within the contractualist tradition, especially following Scanlon, it would seem

that fairness is determined not so much by equal outcomes but equal concern for *each* person (Scanlon 2000, p. 229). The stress is now on the *reasons* for a particular distribution and the competing claims of affected parties. This suggests a different perspective on what an equal distribution would be, one where equality is not to be sought in outcomes, or in chances for outcomes, but in taking the rights or the interests (not to be harmed) of each into equal consideration. Lenman (2008, p. 106) suggests that we could interpret this requirement for equal concern as precautionary measures directed at each.

We can then assume that an equal distribution of risk would be acceptable to each, unless the cost would be too high in terms of increases in the total level of risk. Furthermore, we can also presume that there may be good reasons to allow for less than equal distributions of risk for the right reasons. We shall address these questions one at a time: First, how far will the idea of an equal distribution take us when it comes to fairness in the distribution of risks? Second, how do we distribute unequal shares of higher risks in a fair way? Only after we have answered the above questions shall we attempt to answer the main question: When is a particular distribution of risk fair?

## An Equal Distribution of Risk?

### Distributing Goods Versus Distributing Risks

It would seem that the simplest way to distribute risks in a permissible way would be to distribute risks equally, so that no one faced a greater risk than anyone else. This ideal has a lot of intuitive appeal borrowed from the egalitarian ideals in the distribution of public goods. If there is something desirable for all, one way to distribute it fairly is to divide it equally among those with some claim to it. The same line of reasoning would apply to undesirables or harms. It would then seem only natural to think of *risk of harm* in that same way.

How does this idea of fairness translate onto the topic of risk? Risk is not a divisible public good that we want for each and everyone to have their fair share of. Rather risk is a measurable unwanted side effect of such goods. The two goals to balance in the case of risk are (1) total reduction of risk and (2) equal distribution of risks. Just as we may accept a distribution of goods that is less than equal if it benefits everyone in the name of efficiency or the total amount of goods, we may want to accept a distribution of risk that is less than equal if it benefits everyone in the name of risk reduction. There is the same kind of *leveling down objections* that could be raised against equal distributions of risks as those raised against equal distributions of good (term coined by Parfit in 1997, but objection discussed both before and after). In the standard version, the leveling down objection points out that if equality were of *intrinsic* value, or the *only* value to take into account, then this would lead to absurd or otherwise unwanted consequences (see e.g., Parfit 2002). Equality could demand of us that in cases where it is not possible to raise everyone to the same level of well-being than those who are better off must level down to those who are worse off. This would improve the situation for no one but only serve to make it worse for some. Typically this argument has been brought forward in support for competing theories of equality such as sufficiency or prioritarianism. Frankfurt (1987), for example, defends the sufficiency view, arguing that what matters in cases of fairness is that some people are poor or badly off in absolute terms, not that some people have more. Thus if everyone had sufficient means for their ends, it would not be a problem that some had more than that. Insisting on

redistribution in the name of equality would simply translate into forcing some to level down to the level of those that worse off.

Applied to the risk context the simplest form of the leveling down objection would run something like this. If equality is of intrinsic value then if there is some activity (benefitting to society at large) that brings about a greater risk for some, then everyone must be exposed to that risk. Or, if there is some protective device that would greatly reduce the risk for most individuals but could not do so for everyone (whether some individuals were immune to it or there were not enough to go around) then no one should profit from such protective devices. In the case of risk, we could easily see absurd consequences if we insisted that for every accepted risk everyone must be equally exposed to a similar risk since this would require introducing new risks where they did not naturally occur in order to even out the burden of risk. In other cases, it would lead us to not to employ the safety devices we had access to if they were too few or in some way insufficient to save all. It is for this reason that this chapter follows Rawls' and others in starting from the premise that equality must be balanced against gains for everyone to some degree. In the case of risk this means that there can be cases where we must allow some to use protection that others do not have access to and must allow for cases where we expose risks to some that others are exempt from. In particular, it may be the case that we can reduce the risk for some to start with, before we are able to reduce that risk for everyone.

All in all, it would seem that we can think of fairness and the distribution of risks in much the same vain as that of fairness and the distribution of goods. Altham, for example, suggests that we may think of the “absence of risk” as a primary good among the others to distribute by means of Rawls’ difference principle (Altham 1983–1984, p. 22). Interestingly, Altham does not develop the idea precisely because he does not find it helpful to determine what level of risk would be acceptable. The problem of fairness of risk can then be summarized as the problem of how to strike a balance between fairness and risk reduction.

Risks are not taken or imposed unless they come as part of some package that is advantageous in some respect. We do not just impose a risk on someone, but rather we initiate an activity for the sake of some good that also poses a risk. Nozick expresses this point very well: “For example, it might be decided that mining or running trains is sufficiently valuable to be allowed, even though each presents risks to the passerby no less than compulsory Russian roulette with one bullet and  $n$  chambers (with  $n$  set appropriately), which is prohibited because it is insufficiently valuable” (Nozick 1974, p. 74). We can then add the additional question of how to balance goods and risks (and the distribution of goods in relation to the distribution of potential harm) to the problem of balancing risk reduction and fairness. Take a case of live organ donors, for example, the benefactor will not be the same as the one suffering the risk of donating an organ. Are such cases of risks, when the person who benefits is a different person than the person who runs the risk, fair?

If we return to the parallel case of distribution of goods, there is a further complicating issue when we move from goods to risks due to the uncertainty element of risk. In the ideal case, where there is enough of a particular good for everyone, the egalitarian ideal would suggest that everyone should have an equal share of that good. In other words, the equal distribution entails equal outcomes. In the case of risk even if risks were distributed perfectly equally such that everyone faced the same probability of harm this would not entail equal outcomes in terms of harm. A distribution of risks is not a distribution of harms but of *chances for harm*. The parallel case would be an equal distribution of chances for receiving goods rather than an equal

distribution of goods. But how do we distribute chances equally and what is it that would make equal chances fair if the outcomes are not?

## The Equality Claim

---

A first natural step would be to presume, unless there is a good reason not to, that if we want to distribute risks fairly then what we ought to strive for is *an equal distribution of risk*. Let us refer to this as the Equality Claim (EQ):

EQ: An equal distribution of risk is *ceteris paribus* better than an unequal distribution of risks, even when the unequal distribution would entail a lower total level of risk.

This principle seems to have what we want – it is normatively attractive in the sense that it is fair by respecting equality (not fair in the Rawlsian sense, as that does not require equality). We have yet to say how to weigh it against risk reduction in a fair way. All this claim states is that risk reduction is not by itself a sufficient reason to override an equal distribution of risk. It thereby contrasts with utilitarian ideas of distribution such as risk-benefit analysis, which is a common approach in risk management, and which is insensitive to how risks are distributed as long as they maximize the total reduction of risk (for objections against this approach cf. Roeser and Asvelt 2009). I will however leave the problem of balancing risk reduction and fairness to the side for now and instead focus on the very idea of an equal distribution of risk.

What is an equal distribution of risk? Part of the problem here lies in the ambiguity in the notion of “risk.” This problem becomes even more accentuated when we think of risks as objects to distribute. Hansson (2004, p. 10) identified no less than five different interpretations of risk: an unwanted event that may or may not occur, the cause of such an event, the probability for such an event, the statistical expected value of such an event, and the fact that a decision is made under conditions of known probabilities [for different possible outcomes that may occur]. It is unclear which of these interpretations we have in mind. We know what an equal distribution of goods, or even harms, would be. But in the case of risk, we are neither distributing goods nor harms but *potential* harms. One way to understand equal risk is then to attempt to distribute the *probabilities* for a particular harm equally such that everyone faces the same probability of harm. The EQ claim is then a statement suggesting that an equal distribution of probabilities for a particular harm is better than an unequal distribution of probabilities for that same harm.

One difference between distributing harms and the probabilities of harm is that equal probabilities do not entail equal outcomes (see Broome 1984 for a discussion about *ex ante* versus *ex post* fairness). If we, borrowing an example from Lenman (2008), impose a risk of death with the probability of 1 in 500,000 onto a population of 20 million, then the most likely outcome would be that 40 out of the population die and the rest go unharmed. The kind of fairness that an equal distribution of risk can achieve is that of a fair lottery, not that of an equal amount of well-being. The underlying moral rationale in support of an equal distribution of risk need thus be another one than the one that leads us to prefer equality in distribution of goods and harms that are certain.

What is it about an equal distribution of the prospects of harm, before the actual harm has occurred, that makes us think of it as fair? For one it rules out unattractive alternatives such as selection on ill-willed grounds or for arbitrary reasons. It lends impartiality to the distribution of risk since no one is deliberately favored before anyone else. From this point of view, an equal

distribution of risk would only be fair to the extent that this was the best way to achieve an unbiased or impartial distribution of risk. This, however, could equally well be achieved by applying a fixed rule in the selection of who would be at greater and who at lower risk as long as that rule is applied equally to all, Broome has argued (Broome 1990–1991). It could be objected that a fixed rule is only unbiased in the sense that the decisions would be the same regardless of who made them and thereby arbitrariness would be avoided (see Pettit 1997, Ch. 2 for discussion about arbitrariness and non-arbitrariness), but not the possibility of biased or unfair rules.

Broome interestingly argues that distributions by fair lotteries can be fair in themselves rather than as a means to achieve impartiality (or to break ties between equally strong competing claims) (see e.g., Timmermann 2004 and Taurek 1977 for discussion). In contrast to distribution by selecting one candidate over another candidate on grounds of the stronger claim, in a lottery everyone with a claim, large or small, to a particular good is given a chance to actually get what they have claims to: those with competing but somewhat lesser claims are not simply overridden but are part of the distribution (Broome 1990–1991, p. 94). When fairness in outcomes cannot be achieved, he argues, lotteries can provide “a sort of partial equality in satisfaction [of claims].” He writes: “Each person can be given a sort of surrogate satisfaction. By holding a lottery, each can be given an equal chance of getting the good. This is not a perfect fairness, but it meets the requirement of fairness to some extent” (Broome 1990–1991). He continues: “It does so, of course, only if giving a person a chance of getting the good counts as a surrogate satisfaction of her claim. This seems plausible to me. After all, if you have a chance of getting the good you may actually get it” (Broome 1990–1991).

This line of argument seems to hold in cases where the distribution is entirely controlled like the reoccurring examples of Russian roulette games so often referred to in the ethics of risk literature as a means to illustrate the probability and uncertainty aspects of risk. In its standard adoption to the risk context it goes roughly like this: A game of Russian roulette is played on another person. All the chambers but one are empty such that the person faces a risk of 1/number of chambers risk of death (see e.g., Nozick 1974, Ch 4, 74ff). This example has then been elaborated in all sorts of forms to fit the particular distribution of probabilities for different examples. A risk of 1 in 500,000 can then be translated into a fictive Russian roulette gun of 500,000 chambers of which 499,999 are empty and 1 is loaded. An equal risk of harm imposed on a population of 20 million would then be to impose a risk such that it resembled 20 million independent guns pointed at each one. This way no one would have a greater or lesser chance to be harmed than anybody else. In such a case, we could say about each and everyone out of the 20 million that they faced a 1 in 500,000 chances of death even if only 40 of them actually came to be shot.

One worry here is that we tend to think of such distributions as fair because we associate the idea of equal probabilities to the fairness of a die. But if a die is fair it is because it is expected to land on each side one sixth of the times tossed if repeated a large enough number of times. In other words, the fairness presumes expected equality of outcomes in the totality of events. The question is then if there is anything such as equal chances for one-off games, that will not be repeated (see Ayer 1972, pp. 27–30, about the difference between *a priori* mathematical judgements of chances and actual games of dice). Take the case of the Russian roulette again. Let us presume that 20 million people are subject to the same number of gunmen playing Russian roulette with a one loaded chamber to 500,000 unloaded ones. We may say that the risk is the same for each one of them. We may also conclude that we know something about how

frequent the risk is (1–500,000). But is this sufficient to make it fair? We do not think of a medicine that has a one in 500,000 chances for lethal side effects as particularly fair. Partly this may be because we suspect that even if the guns are the same and the gunmen the same number that if we think of actual cases and actual risks a million and one little differences may influence who actually comes to harm and who does not. (In the case of the Russian roulette where the loaded chamber is placed and how the chambers are spun before they are fired). As Ayer puts it: “If we are going to apply the calculus of chances to actual games, we have to make the assumption that all the logically equal possibilities are equal in fact, and this of course is not a mathematical truth. It is an assumption to which one has to give an empirical meaning” (Ayer 1972, p. 30).

It can be argued that what makes the “equal chances” fair is not some idea of equal shares, but as a means to achieve *impartiality*, to avoid biased or non-neutral decisions (Broome 1990–1991; Mirrlees 1982). In the cases of low probability risks, large populations lotteries would most likely result in a very few people “winning” and most likely not those with the strongest claims and reasons (see Hooker 2005, p. 349 for this point). The conflict here is when random selection is better because more neutral than selection on reasons because they may be biases, or alternatively as tiebreaker when no conclusion can be drawn about competing claims.

Take Broome’s claim about lotteries being fair because everyone has a chance of actually getting the claim satisfied. The lottery metaphor is problematic as soon as we step outside the sphere of abstract fictive cases where we control the probabilities to each person. In most cases, the probability of a particular risk is not about how likely a particular individual is to get this or that but what the frequency of such gains typically is for any member in a particular reference class (Perry 2007). In such a case, a risk may be distributed such that it is true about the activity that it typically results in one death for every 500,000 exposed to it, but that it is not true that each and every person exposed to the risk has a 1/500,000 chance of death. Even if everyone is exposed to the same it may be that due to some medical conditions and other contributing factors only 500 are at genuine risk and the rest at no risk at all. I will refer to such distributions of risk as *indiscriminate distributions of risk*. It seems that in most cases, leaving the hypothetical lotteries and Russian roulette guns aside, that when we talk of equal distributions of risk we refer to indiscriminate distributions of risk rather than equal distributions of probabilities. If this is correct then Broome’s argument that lotteries are fair because everyone has a real chance of actually having their claims satisfied since “if you have a chance of getting the good you may actually get it” simply does not hold.

Thus, to the extent that a risk imposed can be understood as a lottery ticket or a die that gives everyone equal odds for being harmed, the Equality Claim holds (given the *ceteris paribus* before it is weighed against precautionary issues). The second question we need to address is to what extent risks imposed *can* be said to resemble lotteries, Russian roulettes, and games of dice.

## Indiscriminate Risk Impositions

In most cases of risk imposition, what we are distributing is not chances of harm but activities with a certain expected probability of harm. The probability measure is then not describing the risk for any one group of individuals and how likely they are to come to harm but is an estimate of how often such incidents tend to happen for that particular activity. Thus imposing

a risk of 1 in 500,000 on a group of individuals may not imply that any one of them or the whole of the group faces a probability of 1 in 500,000 of harm but that they will be affected by an activity that can be expected to bring about harm in 1 out of 500,000 cases given past occurrences.

We allow chemical emissions to be distributed through factory chimneys, additives into food produce, potentially harmful components in prescriptive drugs, pedestrian crossings over roads but not highways, etc. Take the case of emissions or drugs, how do we know when such distributions are fair? On the one hand we could claim that the factory chimney distributes the risks equally since it just lets it out into the air that everyone in its vicinity breathes. On the other hand, who actually comes to harm may depend upon such factors as how long they are exposed, their medical conditions such as asthma, and whether they are children. We can then say that the source of harm is distributed equally but not the actual risk or the probability of harm, which makes it an indiscriminate distribution of risk, without being an equal distribution of probability of harm. The chances of harm may in such cases be very unequal due to a whole set of circumstances.

This goes even for such cases when we can assess the probability fairly accurately of anyone person out of the population coming to harm. Thus, even if we know for a given harm that the chances are 1 in 500,000 for death, this tells us very little about what determines or influences the unlucky cases. We may distribute a source of harm with the expected risk of death as 1 in 500,000 onto a population of 500,000 and implement that source equally, such that everyone is equally exposed to it, without knowing whether that risk is equally distributed.

Suppose that the risk for a certain population given previous statistics of being hit by lightening each year is  $n$ . However, let us presume that most people who are hit by lightening are in tall buildings or under tall constructions or in some other situation putting them at more risk. Thus not everyone is at the same risk but rather, some are at much greater risk of being struck by lightening than others.

In fact, if the expected number of death is 1 out of 500,000 we may have good grounds to suspect that there are more factors to take into account and that most likely some are at much greater risk than others. The point is that we cannot say what the probability of harm for each individual is and then make sure that everyone has the same probability of harm. Not just because all the causal factors are not known, but because probabilities are estimates of the likelihood of a certain event, typically based on the frequency of it occurring for similar enough cases. A probability estimate is in that sense a qualified guess of how likely something is given what we know about how often a certain harm occurs (for a given reference class). Given this, it is hard to see how probabilities are the kind of thing that can equally be distributed among individuals since they are estimates based on aggregation over many instances and individuals. What we can do is act in response to what we know about possible reference classes with different probability estimates to come to harm from that same source. If we know that some are at greater risk than others, we may seek to lower the risk for that group, or “transfer” them to a lower reference class (such as from the class of smokers to the class of nonsmokers).

What speaks in favor of distributing risks indiscriminately is that in many cases we do not know how the risks fall and if nothing else it can be considered *impartial* in its distribution (not in outcomes but in intentions or motives). In cases where we do not know what particular risk any one individual is facing but only an estimate of how likely anyone of them is to come to harm we have in a way come to knowledge’s end. In such cases, distributing risks indiscriminately may well be the best we can do, presuming that we do not know more about potential

factors that influence the outcomes. But is this sufficient to regard a particular distribution as fair in cases where we both know that the risk to the population as a whole is 1 in 500,000 but also have good reason to believe that some within that population may be at much greater risk than others (even if we do not know who they are)?

The problems discussed thus far when it comes to the idea of equal distribution of risk springs from the fact that probabilities are a way to deal with the uncertainty of the future. It is not chances that we distribute but guesses based on large aggregate data. This means that there is too much room for hidden inequalities for “equal probabilities” to be *an ideal* since it can neither guarantee equal outcomes or equal probabilities for individuals but merely is a way to deal with the uncertainty of who will come to harm. We could, however, think of the sources of risks, and the knowledge we have about their comparative riskiness, as a heuristic tool to get a rough idea about how risks and expected harms will fall. We need not talk about distribution of probabilities to see that placing a nuclear power plant in one place rather than another will, in the case of an accident, affect those closer to it more than those farther away. Thus, placing several industrial plants near the same house will presumably increase the risk from emissions as well as from accidents. Thus, we can distribute chances indirectly by distributing what we can portion out: the sources of risks and the precautionary devices to reduce risks. It would seem that instead of thinking of chances as something to distribute, in trying to seek equality and fairness in terms of risk, we would be much more helped if we sought to identify causal factors that increase the chances of harm and address those causal factors.

## Precaution and the Aggregation Worry

---

Instead of thinking of risk as something we can distribute in a way parallel to other goods we can distribute, we can shift focus to *equal treatment* when it comes to the impositions of risks. Lenman (2008) suggests that what we ought to focus on when it comes to distributions of risk is *precautionary measures aimed at each*. Here a different interpretation of EQ suggests itself: risks should be distributed equally not in the sense of equal probabilities but as *equal precautionary concern* for each person. The concern for risk reduction is here paired with fairness in the way of aiming such risk reduction at each person. First a few things need to be said about Lenman’s contractualist approach before we move on to the idea of precaution.

### Preamble: Justification to Each Person and the Aggregation Worry

---

Lenman’s suggestion stems from Scanlon, both in its insistence on moral justification that takes each person into equal account and in Scanlon’s stress on the role of precaution (Scanlon 2000, Ch. 5, esp. 229ff). Lenman argues that contractualism, in particular of Scanlon’s kind, is better suited to take care of our moral intuitions with regard to fair distributions of risks than consequentialism is because of its stress on each individual’s importance in moral justification (Scanlon 2000). As Scanlon puts it: “the justifiability of a moral principle depends only on various individuals’ reasons for objecting to that principle and alternatives to it” (Scanlon 2000, p. 229). The contractualist starting point for Lenman’s investigation is explained thus:

- ▶ The key distinguishing feature of contractualism, for my purposes, is the thought that the right normative ethical claims are those who are best able to justify to others where, crucially, this

justifiability is understood as justifiability to *each other person*. . . . This kind of contractualism contrasts with rival utilitarian views in insisting that we may not simply aggregate costs and benefits to different persons and seek to maximize this aggregate. Harm to you cannot be straightforwardly compensated by benefits to me (Lenman, 99ff, italics in original).

This last point is not unique to contractualism but would hold for any non-consequentialist critique of cost-benefit approaches to risk. The contractualist take is that any distribution of risk must be such that it is acceptable to each person affected (as if they were to sign a contract with each other), the focus being on the role of reasons.

In the context of distribution of risks, a particular distribution can be considered permissible only if it is justifiable to each of the persons affected by that distribution. That the majority benefits from a particular distribution is not sufficient to make it permissible. Only such reasons that those who are getting the lesser deal can also accept can make a particular distribution permissible. If we allow aggregation of benefits and costs across a population, we may come to violate the Kantian requirement that we must not treat others merely as means and that harms to one person cannot be outweighed by the benefits to others. Let us refer to this idea as *the aggregation worry*: an increase in risk for some cannot be justified by aggregating the benefits for others benefitting from that distribution (see Scanlon 2000, pp. 229–241, esp. p. 235; Ashford 2003; Reibetanz 1998; Parfit 2003). This is simply a version of the classical objection to utilitarianism that it matters who benefits and who is harmed and that harm to one person cannot be justified by the benefit to others, regardless of how many those others may be or how great that benefit is. Risks imposed must be such that they are acceptable to each, or in Scanlon's terminology, such that no one reasonably can reject them. Let us therefore specify *the aggregation worry* further: A distribution of risk is not justified merely by the aggregate total benefits, but the risks and benefits must be distributed in a way that is justifiable to all. A fair distribution of risk would then be one that could not be reasonably rejected by anyone and one that treated each person equally in giving each of their interests equal weight.

## A Precautionary Thesis

---

Now let us return to the precautionary aspect, introduced in the beginning of this section, and the idea that risks must be implemented in a way that precautionary measures are directed at each.

Lenman introduces his *precautionary thesis* in two steps. The first step is to merely acknowledge the obligation to reduce risk or to “contain it” as he puts it. The second step is to insist on the need for the justifiability to each person. Thus, in the first instance the precautionary thesis merely suggests: “. . . where risk of harm to people cannot be avoided except at unreasonable cost, we should take reasonable precautions to contain that risk” (Lenman, p. 106). Again, this risk reduction element has not specified any requirements on how such precautions are achieved or how this is done in fair way. Lenman writes:

- ▶ If we are to impose risks on others, each of them might very reasonably require of us as a condition of accepting this, that we take all reasonable precautions to avoid their coming to harm. If you have set aside a special site for the disposal of dangerous waste, you should put a fence around it, post signs warning of the danger, and so forth. If you are going to drive your car,

you should do so carefully, having made reasonable checks that the car is in a safe condition. Such precautions do not mean that nobody will be hurt or killed. Indeed, we can often be pretty sure some people will be hurt and killed as a consequence of the risks we all accept. That reasonable precautions are in place plausibly makes this acceptable (Lenman 2008, p. 106).

The next step is then to stress that precautionary actions must be directed at each individual.

- ▶ We may thus note that for a contractualist it will not suffice to insist that for a population on whom we impose some risk, we must seek to minimize the risk of harm to them by taking precautions. We might insist further that we seek to minimize the risk of harm to *each* of them, aiming any precautions we take at the safety of *each* affected person (Lenman, p. 106).

Thus far we have a normative restriction saying that we must minimize the risk of harm to each individual by taking precautions and that such precautions must be aimed to each person's safety. It is this twofold claim that Lenman refers to as *the precautionary thesis*.

## Two Policies

---

Lenman addresses the topic of precaution and risk distributions by way of a number of hypothetical cases. In each case there is some risk to the general public that can be reduced in various ways. In the example below, there is an initial 1 in 500,000 risks of death imposed on the entire population of 20 million. The choice is now between two possible risk-reducing policies:

- ▶ The first (Policy E) is to reduce the risk to each of the 20 million to 1 in one million.
- ▶ The second (Policy F) is to reduce the risk to 19 million of them to 1 in 19 million, while the risk to the remaining one million is increased to 1 in 100,000 (Lenman 2008, p. 107).

The example is intended to bring out the difference between the contractualist and the consequentialist approach when it comes to risk distributions and precautionary measures directed at each. The crucial point is that Policy F is clearly preferable from a consequentialist point of view since the risk reduction is larger (from 40 to 11 expected number of deaths compared to 20 in Policy E) but achieves this by disregarding the precautionary interests of the one million it increases the risk for. In Policy E, the reduction is the same for everyone. Policy F thus violates the precautionary thesis of aiming precautionary measures to each since instead of lowering it for all individuals a minority has their risk increased with this policy. Increasing a risk for some in order to decrease the total would make it a case of precisely the sort the aggregation worry that Lenman seeks to avoid. Lenman therefore prefers Policy E, “for in E we may be in a position to satisfy each person that we have taken reasonable precaution to avoid their coming in harm’s way. Moreover, we may be able to do this in spite of the fact that we know some of them *will* come in harm’s way” (Lenman 2008, p. 107).

But what is the difference between the two policies? In E there is a general reduction of risk. In F there is a reduction for the majority achieved through an increase for a minority. This, Lenman seems to suggest is sufficient to make distribution like that in F, in most cases, unfair for the minority who had their risk increased. They can claim that precautionary measures have not been directed at them at all since their risk increased. What is interesting here is that Lenman argues that it is *the structure* of the redistribution in F that makes it morally

problematic (Lenman 2008, p. 107). The structure he has in mind is that of imposing a greater risk on some individuals for the sake of risk reduction for the many. Yet, if the very structure of this kind of redistribution would always be a reason counting against it then such reasons must count against all cases where we reduce risk by the aid of someone actively reducing that risk at some increased risk to himself or herself. We would need to exclude cases like reducing the risk of fires by letting fire-fighters combat fires. The reason we may find such risks acceptable may however be due to voluntariness and consent. The point here is directed at Lenman's argument that it is the structure of distributions that ought to worry us. Fairness sought by means of avoiding anyone being put at greater risk seems to come at a high cost in terms of risk reduction since many risks cannot be reduced without putting some at greater risk in order to reduce it. In any society, there is the need for some to take on greater risks for the sake of others and some risks will occur in greater proximity to some individuals than others. Rather than excluding cases like Policy F, we need to ask in which circumstances are such policies acceptable and when not? Here other factors presumably play a role: How high is the higher level of risk? Which precautionary measures are in place in order to lower that higher risk? How justified is the mission? Is there any way to get someone to freely volunteer to take that risk (i.e., not forced by unfortunate circumstances)? What kind of compensation can be expected?

Policy F is underdescribed. It is both compatible with cases like the volunteering, especially trained, and compensated fire fighters as well as cases where a government would deliberately target a group of dissidents to be exposed to a higher risk. Lenman seems to rely on the contrast between E and F to the explanatory work, or, rather, the presumed fairness of E. But given the nature of probabilities, E does not guarantee an equal distribution to each one, but merely a general distribution at a certain level of risk with the actual distribution unknown. The difference then comes down to whether it is worse to distribute a risk at a certain level with the actual risks to each person unknown or to distribute it such that a known group is exposed to a larger risk. In favor of E speaks an argument from intentions: It is morally better to not deliberately aim at increasing the risk for any one group. In favor of F speak arguments from consent, precaution, and compensation: It is only when we know who is at greater risk that we can obtain their consent, tailor precautionary measures to their greater risk, and compensate them *ex ante* for taking such risks.

## Another Look at the Precautionary Thesis

Let us return to the idea that aiming precautionary measures at each person affected as equal treatment and thus as an alternative to equal distribution of chances. Let us first distinguish between on the one hand the distribution of a particular risk (as it is imposed or occurs naturally) and the precautionary activities implemented to protect individuals from that risk once in place. Let us place the aim to minimize the harm to each in the former category and the aiming of precautions at the safety of each affected in the latter category. These two may or may not match each other. The notion of precaution seems to presume some level of risk already expected that the precautions are directed at. Thus, we have two different levels to apply fairness to: the level of justification for a particular imposition of risk and the precautions directed at a person. We could, for example, have dangerous road crossings near some schools but put in extra traffic policemen or volunteers to help children across the roads near the safest roads. There are thus several dimensions to fairness and spread of risk here: we

can have an even or uneven spread of risk; we can have an even or uneven spread of preventive measures, and furthermore those preventive measures can match more or less well those at greater risk in the spread. In order to bring out this distinction let us reformulate the precautionary thesis thus:

Any risk policy must: (a) seek to minimize the risk of harm to each person in the population and (b) aim precautions to each person affected by that risk.

Read in this way, the precautionary claim consists of two rather separate requirements on fairness and risk reduction: on the one hand an obligation to lower the level of risk and on the other hand a requirement to treat each person equally when planning precautionary measures. This would allow us to address both claims to fairness and precautions separately, and furthermore to employ precautionary aims to adjust inequalities that arise through inequalities that would arise on the level of risk reduction or distributions generally. This idea of fairness and risk does not imply equal risk or a particular distribution, only that a particular distribution is only acceptable if it seeks to minimize the total level of risk *and* anyone who is affected by that risk is treated equally with regard to implemented means to counteract, reduce, and protect them from that risk in a way that would not violate the aggregation worry or the stress on reasons acceptable to each.

Lenman, however, does not explore this possibility since he does not acknowledge the difference in seeking to minimize the risk to each and aiming precautionary measures at each. In other words, introducing a risk-reducing policy such as E or F seems to be taken to be the same as to implement precautionary measures in that they aim at risk reduction. Or, put differently, to direct greater risk onto some individuals is incompatible with aiming precautions at that same person.

## Fairness and Precaution in Unequal Distributions of Risk

---

Let us return to the question of what a fair distribution of risk is, as defined by on the one hand the need to reduce risks and on the other to do so fairly. We have discussed the ideal of equality in risk distributions. Let us briefly return to this idea of equal distribution, not of exact probabilities but as a goal to achieve approximate equality in terms of equal concern or respect in risk impositions, or at the very minimum, in planning how to distribute resources of precaution or when imposing higher risks. I addressed this question in terms of the aggregation worry: Risks imposed cannot be justified in terms of the total benefits it brings. How do we then address policies where an individual or a group is put at greater risk than the rest? There is, as I have said before, a conflict between on the one hand fairness and the reduction of risk on the other. In particular, if we take the reduction of risk as an action that needs to be performed by someone or other in order to reduce the total risk and fairness to require that we do not use others merely as means for the benefit of others. On the one hand we have a precautionary thesis that asks us to whenever possible to lower the risk or at the very least keep it at a low level. According to Lenman's precautionary thesis, for example, we have, when "a risk of harm cannot be avoided except at unreasonable cost," an obligation to take "reasonable precautions to contain that risk" (Lenman 2008, p. 106). On the other hand, we have a requirement that tells us not to use others as means and not to increase risk for some in order to lower it in total. A concern is that a too strict application of the aggregation worry may rule out too many cases of risk reduction where someone is called upon to bring about that reduction of risk.

Arguably, most particular risk reduction involves increased expected risks to some of the population.

Now let us turn to two questions: (1) Is it ever justified to impose a greater risk onto a person in order to reduce the general level of risk? (2) If so, how can that justified greater level of risk be duly compensated or in other ways addressed such that it can also be considered fair?

## Justification for Unequal Distributions

---

Before I turn to the question of whether it is ever justified to impose a greater risk onto a person than the level of risk that others are facing, I spell out more clearly ways in which we may impose a higher risk on an individual.

In some cases, I have referred to those as *indiscriminate* impositions of risk, we simply do not have the relevant knowledge to know *that* some will be more at risk than others. We may think that we impose the risk to the same degree to everyone, only that some of those individuals, unknown to us, are more vulnerable to those risks. The permissibility of such cases depends upon what stand we take on moral obligations to know.

In other cases, what is sometimes referred to as cases of *anonymous risks*, we know that imposing a risk onto a large population will lead to some expected number of deaths but *we do not know who* are more likely to die. It may be that we had more knowledge about the differences within that population and about the active causal ways of that risk that we would be able to further narrow down our predictions and identify certain high-risk groups. These kinds of cases can be roughly divided into two categories: those cases where who will come to harm is merely a case of bad luck (a pure Russian roulette case) and those cases where those who will come to harm were more vulnerable in ways that could have been predicted given more knowledge.

Leaving both indiscriminate and anonymous risk impositions to the side we are left with the following two kinds of cases:

1. *Unequal imposing of risk.* We impose a source of risk such that only some are exposed to its hazard and others are not at all exposed to it or at a much smaller level of risk.
2. *Unequal provision of protection.* We provide safety measures to some but not all out of a population exposed to a risk.

In both cases, we impose a risk, or introduce a risk policy, such that we know that this will affect an individual or a group of individuals more than the others. Unequal provision of protection (case 2) for cases of equal exposure of risk would simply be a matter of either scarce resources where the case needs to be solved in an as fair manner as possible (as through a lottery), or it is based on arbitrary or discriminatory reasons. Unequal provision of protection can however be a case of matching unequal distributions of risk (combination of cases 1 and 2) such that those at higher risk are also better protected in a way that reduce their higher risk whether or not it is reduced to the same level of risk as those at lower risk with less protection. I will return to this aspect of unequal provision of protection in the section about compensation below. For now let us turn to the question of knowingly imposing a higher risk onto somebody (case 1).

Some public goods are of the nature that they bring a certain level of risk with them either in their making, in their operating, or by the mere fact that they have to be situated closer to

some individuals than others. When is it justified to impose a greater risk onto some in order to achieve such goods?

There is a distinction that we need to keep in mind made here between the justification for an activity that also happens to be risky and the justification for exposing some individuals to that risk. The justification for building a bridge comes from its value. The justification for exposing the constructors of that bridge comes partly from the value it is expected to bring and partly from how safe it is to build that bridge and how worthwhile it would be for those workers. That everyone can reasonably accept the need for building bridges is not sufficient to conclude that it would be reasonable to put the workers to any level of risk to build it or that it would not matter whom it benefits. We may think that the harm resulting from untamed fires are so devastating that we need to allot the task to put fires out to some individuals even though this would increase the risk to them. Whether the way that is done in a fair way that makes up for the greater risk or not is a separate issue. In other words, even if we accept that some may be put at greater risk than others if the public good is important enough this does not mean that we can require such services at any cost.

I shall assume that any deviations from equal distributions need to address two rather separate lines of justification in order to be morally acceptable. First, if we expect some individuals to be put at higher risk for some public interest this requires a higher demand on the justification for that activity than otherwise. Activities that would have been justified may no longer be so when they come at the cost of asking someone to put himself or herself at risk for it. Second, even if a particular activity were justified even at the cost of some being at a higher risk, this would still require us to address that greater burden for those expected to risk their lives. In particular, I shall argue that in this more specific case the following considerations are of central importance: the degree of consent, the level of risk, and level of compensation. If the second line of justification is not satisfactorily answered, then this may affect the justification of the activity or spread of risk itself (although there may be cases where the activity is of such importance that the activity is justified even when the demands of the second line of justification are not satisfied). The point here is that in order to be justified in imposing a greater risk on some, at the very minimum, we need to make sure that the project that requires that level of risk is worthwhile, presumably in a way that is convincing also for those at risk.

There is a conflict of interests here between those who would benefit from the goods to be achieved by a risky activity and those whose lives would need to be risked for it. Scanlon brings out this conflict in the following way:

- ▶ Suppose, then, that we are considering a principle that allows projects to proceed, even though they involve risk of serious harm to some, provided that a certain level of care has been taken to reduce these risks. It is obvious what the generic reason would be for rejecting such a principle from the standpoint of someone who is seriously injured despite the precautions that have been taken. On the other side, however, those who would benefit, directly or indirectly, from the many activities that the principle would permit may have good generic reason to object to a more stringent requirement. In meeting the level of care demanded by the principle, they might argue, they have done enough to protect others from harm. Refusing to allow activities that meet this level of care, they could claim, impose unacceptable constraint on their lives (Scanlon 2000, 236ff).

The above conflict has parallels to *the problem of paralysis* that in particular rights-based theories of risk would run into. If we were to have a right that others do not impose risks of

harm on us, then their many everyday activities would be ruled out (see Hayenjelm and Wolff, *forthcoming*, for overview). The problem, as pointed out by Nozick (1974, 74ff) and later discussed by others (see e.g., Railton 1983 and Hansson 2003, 297ff) is that traditional rights theory does not come in degrees. Thus if we have a right that others do not impose a risk of harm upon us then it does not matter how small that risk is since the point with rights is that they mark out firm moral boundaries that may not be trespassed unless consented to by the person (Nozick 1974, 74ff; Railton 1983, p. 3). Here, if the claims against risk of harm for an individual were greater than the benefits for another individual, then this would suggest that such activities were not to be permitted no matter how many individuals benefited from that activity since we are not allowed to aggregate interests according to rights-based theories of risk.

The interesting thing to note again is Scanlon's stress on precaution when it comes to the justification of risk. The cases to reasonably reject are those where the reasonable precautions to avoid harm have not been taken. To rule out all cases that would pose a risk of harm would be too restrictive. He writes: "Our idea of 'reasonable precautions' define the level of care we think can be demanded: a principle that demanded more than this would be too confining, and could reasonably be rejected on that ground" (Scanlon 2000, p. 209). Let us take notice of the fact that the justification for unequal risk, on his view, thus depends to a large part on *the level of protection* and care directed to those at greater risk.

Others have stressed the degree to which the benefits in question befall those put at greater risk. Although it seems obviously unfair to let someone run a risk for the benefit of others, it is not clear what the claim to benefit can achieve on its own in terms of justification (Lenman 2008; Hansson 2003). In some cases such as individual risk taking, the very fact that the person running the risk is the person who also is the sole beneficiary of it is what makes it morally relatively unproblematic. But in the cases of large projects that impose a greater risk on some, whatever benefit it will bring to the person at higher risk, is presumably the very same benefit that it will bring to others. Thus, although it would be unfair to exclude the person at risk from the benefits, or to merely make him or her work for the benefit of others, giving him or her an equal share in those benefits cannot justify his or her greater risk. It could be argued that what we need to provide is a larger share of the benefits, but this is hardly likely to be possible in cases of public goods such as the construction of tunnels and bridges. The justification for such cases of increased risk cannot be fulfilled looking at the level of benefits alone.

This problem, however, only arises if we look at the risks and benefits for each case of risk impositions separately. Hansson (2003) suggests a reciprocal system of risks, such that each risks does not need to be beneficial to the person at risk, but that the social system as a whole need to be. He introduces the following example:

- ▶ In your neighbourhood there is a factory that produces product A, which you do not use. The factory emits a chemical substance that gives rise to a very small risk to your health. At the same time, another factory, far away from your home, emits other chemicals in the production of product B that you use. One of the neighbours of this second factory does not use product B, but instead uses product A. In this way, and sometimes in much more complex chains, we may be said to exchange risks and benefits with each other (Hansson 2003, p. 305).

This approach suggests a way forward, perhaps much along the lines of Rawls' ideal of a fair cooperative system. The point Hansson makes is that not each project needs to be beneficial for the person who is at greater risk from that project, if there are other risks that he or she does benefit from in a cooperative system working to everyone's advantage. However, even such

a system that works to everyone's advantage is compatible with unequal distributions of risks and benefits. There may for example, Hansson suggests, be two different groups in society: one that benefits largely and faces smaller risks and another that benefits much less but carries more of the risk burden. Hansson therefore adds an equity requirement: "Exposure of a person to a risk is acceptable if and only if this exposure is part of an equitable social system of risk-taking that works to her advantage" (Hansson 2003, p. 305). Hansson does not develop what, more precisely, an "equitable social system of risk-taking" would entail. This principle seems to fit well for a system of exchange of comparable risks and benefits such as the mentioned example with the two factories. But it is unclear whether it can provide much guidance for odd risks that pose so much greater risks than the average risks within such a system that they are not compensated for. We could, for example, presume a system where all young men were expected to enrol into military service and all women were expected to give birth and that at some point in time these two risks would be comparable in the number of expected deaths. Let us also presume that both these kinds of risks were at this point considered equally beneficial to society. Now, consider a change for the better, that either military service or birthgiving is made much safer, but not both. Presumably the benefits would be the same. In such a case, it is not obvious what Hansson's principle would suggest. Would it make the now less safe risk impermissible? Would it require greater benefits for those taking the greater risks than before? Would it simply require us to reduce the other risk to the same degree as before? Would it require us to protect those at greater risk with greater protection from all other risks? Similar problems arise with all risky activities that are not obviously counterbalanced by other comparable risks or extra benefits. Consider the benefits from information technology benefiting most or all and the extra risks such technologies require from miners to retrieve the necessary minerals and metals for circuit boards and other hardware.

Furthermore, there is the question of risks that affect those that choose to not be part of the social system or do not enjoy the benefits unanswered such as the problem of the risk of falling planes and the Amish farmer who does not enjoy any of the fruits of technology (Munoz-Dardé, forthcoming).

There is a third aspect, besides level of precaution and share in benefits, which affects the justification for activities that put some under greater risk. This aspect is that of voluntariness or consent. This aspect comes most clearly into view when we ask someone to do something for the rest of society that is either not balanced out in a reciprocal way, as participating in a medical trial or taking up a place in the army, or due to some special skill, talent, training, or knowledge that they have that makes them particularly well-suited for this task. Scanlon, for example, already presumes that his higher-risk workers engage in the risky project voluntarily: "Our sense that it is permissible to undertake these projects also depends crucially on the assumption that precautions have been taken to make the work safe and that, in addition, workers have the choice of whether or not to undertake the risks involved" (Scanlon 2000, p. 236).

To some extent the justification for imposing greater risks presumes consent. In some cases, we are not in a position to obtain such consent for practical reasons. Nozick mentions the cases of small or diffuse risks onto a large public where we do not know who will be put at risk (Nozick 1974). Other cases where such consent would not be possible concern deflecting a bomb from a larger city onto the countryside (a much discussed example introduced by Thomson) and examples related to the so-called *doctrine of the double effect*, where a beneficial activity has foreseen but unintended side effects (Thomson 1986, p. 89). In such cases, consent is not possible because there is no time, or we simply do not know who will come to harm.

There is a kind of case that is of particular interest because it brings out the conflict between the risk reduction aim and the fairness aim more clearly. I am here thinking of the cases where there is a public risk to all that can only be lowered if some particular individual or individuals take on a greater burden. Do we have a right to send the trained soldier, the trained policeman, the trained fire fighter onto missions of clear risk, or would it be fairer to conduct a lottery and select anyone out of the population? Consider the following case:

A threat of some sort is putting an entire population of a hundred individuals at risk. Let us say it is a tiger attacking the village (or an invading army or a bush fire). You, being the politically elected head over this village can choose to do one of two things:

- (a) Make the skilled person P, with risk to his own life, confront the threat for the safety of the population at large. If he succeeds the threat is completely abolished (let us say the tiger is slain). The probability that he will succeed is 0.8 and the probability that he will die while trying and failing is 0.2.
- (b) Conduct a lottery where any one out of the population is made to tackle the threat with risk to his, or her, own life. If he or she succeeds the threat is completely abolished. The average probability that any random man or woman succeeds is 0.2, the risk to his or her own life 0.8 (and no one besides P has a greater chance at killing the tiger than 0.3).

The rationale for choosing (a) could easily be motivated from a consequentialist point of view. It would simply minimize harm for all involved parties. But this rationale will not do if we look for a contractualist justification since this would precisely lead us into the lap of the aggregation worry. The lottery in (b) could on the other hand be defended since everyone would be doing their fair share for something that is the common interest of all. It would seem that the contractualist ought to prefer the lottery, even at the foreseeable cost of several people dying trying, and the tiger still at large. But that scenario is clearly suboptimal; every person selected by the lot is put to a much greater risk than necessary, given that P could have done it at a much smaller risk, for the benefit of all. Cases of a similar structure have been addressed in the literature, but often with the assumption that the person put at risk would almost certainly die. Hansson discusses a similar case where a repairman can be sent in to repair a gas leak at a 0.9 risk of death for himself, or this gas can be let out into the environment at the risk of 0.001 for the entire population (Hansson 2003, cross-reference to Hansson's chapter). In such cases, it seems that the risk for the person in question is so high that we could not reasonably require anybody to take on such missions.

Broome discusses a case where one man is more skilled than anybody else to take on a dangerous mission but no more likely to survive than the rest.

“Someone has to be sent on a mission that is so dangerous she will probably be killed. The people available are similar in all respects, except that one has a special talent that make her more likely than others to carry out the mission well (but not more likely to survive). This fact is recognized by her and everyone else” (Broome 1990–1991, p. 90). In Broome’s case the success of the task does not imply a greater chance for survival, and almost certain death is expected. In such cases, Broome suggests that it may be unfair to send the talented person and in fact more fair to conduct a lottery among all of them. If the mission is a threat to all, however, and the chances of failure is in itself a danger it may be the case that we ought to send the talented man. But, Broome argues, this would be a case where other interests are weighed against fairness, not what fairness requires.

Such extreme suicide missions do not answer our more modest question: When is it justified to reduce a risk by expecting someone tackle a risk for everyone else’s sake? On what

grounds can we expect others to fly planes, give birth, fight fires, and fight wars? In many such cases where there is professional expectation to tackle a risk there is also the skills and training such that not only is the chance of success greater but the actual risk is comparatively speaking lower than had anybody else taken on that particular kind of risk. In such cases, conducting a lottery would mean that we would put someone at higher risk than necessary rather than that the person most skilled and who would be at a lower risk. Furthermore, everyone else would be at higher risk since the probability of failure would increase and it could be claimed that the appropriate level of care had not been aimed at them by letting someone unskilled to do the job. What is missing from these examples is the role of consent.

Thus far we can conclude that part of the picture when assessing the justification for activities that require that someone is put at higher risk for the sake of everyone else we need to address all these aspects: the level of risk for the person at higher risk and for the public at large, the benefits of the project in general and for the person at higher risk, and the degree of willingness of the person expected to be put at higher risk. In some cases, such projects seem very straightforward: the mission is undertaken voluntarily, the level of risk is not too high, and the benefits are of great importance. In other cases, the risk may be low, the benefits great, but none is volunteering. Or, the risk may be very high but someone volunteers and the benefits are high. Yet, in other cases, the risk may be small and taken on voluntarily but the benefit is negligible. I suggest that none of these three aspects can by themselves serve as sufficient ground for justification for putting someone else at risk, but that they need to be addressed in some respect. It may be that in certain cases one of the aspects can be overlooked but that can only be if the other two are sufficiently outbalancing it.

## Compensation for Unequal Distributions

---

We now turn to the second question: how can an unequal but justified greater level of risk be duly compensated, or in other ways addressed, such that it can also be considered fair? Let us rephrase this question to a distinction between activities that are socially justified and those that are justified to those that are put at risk. This distinction was somewhat blurred in the previous section since part of what we take to justify an activity that poses greater risk on some, is to address the particular risks and benefits and consent of those at risk. Here we will look more closely at the high-risk group and the fact that they are put at greater risk.

As suggested in the previous section, the three reoccurring themes in the literature on risk is to look at consent, benefits, and level of risks. Some stress the level of risk, others the role of consent, and others still the role of benefits. I have suggested that we take all three into account as a triad when we assess risks. Now benefits and risks can both be adjusted to address the fairness of such greater risk for public benefits. We can add extra protective devices to counteract the level of risk directly targeted to high-risk groups. We can add extra benefits in terms of compensation to the benefits of particular risky activities. Both these aspects can thus increase the fairness of such otherwise unfair distributions of risk, and they may also affect the degree of its reasonableness and the extent to which it is agreed to by the people put to higher risk.

Keeping the triad of compensation, consent, and level of risk in mind, these can to some extent be used to replace the role of each other. Compensation can be used as a means to justify risk impositions when consent cannot be obtained (Nozick 1974). It can also be offered as

a means to persuade someone to willingly accept a risk or encourage them to take up a risk role. In such cases, compensation is a substitute for consent or forms part of the reasons for a person to consent. Compensation can also be offered as a means to acknowledge harm or risk *post ante*. In such cases, it serves as restoration for harm brought about as a result of risk. Compensation can thus stretch from merely being an acknowledgement of risk already having resulted in a harm to making a particular task with a certain risk into a good deal for the risk-taker when the risk is very small. The fact that there is compensation, or even that it is a generous one, must again be understood against the level of risk and the level of precaution. Imposing a risk with a generous compensation may still be an unfair way to impose high risks instead of implementing the appropriate safety devices if those are more expensive. A point to explore further is that of nonmaterial compensation. Historically there are cases where greater risk-taking has been compensated for not so much through monetary compensation but in higher social status or social recognition.

Freely accepted risks do not automatically make all kinds of compensation or safety precautions redundant. We would probably not consider as fair a differential treatment of workers in a dangerous industry where one person was freely volunteering to work without safety measures, while everyone else worked with such measures in place.

However, all that said, in contrast to the distribution of risk, the distribution of compensation and precautions seems to fall much more easily in the already well-developed theories of distributing goods. Here the extra point is made about how those aspects can be used to make unfairness in distribution a little fairer. Furthermore, the justification of a particular distribution of risk may depend upon the level of precaution and compensation.

## What Is a Fair Distribution of Risk?

---

What, then, is a fair distribution of risk? In this chapter, we have looked at several ways to approach this question. First of all we started with the presumption that fairness is a relative term. What is a fair share to me is determined by what others receive. In contrast to parallel treatments of fairness in distribution about goods, the problem lies not in the tension between scarcity and equal shares, but rather in the tension between risk reduction and equal shares. A too strict requirement on equality of shares could slow down the risk reducing aims since many reductions may come gradually and not be able to protect each equally. A further problem is that many reductions of risk would require that some individuals put themselves at greater risk for the safety of others. The problem of fairness of risk is then not so much one of equal distribution, at least not of risks, but one of balancing equal treatment and equal concerns with the overarching goal of protection against risk. Sources of risks can be distributed in more or less equal ways, dangerous missions can be equally or unequally taken on and more or less voluntary, and precautionary measures can target those at risk equally or unequally.

We investigated the idea that perhaps we could address fairness in terms of equal treatment for each person in terms of protection against risk. It was suggested that we need to distinguish between fairness at the level of distribution and fairness at the level of precaution. This distinction was further elaborated into a twofold approach to think about fairness and risk in general. On the first level, we seek justification for a particular spread and distribution of risk, including any inequalities it may impose. On the second level, we seek to as far as possible address the claims to fairness that the inequalities in the first distribution gives rise to in terms

of compensation and precautionary attention. It was suggested that greater risk imposed on someone needs both a general justification for that inequality and a specific justification in terms of consent, benefits, and level of risk to those at higher risk.

## Further Research

The whole field of fairness of risk is relatively underexplored. The current chapter has suggested that while it is hard to apply distributive reasoning onto chances of harm there are interesting parallels to explore when it comes to that which we can more easily distribute: the sources of harm and the resources to redress inequalities of risk in the form of precautionary measures. Much remains to be said about how we can combine the ideals of equality with the special requirements on risk reduction. Topics merely touched upon in this chapter that could be further developed include developing Rawls' difference principle, consent or voluntariness, and compensation for the particular problems of societal risk. Another topic worth exploring, merely mentioned in this chapter, would be to further Pettit's ideas about nonarbitrariness and non-dominion and exposure to risk.

**Abstract:** Intergenerational risks are intuitively defined as long-term threats of harm that will affect future people. The nonidentity problem, however, challenges our ability to accept this definition. This chapter offers an interpretation of intergenerational risks as threats of *de dicto* harm or as threats of harmful conditions (drawing on distinctions made by Casper Hare and Joel Feinberg, respectively). One of the challenges of intergenerational risks may be understood, following Stephen Gardiner, as the fact that it may never be a generation's interest to engage in an intergenerational cooperative scheme. This may make promoting intergenerational risks tempting when, for example, such risks involve a deferment of potentially harmful outcomes. A challenge for intergenerational ethics is how to understand which intergenerational risks are morally acceptable and which are not. Several (usually implicit) approaches to addressing intergenerational risks are discussed including economic approaches, precautionary principles, and intergenerational justice. The chapter calls for much more work to be done to better understand the challenges posed by intergenerational risks. Despite the fact that intergenerational risks abound in today's increasingly globalized world, we – as a society – do not yet grasp the complexity of intergenerational risks or how we should address them.

## Introduction

---

Most often when we think about risks, we do not think about especially long timeframes. We tend to think about activities and events that could have harmful effects during our lifetimes. But there are many activities and events that pose threats of harm over much longer timeframes. Greenhouse gas emissions, for example, pose long-term risks because of their delayed impact on the climatic system. It is long-term risks like these that are the subject of this chapter. Since long-term risks will primarily affect future generations the discussion focuses simply on intergenerational risks (hence the title of this chapter).

Intergenerational risks raise special theoretical and practical challenges because of the very fact that these risks span more than one generation. One potentially challenging feature of such risks, for example, is that those who might be affected by risky activities cannot even in principle participate in the regulation of the risky activities in question. Another challenging feature of intergenerational risks is that risky activities may in part determine *who* will be affected because such activities will usually affect the personal identity of future people. For these reasons, intergenerational risks present challenges not present in intragenerational risks. Yet these features are much more common than we may think. Many risks that at first appear to be intragenerational are in fact intergenerational. The prominence of intergenerational risks only highlights the importance of addressing questions such as how we should think about risky activities that might affect future generations.

In asking how risk is related to moral value, Sven Ove Hansson identifies three major approaches: “1. Clarifying the value dependence of risk assessments; 2. analyzing risks and risk decisions from an ethical point of view; 3. developing moral theory so that it can deal with issues of risk” (Hansson 2007: 21). This chapter will touch on all three of these approaches as they pertain to intergenerational risks, though in so doing it will identify the need for much more work in all three areas. This discussion will reinforce Hansson's ultimate conclusion that “Introducing problems of risk is an unusually efficient way to expose moral theory to some of the complexities of real life. There are good reasons to believe that the impact on moral philosophy can be thoroughgoing” (Hansson 2007, p. 33). The need for conceptual clarity

about the challenges posed by and ways of addressing intergenerational risks drives the philosophical perspective taken in this chapter.

Throughout the discussion the intergenerational risks posed by anthropogenic climate change are used as paradigm examples. After all, historic emissions of greenhouse gasses have put us in a position in which we are facing threats of harm and in which our current options are limited. Further, in continuing to emit such gases we impose threats of further harm on future generations. What climate policies we adopt will not only shape Earth's future climate but also who will live and under what conditions. During the industrial revolution people may not have known they were imposing threats of harm upon us – a future generation. From our perspective, however, their actions were risky because they not only emitted greenhouse gasses without an understanding of the consequences of such actions but also made choices that shaped the way people all over the world lived in ways that posed at least some clear (and other unclear) threats of harm. Climate change is therefore not only a paradigm example of intergenerational risk from a forward-looking perspective, but it raises ethical questions about, for example, the significance of the knowledge or lack thereof on the part of risk-takers from a backward-looking perspective.

In the following section, I consider interpretations of the challenges posed by intergenerational risks both from the perspective of the pure intergenerational problem (as introduced by Stephen Gardiner) and the nonidentity problem (most prominently attributed to Derek Parfit). This discussion first illustrates the challenges of intergenerational risks and then reveals that it may be hard for us to even conceptualize intergenerational risks as posing threats of harm to future generations, the definition that otherwise would seem most intuitive. In response to this challenge, I draw on the work of Casper Hare and Joel Feinberg and argue that intergenerational risks may be understood as posing threats of *de dicto* harms or as imposing threats of harmful conditions on future people.

After articulating the nature of the challenge of intergenerational risks, I discuss several ways of thinking about how we should address such risks. I begin by briefly considering economic approaches to addressing intergenerational risks, illustrating that cost-benefit analyses may leave out or obscure important normative considerations. I further argue that if cost-benefit analyses are to guide decision making about such risks, these should use a very low discount rate, if they should discount at all. I then go on to consider the ways in which precautionary principles, which push us to err on the side of caution, may be understood as guiding action in the face of intergenerational risks. Finally I discuss the relevance of work on intergenerational justice to intergenerational risks, highlighting specific examples from theorists working on climate change.

In the process of surveying these issues, this chapter will identify those areas in need of further research. Despite the fact that intergenerational risks abound in today's increasingly globalized world, we – as a society – do not yet grasp the complexity of intergenerational risks or how we should address them.

## History

The first thing to note about intergenerational risks is the fact that very little has been said about them, especially by philosophers. As Martin Kusch has said of risks more generally, "It is striking and perhaps surprising to note that very few contemporary strands of political philosophy

contain explicit prescriptions on how to deal with risk and uncertainty” (Kusch 2007, p. 131). And while there is a body of literature on intergenerational ethics and intergenerational justice, the relevance of these issues to intergenerational risk has been underexplored. A recent collection addressing philosophical perspectives on risk, for example, fails to explicitly address intergenerational risk at all (Lewens 2007). Given this, I will devote this section to exploring the nature of intergenerational risks so that I can discuss the relevance of work on intergenerational ethics and justice to intergenerational risks in the following section.

## Defining Intergenerational Risks

---

Before delving into a philosophical discussion of intergenerational risks, we must be clear how we define such risks. It is not obvious, however, what intergenerational risks are. Risks are generally understood as threats or possibilities of harm, though colloquially the term is sometimes applied to both negative and positive possibilities. Stephen Perry, who has worked on the ethics of risk, defines harm as “a relatively specific moral concept which requires that a person have suffered serious interference with one or more interests that are particularly important to human well-being, and which for that reason are appropriately designated as fundamental” (Perry 2007, p. 202). Perry argues that the imposition of risk, even of physical harm, is not a form of harm in itself (Perry 2007, p. 190). But it does not follow from this, he argues, that risky actions cannot be wrongful. Rather, this implies that we should understand risks as posing threats of harm. Intergenerational risks then pose threats of harm to future people, possibly in addition to existing people. Upon initial consideration then, intergenerational risks may be understood as threats of harm to future generations or which involve more than one generation. This chapter will focus on negative intergenerational risks, those that involve threats of harmful outcomes, but much of the discussion may be reinterpreted to apply to positive “risks” as well.

A more technical definition of risk comes from economics. Economists are very precise about defining risks, distinguishing *risk* from *uncertainty*, where the former is defined as randomness with knowable probabilities and the latter randomness with unknowable probabilities (Kight 2002). The distinction between risk and uncertainty may also be understood as being between measurable and unmeasurable uncertainties. On this description, intergenerational risks are those that will affect future generations and about which we know how probable the possible outcomes are. That is, intergenerational risks involve measurable uncertainties. But how often are we able to measure the likelihood of possible outcomes when these span more than one generation? I suspect the answer is not very often. While I will elaborate on why this is the case in what follows, intuitively I hope it is not hard to see why there are probably very few intergenerational risks on the economic reading of risk. There are simply too many unknowable or simply unknown variables and possible outcomes when it comes to (distant) future outcomes for us to usually be able to measure the likelihood of the outcomes of a risky activity or event.

On the one hand a chapter on intergenerational risk may therefore seem misplaced or misguided. It seems there will almost always be uncertainties that render intergenerational “risks” to be “uncertainties,” at least in the technical language most often used to describe risk. On the other hand, we need a way to talk about risks, such as those posed by climate change, that are in fact intergenerational. And when we think about intergenerational risks we are

most often thinking about uncertain threats of harm to future generations (though we may also think about risks taken by earlier generations that threatened temporally delayed harmful effects as well). As a starting point for a discussion of intergenerational risks, then, we need to expand the narrow economic definition of risks to include long-term, uncertain threats of harm. This means that as I use the term here, there is rarely such a thing as a “calculated intergenerational risk” because there will almost always be uncertainties given the temporal scale of intergenerational risks.

Climate change presents many paradigm examples of intergenerational risks, both from backward- and forward-looking perspectives. Climate change is spatially and temporally diffuse in both cause and effect (IPCC 2007). People all over the world have contributed and contribute to climate change through the emission of greenhouse gases (including through causing land use and other environmental changes). And people all over the world have been, are, and will be differentially affected by climatic changes in diverse ways. Because climate change effects are also diffuse in time, it is an intergenerational problem. Climate change effects are temporally delayed from the actions that caused them and they are long lasting, meaning past and present greenhouse gas emissions will affect many future generations of people. People from different nations and even different generations will also experience the effects of climate change differently. Many, but not all, climate effects will be harmful in a diversity of ways. Some individuals will lose their lives because of direct effects of climate change (such as from especially strong hurricanes). But climate change is having and will have not only direct effect on people through its physical effects; it is having and will have derivative social effects. Changes in agricultural productivity will affect both local and global economies. Health-care systems will be stressed in areas highly impacted by climatic effects. Lifestyle choices might become limited. Climate change clearly poses threats of harm to future generations, thus actions contributing to climate change contribute to the creation of these intergenerational risks. And past emissions of greenhouse gasses have affected and will affect relative future generations as well.

## The Pure Intergenerational Problem

Stephen Gardiner points out that there are severe moral problems that are conceived of in terms of generations, those posed by intergenerational risks being a prime example. He addresses the issue of temporal moral distance, identifying what he calls “the pure intergenerational problem” or PIP (Gardiner 2002, 2003, 2006a, 2011). Gardiner’s discussion of PIP helps make sense of the role generations play in ethics and as such is helpful to the present discussion of intergenerational risks and the challenges they present. Gardiner (2003) conceives of PIP by imagining a world with temporally distinct groups of inhabitants, each of which is solely concerned with its own, independent interests. He asks us to imagine that each group has access to goods that give their generation a modest benefit but which impose high costs on all later groups. PIP arises in this situation from the following dilemma:

- ▶ (PIP1) It is *collectively rational* for most generations to cooperate: (almost) every generation prefers the outcome produced by everyone restricting pollution over the outcome produced by everyone overpolluting.

- ▶ (PIP2) It is *individually rational* for all generations not to cooperate: when each generation has the power to decide whether or not it will overpollute, each generation (rationally) prefers to overpollute, whatever the others do (Gardiner 2003, p. 484).

This presents a rather intractable problem in that the asymmetrical position of the first group makes it rational to overpollute. This problem is iterated such that each subsequent generation will also be in a position where it is rational to overpollute. This problem is made worse by the fact that the description of this world rules out the possibility of reciprocity. It is never rational for a generation to be the first to cooperate. If there are ever moral reasons in favor of cooperation, which I suspect there are, PIP then presents a problem of fairness.

Gardiner (2003) identifies six features of PIP, which help us understand its relevance to talk of generations in ethics. The first feature is *temporal asymmetry*, which relates to the fact that groups are temporally distinct in the description of the problem. The actual world does not have this feature since generations overlap, though this concept helps define generations in the description of PIP. Second, there is *causal asymmetry* such that earlier groups can affect later groups, but not vice versa. This feature applies to the actual world as well and may imply that PIP has some practical application. Third, there is *asymmetric independence of interests* in PIP such that the interests of earlier groups are independent of those of later groups. While this is not strictly a feature of the actual world, it seems empirically likely that the interests of earlier people dominate those of later people in practice, making a degenerate form of PIP potentially applicable. Fourth, in the description of PIP groups are generationally *self-interested* (have a self-interest relative to their own generation), which, while not true of actual individuals, may partially describe the way people will act in time-indexed ways as generational groups in practice. Fifth, PIP involves *temporally diffuse goods* that offer modest benefits to a group while imposing costs on future generations, but other goods with deferred costs present similar challenges. Again degenerate forms of the problems presented by PIP arise even if the nature of the deferred costs is different. Finally, PIP has a *sequential* aspect that gives rise to its iteration aspect, and here again the details of this feature may be changed to similar effect.

Together these points help illustrate that many of the reasons for describing the groups in PIP as generations applies to talk of generations in the actual world, and many of the challenges presented by PIP apply in some degenerate form to intergenerational ethics. PIP most clearly applies to the actual world if we imply a wide definition of generations and include those future people whom the presently living will never meet. But Gardiner argues that many cases in which generations overlap will have much the same structure as PIP and thus present many of the same challenges. We can learn from PIP even if its claims are not all true in all cases.

One way of thinking about intergenerational risks is as the imposition of the possibility of harm on future generations by an earlier generation. The pollution example Gardiner uses to articulate PIP may be understood as an intergenerational risk since it involves one generation imposing the potentially harmful effects of their polluting activities on future generations. Even if all generations could agree that it would be best if no generation polluted, polluting activities in virtue of presenting intergenerational risks are attractive to whoever is polluting because the pollution's harmful effects are deferred. PIP helps us see why it may be tempting to impose such risks, especially when doing so incurs a benefit to the present generation. This is because intergenerational risks involve conflicts between the interests of generations since by definition such risks are taken by one generation to the potential detriment of others. Intergenerational risks therefore raise the questions of fairness that arise in PIP, though the

context in which such a risk is taken and the nature of the risk are certainly relevant to any detailed account of the fairness issues a particular risk raises.

In identifying climate change as presenting a perfect moral storm, Gardiner uses PIP to explain the intergenerational challenges or intergenerational storm of climate change (Gardiner 2006a, 2011). As we have seen, climate change will have potentially harmful effects that are significantly deferred. As such it presents intergenerational risks that can be understood as manifesting some form of PIP. Activities that contribute to climate change, such as the emission of greenhouse gasses and deforestation, are akin to the polluting activities in the description of PIP. From our perspective it may seem rational to engage in activities that contribute to climate change because of the very fact that the harmful effects of these activities impose risks on future generations rather than ourselves. But this quite clearly raises questions of fairness. It seems almost certainly unfair of us to impose risks on future generations when we know that our actions will have seriously harmful consequences. (Note that it is less clear whether it is unfair that earlier generations, who did not know what the consequences of their emitting activities would be, treated us unfairly when they emitted greenhouse gases.) Gardiner worries that the nature of PIP makes us vulnerable to moral corruption such that we may engage in manipulative or self-deceptive behavior as a means of avoiding accepting and/or addressing the complex moral obligations we face. This may mean that we will be able to act as if we are acting ethically when in fact we are avoiding addressing the full range of ethical implications of our actions and corresponding obligations. This is reinforced by our theoretical ineptitude with respect to how to address the ethical challenges of intergenerational risks, which comprises the theoretical storm of the perfect moral storm.

Understanding intergenerational risks through the lens of PIP helps us see that it is the very intergenerational nature of such risks that raises moral and practical challenges. Intergenerational risks by definition involve deferring potentially harmful outcomes on to future generations such that future generations may be unfairly disadvantaged by the activities of earlier generations. The fact that future generations cannot even in principle participate in the decision-making processes that lead to risks being imposed upon them may make it tempting for those considering engaging in risky activities to do so, even when such risks are unfair or unjust. A major challenge for intergenerational ethics is to identify when and why we ought not contribute to intergenerational risks, sometimes in the face of significant practical challenges.

## The Nonidentity Problem

Derek Parfit (1976, 1984, 2001) implicitly addresses the challenge of intergenerational risks by examining the different kinds of choices we have with respect to the future. Key to understanding the different kinds of choices we make is the assumption that the cells out of which a person develops determines who a person is. This view appeals to the *Time-Dependence Claim* that a person would have never existed if she had not been conceived when she was in fact conceived (Parfit 1984, p. 351). Two questions that Parfit asks to distinguish three different kinds of choices are: "Would all and only the same people ever live in both outcomes?" and "Would all and only the same number of people ever live in both outcomes?" (Parfit 2001, p. 295).

When the same people would live with either outcome, the decision is what Parfit calls a *same people choice*. In general, these are choices that do not significantly affect the future. A clear example of a same people choice is your decision to brush your teeth or not this morning. Whether you brushed your teeth or not mostly likely did not affect who will live in the future. When the same number but different people live with either outcome, the decision is a *same number choice*. An example of a same number choice is a woman's successful choice to use birth control to determine when she will have a set number of children. By using birth control a woman affects the personal identity of her offspring, at least in part, by determining when her children are conceived and hence their genetic makeup. Finally, when different people and a different number of people live with either outcome, the decision is a *different number choice*. These are choices that very much affect the future. A straightforward example of a different number choice is a woman's decision to have regular sex without using any form of birth control. Her choice affects how many children she will have, though she cannot predict the outcome of this choice in advance. (It is worthwhile to note that even the same people and same number choice examples given here could turn out to be different number choices if, for example, whether you brushed your teeth affected whether or not you had sex with your partner or if we consider the fact that children conceived at different times may themselves be more or less likely to have more or fewer children.)

Parfit argues that different kinds of choices require different moral considerations. He points out that we often apply our intuitions about same people choices to different people choices. This is not appropriate, however, because of the issue of personal identity. The fact that our personal identity is in part tied to our genetics has significant implications. Parfit poses a powerful question when he says: "It may help to think of this example: how many of us could truly claim, 'Even if railways had never been invented, I would still have been born?'" (Parfit 2001, p. 290). On reflection, the answer to his question for virtually all of us is "no." The invention of the railroad was significant enough to have affected the lives of the people who existed at the time and consequently who their offspring were, leading up to our current population. Had the railroad not been invented and introduced to society when it was, history would not have lead to our collective existence.

Climate change policies have the potential to be as or even more significant in the course of history as the invention of the railroad. Policies geared toward the development of new technologies could lead to advances or changes as or more significant than the development of the railroad. If this happens, future people 200 years from now will be able to answer the question "Even if such and such technology had never been invented, would you have still been born?" in the negative the way we today answer the question about the railroad. Similarly, if policies allowing the status quo to continue are adopted, future people 200 years from now will owe their existence to society's historical reliance on fossil fuels. Looking back in time we can also see that policies supporting the industrial revolution and the development of a fossil fuel based economy lead to our collective existence today. Not only would we not have existed if the railroad had not been invited, we most certainly would not exist had the industrial revolution not occurred.

By identifying the relationship between personal identity and choices that affect the future, Parfit exposes that fact that many decisions affect who will exist. When a decision affects who will exist, however, it is unlikely that different actions will result in the same number of people. Even if a decision causes the existence of just one extra person, or causes there to be one less person, it is a different number choice. Different number choices do not require a total change in the number and personal identity of future persons. When the quality of people's lives is

changed, the timing and parenthood of conceptions is changed. Therefore most of our choices that affect the lives of even small groups of individuals are different number choices. This means that most societal level choices are different number choices.

Casper Hare sums up this point nicely when he says, “Given that world history is a large and encompassing thing, it seems likely that most decisions that affect who exists will reverberate through it for many generations and unlikely that, when all is said and done, the numbers of people who ever exist will turn out the same whatever we decide” (Hare 2007, p. 520). Most, if not all, intergenerational risks involve different number choices. Acting in a way that imposes a threat of harm on future people is a different number choice in part because there is often uncertainty as to the outcome of such an action; this is part of what makes it an intergenerational risk. This implies that societal level choices that involve risk taking pose intergenerational risks, which in turn implies that very often when we are talking about risks we are talking about different number choices and hence intergenerational risks.

One of the most significant challenges posed by different number choices is the widely discussed nonidentity problem. The nonidentity problem is the problem that our choices can affect the future in normatively bad ways despite the fact that we cannot harm in causing to exist. Parfit states this as the problem of identifying the moral difference between outcomes that are worse for no one (Parfit 1984, p. 378). If we assume that causing to exist cannot be worse for someone who has a life worth living, then it is hard to see how choices that affect the personal identity of future people can be wrong, though they are worse for no one. The nonidentity problem is particularly challenging for different number choices, as most personal identity-affecting choices are, since in such cases it is hard to think about how to compare possible future populations of different sizes. It is hard to answer questions such as: Would it be better to have a large future population in which many people suffer? Or would it be better for there to be a smaller future population in which there is less suffering? In either case whoever lives owes their existence to our choices and hence as individuals cannot have been made worse off by our choices.

Parfit utilizes a generalized example of a policy decision involving a choice between depletion and conservation to illustrate and clarify the nonidentity problem (see Parfit 1984, section 123). I will use a more specific application of this example to the same effect that can help us understand its relevance to intergenerational risks. A nation must decide how it wants to regulate the use of fossil fuels. Initially, policy-makers take into account the fact that there are an infinite number of possible policies they could adopt that would result in an equally infinite set of possible outcomes. For the sake of example it is assumed that they have narrowed their decision down to the following three policy options:

- ▶ *Great Depletion:* This policy would allow unlimited use of fossil fuels until such materials become unavailable in 200 years. This policy will likely lead to a higher average quality of life in the short term, but a much lower average quality of life in the long term.
- ▶ *Lesser Depletion:* This policy would allow the use of fossil fuels, but would restrict this use more than the Great Depletion policy to extend the time fossil fuels would be available to 500 years. This policy will likely lead to a somewhat higher average quality of life in the short term, but a lower average quality of life in the long term.
- ▶ *Conservation:* This policy would greatly restrict the use of fossil fuels such that the use of fossil fuels would be distributed over a thousand years. This policy will likely lead to a lower average quality of life in the short term, but a much higher average quality of life in the long term.

We can assume that whichever policy we choose will affect population size, though we cannot know in advance in what way population size will be affected. The decision of which policy to adopt is therefore a different number choice. This is due to the fact that the different policy options will entail, among other things, different qualities of life for the citizens of the nation in which the policy is adopted, which we have already seen will affect the identity and number of future people.

Each of the different policy options will causally contribute to a different set of people living in the future. Although the future people in these possible futures would each experience different qualities of life, even when it is not assumed that causing to exist can benefit, it can at least be concluded that none of the policy alternatives are worse for anyone. The nonidentity problem arises when we nonetheless believe that there is a moral reason to adopt one policy over another. Parfit says, “The great lowering of the quality of life must provide *some* moral reason not to choose Depletion” (Parfit 1984, p. 363). He believes that the mere intuition that the Conservation policy should be morally preferred to the Greater or Lesser Depletion policies illustrates that the view that what is bad must be bad for someone must be rejected.

The challenge for intergenerational ethics is explaining why one policy is better than another when none of the policies would be worse for anyone. Key to the present discussion is that the nonidentity problem challenges the way in which we colloquially talk about harming future generations. If to harm someone is to somehow make her worse off or to negatively affect her interests, it seems we cannot harm future people whose existence we in part determine. The very definition of intergenerational risks as threats of harm to future people is threatened by the nonidentity problem since it is no longer clear that future people can be harmed at all.

One of the most significant aspects of the temporal delay between actions that contribute to climate change and their effects is the fact that these very same actions shape who will live in the future. Greenhouse gas emissions today will cause climatic effects in the future, but these actions will also simultaneously shape the future. What we do today with respect to greenhouse gas emissions policies and practices will affect what the future will be like. It will also affect who will live in the future. So in at least one important sense actions contributing to climate change are different number of choices insofar as these actions contribute to intergenerational risks. Similarly if we look back in time, greenhouse gas emissions helped shape what has become our present. Whether there was explicit acknowledgment of this fact or not (and at times there certainly was not while at others there was), previous actions that caused greenhouse gas emissions contributed to the intergenerational risks associated with the climatic changes we are experiencing today and which will continue into the future. Since we have already identified those actions that contribute to climate change as contributing to intergenerational risks, the question now is whether we can understand climate change as posing threats of harm to future generations, as our working definition of intergenerational risks suggests.

## Harm and Intergenerational Risks

---

Is there any means left for interpreting the risks posed by climate change or any intergenerational risks as being harmful? For identifying actions that further contribute to climate change as harmfully affecting future people? I think there is. But before offering an interpretation of intergenerational risks in response to the nonidentity problem, I should point

out that not everyone is so moved by this problem. Edward Page (2006), for example, after offering an in-depth discussion of the nonidentity problem and responses to it, in particular as these relate to intergenerational justice, takes the “no difference view” of the nonidentity problem. Much like Parfit, he argues that the “the problem should inspire us to think seriously about the theoretical basis for the responsibilities to which many of us are already intuitively committed” (Page 2006, p. 165). Nonetheless, in order to even make sense of intergenerational risks, given that these intuitively are threats of harm to future generations, we need a way to talk about harming relationships that span generations and the nonidentity problem challenges this possibility.

Casper Hare’s (2007) use of the *de re* (of the thing) vs. *de dicto* (of the word) distinction can help clarify how we may understand intergenerational risks without having to give up the notion that such risks involve threats of harm. Hare identifies two kinds of harm: one of which is the traditional kind of harm and one of which is essentially impersonal. He uses a helpful joke to illustrate this distinction: Zsa Zsa has found a way to keep her husband young and healthy. The joke is that the source of Zsa Zsa’s proverbial fountain of youth is that she gets remarried every 5 years. Zsa Zsa’s method for keeping her husband young and healthy promotes these good qualities in an impersonal *de dicto* way. Promoting these qualities in a *de re* way would require that she always have the same husband because *de re* goodness attaches to a particular person. While Hare’s paper focuses on *de dicto* goodness, it is *de dicto* badness or wrongness that is helpful for understanding intergenerational risks. Adapting Hare’s definitions we get:

- ▶ *De Re Worse*: Where S1 and S2 are states of affairs, S1 is *de re* worse for the health of \_\_\_ than S2, when the thing that is actually \_\_\_ is sicker in S1 than in S2.
- ▶ *De Dicto Worse*: Where S1 and S2 are states of affairs, S1 is *de dicto* worse for the health of \_\_\_ than S2, when the thing that is \_\_\_ in S1 is sicker in S1 than the thing that is \_\_\_ in S2 is in S2 adapted from Hare 2007, p. 514.

As Hare notes, and I agree, *de dicto* badness does not always matter, but the point is that it sometimes does. *De dicto* badness can apply to different number choices where “normal” *de re* badness cannot. As Hare says, “there are nonidentity cases . . . about which the *de dicto* betterness account gives clear answers, though they may involve actions that affect how many people ever exist” (Hare 2007, p. 521). Choices may be *de dicto* worse for future people even though they are different number choices.

A version of the classic Parfit example of two mothers who knowingly give birth to children with deformities or defects illustrates this point (see Parfit 1976). Imagine Katie conceives a child against the recommendation of her doctor while on a certain medication that causes her child to have a birth defect. Had Katie waited 1 month to conceive until she was off the medication, she would have had a normal child. Hare points out that we are right to think that Katie “makes things *de dicto* worse for the health of her future child, and this is something she should have been concerned to avoid” (Hare 2007, p. 516). Before deciding to conceive, there was no way for Katie to express *de re* concern for her child, since she could not at that point know the personal identity of her child. Yet it is appropriate to be concerned about one’s future children; this concern is a type of *de dicto* concern. Parents have especially strong *de re* obligations not to harm their children. But while parents cannot *de re* harm their possible future children, they can create or promote *de dicto* harmful conditions for

their future children. Katie's case is a clear example of this possibility. Ignoring her doctor's recommendation and trying to conceive while on the medication amounts to Katie's knowingly *de dicto* harming her future child, whoever he turns out to be. And this is a kind of *de dicto* wrong.

This distinction can help us understand the badness of climate change and other actions contributing to intergenerational risks in a way that avoids entanglement with the nonidentity problem. Actions contributing to climate change are (or contribute to) different number choices, affecting not only the personal identity of those who will exist but also how many people will exist. In terms of their interest-affecting climatic effects, such actions in contributing to the creation of future people cannot make these people *de re* better or worse. These actions can be, however, *de dicto* better or worse for whoever lives since these actions can impersonally affect the interests of whoever lives. It seems that in this case the way in which climatic effects can be *de dicto* worse for people matters morally speaking, though we still need an account of why this is so and what it says about the morality of climate-affecting actions.

While this helps us understand the badness of climate change we still need to explain the way in which intergenerational risks impose threats of harm on future people. My argument is that we cannot harm future people in the everyday *de re* sense, though we can do things that will be *harmful* to future people in a weaker, less direct sense. Namely, we can act in ways that will create *harmful conditions* for future people. We can *de dicto* harm future people. The climatic effects of actions contributing to climate change cannot *de re* harm, but these actions are harmful insofar as they can *de dicto* harm.

(Note that I am not claiming anything about responsibility here. It may turn out that nations, rather than individuals, should be held responsible for the *de dicto* harmful actions of their citizens. Sinnott-Armstrong (2005), for example, argues against individual responsibility. The present account of intergenerational risks does not immediately weigh in on the debate over who – nations, individuals, and/or other actors – should be understood as bearing responsibility for addressing climate change.)

Joel Feinberg's introduction to the concept of harmful conditions in the context of discussing harmless wrongdoing is helpful for further understanding *de dicto* harms. Feinberg says: "We can mean by the phrase *harmful condition* a state in which a person is handicapped or impaired, a condition that has adverse effects on his whole network of interests. By a *harmed condition*, on the other hand, we can mean a harmful condition that is the product of an act of harming" (Feinberg 1990, p. 26, original emphasis). An act can have harmful effects that do not actually harm by creating or promoting harmful conditions. The same kind of effect can be a harmed condition in one instance and a harmful condition in another. The key difference is the nature of the causal relationship between the act or actions in question, the effect(s) of this act(ions), and the person or people affected.

The harmful vs. harmed condition distinction helps clarify at least one key difference between contemporary and future effects of actions. An action puts one's contemporary into a harmed condition when it adversely affects her network of interests. But no present action can put a future person into a harmed condition since no present action can *de re* harm future people. Put another way, no future person will ever be able to rightly claim she exists in a harmed condition because of acts performed before her conception. Along these lines we can understand intergenerational risks as imposing threats of harmful conditions or *de dicto* harm on future people.

It is important to be clear about the context in which Feinberg uses the notion of harmful conditions, which is much more limited than the present context. Feinberg discusses the same Parfit example that Hare uses of a woman who wants to conceive but who is informed that if she conceives now she will have a child with a defective condition. If the woman waits 1 month for her temporary illness to reside she will conceive a child who will be completely healthy. In this case, when we consider the life of the “defective child” Feinberg points out that this child will not have been (*de re*) harmed should she come to exist. So long as her life is worth living, she will be able to say that she is glad her mother conceived her when she did, for if she had not *she* would not have existed, which would have been a much worse fate than living with her defect. Feinberg says of the state of the “defective child” if she is conceived, “I prefer to call it, therefore, a *harmful condition* rather than a harmed condition” (Feinberg 1990, p. 27, original emphasis). That is, he says she is not in a *harmed condition* because there was no prior act of harming that caused her to be in the state she is.

Feinberg says that cases of harmful conception are the only cases where a person is, “put in a harmful condition by the very act that brings him into existence, and the only example where determinations of harm require comparison of a given condition with no existence at all” (Feinberg 1990, p. 327). Feinberg appears to assume that the only cases where the same action that causes an individual to exist also causes her to live in harmful conditions will occur on the level of individuals conceiving or not conceiving in particular instances. While it is true that there is something special about cases in which the harm relationship is relative to the fact that the person would not exist were it not for the very thing that caused her to exist in harmful conditions, our actions also causally contribute to the existence of (distant) future people in ways that cause them to exist in harmful conditions where our actions are not those of harmful conceptions. When we contribute to an intergenerational risk we are potentially imposing harmful conditions on future people. Feinberg incorrectly concludes that the harmful conception cases are the only cases where this is so.

The implication of this is that Feinberg’s identification of the fact that we can create harmful conditions in which a person lives without and in spite of the fact that we cannot *de re* harm her is much more significant than he realized. It is not merely that so-called wrongful conception is harmful for the person it creates, our actions can be harmful to the people whose existence we causally contribute to, despite the fact that we cannot *de re* harm them. The important point is that Hare’s and Feinberg’s distinctions can help us see that there is a distinction to be made between *de re* and *de dicto* harming relationships, only the latter of which can hold between generations. *De dicto* harms impose threats of harmful conditions. This in turn can help us understand the nature of intergenerational risks as threats of harm to future people. Actions posing or contributing to intergenerational risks pose threats of *de dicto* harm to future people. And at least some of these threats of *de dicto* harm matter morally. The challenge is then to determine which intergenerational risks are morally acceptable and which are not. This is where we need to look to work in intergenerational ethics.

## Present Versus Future Harming

Before moving on to discuss how intergenerational risks may be addressed, it is important to recognize that there is a vast literature on the nonidentity problem. (One recent collection that

addresses this problem and points to the relevant literature is Roberts and Wasserman (2009). For non-consequentialist responses to the nonidentity problem see also Reiman (2007) and Kuman (2003). Here I will consider but one especially illustrative view that bears on the above distinctions so as to reinforce the interpretation of intergenerational risks presented here.

Elizabeth Harman (2003, 2004, 2009) has a very different view of what harm is than that which has been presented so far. On her view, we can in fact harm future people and not in a merely *de dicto* way. Harman asserts that a sufficient condition for harm is that, “An action harms a person if the action causes pain, early death, bodily damage, or deformity to her, even if she would not have existed if the action had not been performed” (Harman 2004, p. 107). On this account that something is a harm is a reason against it, but other reasons could outweigh the negative reason provided by the harm (Harman 2003, p. 116). Essential to Harman’s view is that benefits to future people offer reasons in favor of actions, but reasons against harm are “morally serious” and hard to outweigh (Harman 2004, p. 108).

The commonly used case of surgery illustrates Harman’s view. Suppose Susie is having her tonsils removed because she suffers from frequent bouts of tonsillitis. I, along with Feinberg and others, do not believe that the surgeon harms Susie when she cuts away her tonsils if the removal of Susie’s tonsils is in her interest. Harman, however, does believe the surgeon harms Susie when she cuts into her since in so doing she injures Susie’s body. Nonetheless, Harman would say that it is permissible for the surgeon to harm Susie in this way since she has good reasons for doing so, namely, to promote Susie’s overall health and well-being. So on Harman’s account this harm is not wrong. The implication of Harman’s view that is relevant to this discussion is that Harman argues that we can in fact harm future people and that the nonidentity problem is only a problem because it confuses what constitutes harming.

(I should note that in her 2009 paper, Harman discusses different number choices for which we do not know whether more or less people will exist depending on whether an action is performed or not. Most actions that pose or contribute to intergenerational risks are of this kind. Harman suggests that in such cases we will often have strong reasons not to act because, given the possibility that such choices will lead to fewer people existing, we should be cautious and refrain from acting. I do not find her discussion there particularly relevant to the present discussion, which is why I focus my discussion here on the implications of her general account of harm.)

Critical to Harman’s argument is her position “that an action may be wrong *in virtue of harming* even though it makes a person better off than she would otherwise be” (Harman 2003, p. 105, original emphasis). She articulates this more clearly when she claims that reasons against harm are so morally serious that the mere presence of greater benefits to those harmed is not in itself sufficient to render the harms permissible: When there is an alternative in which parallel benefits can be provided without parallel harms, the harming action is wrong (Harman 2004, p. 93).

Looking at some of the cases Harman uses to support her position helps to clarify where I believe her account goes wrong. One case Harman considers is that of a woman whose life is better because she had a child conceived as the result of a rape in part because she is remarkably able to separate the trauma of the rape from her attitude toward her child such that they have a normal parent–child relationship (Harman 2003, p. 103). A second case Harman discusses originally comes from James Woodward (Woodward 1986, p. 809); Viktor Frankl believes his imprisonment in a Nazi concentration camp actually made his life better than it would have been had he not been imprisoned because it enriched his character and deepened his

understanding of life. Harman further supposes that Frankl does not wish that the Nazi's had not imprisoned him, despite the fact that they clearly impermissibly harmed him (Harman 2003, p. 104). Harman rightly claims that both the raped woman and Frankl are better off because of the very acts that harmed them insofar as these events were pivotal life-experiences that lead them to be better off than they were before they were harmed. Harman is also correct to say that both the raped woman and Frankl need not regret that they were harmed for these harms to have been impermissible and for the victims to have legitimate complaints against those who harmed them. But, I think that Harman's discussion of these examples and their implications, while valid for the cases she discusses, is misleading.

The very nature of rape and imprisonment in a Nazi concentration camp clearly identify these actions as harms on any reasonable account of harm. I do not think anyone would disagree that at the time, the act of raping harmed the woman in question. And no one would disagree that Frankl was harmed by his imprisonment. Being raped or unjustly imprisoned are both physically injurious, damaging to one's interests, and a violation of one's rights. But not all acts of harm prove to be bad for us in the long run. We do not necessarily regret all the harms we have suffered despite having legitimate claims against those who harmed us. This is why perspective matters.

Acts of harm can be direct and immediate between persons: the rapist harmed the woman through the act of raping her. The harm incurred by an act can also be temporally delayed from the moment of harming: a rape victim could suffer psychologically days, weeks, or even years after the immediate harm such that they experience harm long after the physical act and a car accident victim could have a physical injury that does not manifest itself until hours after being hit by a drunk driver. Whether we regret being harmed in a given instance and whether it ultimately makes us better off depends on how we deal with being harmed and on the many other things that happen to us in our lives. Harman's rape victim was clearly impermissibly harmed since the act of rape not only violated her rights and injured her body but also thwarted her interests at the time. The fact that she later was glad for having been raped because of both its consequences and her choices says something about who she is and later occurrences in her life; it does not say anything about the impermissibility of the rape itself. Rape is always harmful; it is never in one's interests to be raped.

The significant point I want to make is that Harman's position about something being wrong in virtue of harming despite making a person better off than she would otherwise be does not apply to future people. Just because a person who has been harmed by a contemporary can later not regret this impermissible act of harming, and in fact may have benefited from it in the long run, does not mean that future people who would not regret the alleged harms against them would be in fact harmed. A future person whose interests are negatively affected by and/or is injured by the effects of climate change will almost certainly be glad that she came to exist, but she cannot believe that actions that causally contributed to her existence made her worse off because the alternative would have been her nonexistence, not her being in some better state. But this does not mean that she has been harmed by those actions in the same way the rape victim and Frankl were harmed. The rape victim and Frankl already had interests and bodies at the time they were harmed. So, while later they come to believe that the acts that harmed them were good for them despite having been impermissible harms, the reason they understand these acts to have been impermissible is in part because they were not necessary to their existence. The future person, however, cannot make such a claim. The acts that led to her interests being negatively affected and/or her being physically injured *had* to have happened in order for her to even exist and have a body and interests in the first place.

Harman tries to avoid the nonidentity problem by making the point of comparison for determining when something constitutes a harm as an ideal healthy bodily state. In so doing she avoids the problem that future people cannot be harmed because they cannot be made better or worse off, as is required to judge whether something is a (*de re*) harm or benefit. For Harman, *any* act causing bodily injury is an act of harming. It follows that any act that causes a future person to suffer a bodily injury would thus also be an act of harming. But, any act that causally contributes to a future person's existence also causally contributes to the creation of his body. It is hard to understand how from the perspective of any future individual, even if such an act also causes his body to be injured, it could be deemed wrong by Harman since it seems the goodness of the creation of the future person's body will always outweigh any later injury to it. So long as a person's life is worth living, as I assume virtually all people's lives are, the creation of his body will outweigh any wrongness of injuries to it caused by the same acts that created it. While Harman can say that a future person has been harmed on her view when he suffers bodily injury, none of these harms will be able to be judged as wrongs when judged independently. To me this takes away a key part of the meaning of "harm." This is why it makes more sense to focus on the way in which such actions are harmful such that we need distinct ways of thinking about intergenerational ethics. The clearest way to make sense of the way in which intergenerational risks pose threats of harm is by understanding the way in which such risks may create harmful conditions or constitute *de dicto* harms despite affecting the identity of future people.

## **Current Research**

---

Having now established a way of making sense of intergenerational risks, in this section I will discuss several approaches to addressing intergenerational risks. My intention is to survey work relevant to understanding how intergenerational risks should be addressed. In order to address intergenerational risks we must decide what (intergenerationally) risky activities are acceptable. But since very little has been written on intergenerational risks directly, I will focus on aspects of the literature that I find to be particularly relevant and/or promising for being able to contribute to a better understanding of the relevant issues. In what follows I will first consider the way in which economics addresses intergenerational risks and the use of discounting in cost-benefit analyses in particular. I will then discuss the precautionary principle as a possible guide to addressing intergenerational risks. Finally I will briefly look to the literature on intergenerational justice, using examples from work on climate change, to illustrate the potential applicability of work in this field to the ethics of intergenerational risks. This discussion will illuminate the fact that thinking about how to address intergenerational risks pushes us to think deeply about intergenerational ethics. What we think we owe future people, after all, affects what risks we believe we can permissibly impose upon future generations.

### **The Limits of Cost-Benefit Analysis**

---

It is especially important that we consider what is probably the dominant approach to addressing intergenerational risks, namely, economic approaches. When faced with a threat of harm we often perform cost-benefit analyses to determine an appropriate course of action.

There are two primary ways, however, in which cost-benefit analysis is understood. First, cost-benefit analysis is sometimes understood as a method for analyzing quantitative economic information. Understood as a quantitative method, cost-benefit analysis is merely an analytic economic tool, a quantitative method that produces quantitative results. Second, cost-benefit analysis is most often understood as a decision-making framework that makes policy recommendations based on assessments of the costs and benefits of different policy options. This distinction is supported in the literature, though it is not consistently discussed or identified in exactly the way I describe. Many authors have noted that what is implied by “cost-benefit analysis” varies widely from context to context. As Richard Posner says, at the highest level of generality this term is used synonymously with welfare economics (2001). At the other end of the spectrum it is meant as a principle of wealth maximization. Both of these interpretations identify cost-benefit analysis as a decision-making framework, but they associate cost-benefit analysis with different decision rules. Posner, however, also identifies the interpretation of quantitative cost-benefit analysis as “a method of pure evaluation, conducted wholly without regard to the possible use of its results in a decision” (Posner 2001, p. 318).

When understood as a framework for rational decision making, cost-benefit analysis is associated with certain norms. The most general form of the normative cost-benefit analysis decision rule, or cost-benefit principle as it is sometimes called, tells us to take the action with the greatest expected net benefit. The rule is also sometimes stated such that one ought to choose the project that maximizes the present value of net benefits, where the net benefits of projects are generally equated with the aggregate welfare consequences of those involved in or affected by the activity under consideration. This rule is also often understood as saying that benefits should be maximized and costs minimized, or that benefits should be maximized in the most cost-effective way possible. The welfare consequences in cost-benefit analyses are usually measured by individuals’ willingness-to-pay.

The first thing to note about cost-benefit analysis is that it may leave out and obscure important normative considerations. First, cost-benefit analysis may be misleading insofar as what gets counted as costs and benefits involves making both normative and pragmatic judgments. Cost-benefit analysis requires assigning a monetary value to everything it evaluates. But what costs and benefits get accounted for in cost-benefit calculations is often in part determined by what is readily monetized, which can lead to both errors (i.e., assigning wrong values) and omissions (i.e., excluding things of value). Second, cost-benefit analysis can appear to be an objective or scientific method for making decisions when it is in fact not. The clear procedural structure of cost-benefit analysis obscures both the fact that a range of normative judgments underlie the quantitative information that it assesses and that it sometimes fails to consider important normative issues.

Imagine a cost-benefit analysis of the decision to log an area in the Amazon. What is the monetary value of a hectare of the Amazon rainforest? Economists often quantify this in terms of how much money could be gained by logging the area, but clearly there are other ways in which a hectare of rainforest is valuable, some of which are more difficult to quantify than others. Instrumentally a hectare of rainforest is valuable to humans in all kinds of ways. Locally, the rainforest provides food, firewood, and other resources to its residents. Globally, the Amazon plays a role in the climatic system and would contribute to climate change if it were deforested. But how much monetary value should we assign to the costs associated with deforesting a hectare of the Amazon? Tropical rainforests also contain plants with potential medicinal value. If we cause these species to go extinct, we lose the potential to benefit from

their medicinal uses. But how much value does this add to the rainforest quantitatively? There are also people who believe that the rainforest is valuable for its own sake, that it is intrinsically valuable. How could the intrinsic value of the rainforest and of the species that exist there be included in cost-benefit calculations? And how do we incorporate or assess the long-term instrumental and/or intrinsic value of the Amazon?

It is difficult to imagine that any cost-benefit analysis involving the Amazon could fully capture the full value of this resource. What costs and benefits are quantified will depend both on pragmatic limitations and normative judgments about what aspects of the Amazon are valuable and how these values should be monetized. The results of such cost-benefit analyses will therefore be influenced by what were considered and quantified as costs and benefits and will obscure possible impacts and outcomes that never made it into the calculations. This may be particularly important if we are trying to assess and make decisions about intergenerational risks that may have long-term effects.

The first point about the value-ladenness of cost-benefit analysis is therefore that how costs and benefits are measured involves value judgments because of the subjectivity of the metrics used. The willingness-to-pay metric usually used to measure costs and benefits depends on the values and preferences of individuals. How much individuals are willing to pay to protect the environment, for example, will likely be informed and influenced by their preexisting normative stances such as how much they value the environment as a means (e.g., for recreation) or for its own sake. One person might judge the paving of a wetland for the development of a shopping center as a benefit if they dislike wetlands for aesthetic reasons, whereas someone else might judge this as a cost because they value natural areas and the species that live in wetlands. Uncertainty further complicates and distorts willingness-to-pay assessments. Often people do not have enough information to fully understand and assess all possible outcomes even when such information is available.

Any objectivity in cost-benefit analysis comes from the quantitative methodology it uses. But it is important to recognize, as most people do, that the inputs into cost-benefit calculations can be subjective and/or normative. (I should note that the use of willingness-to-pay as a key measure of value in cost-benefit analysis is the basis of many objections against cost-benefit analysis. I too worry about the use of this metric, but I will not pursue this issue at great length here.) The very fact that quantitative cost-benefit analysis is quantitative can make it appear to be a value-neutral methodology for assessing costs and benefits. But since what gets counted as costs and benefits in the first place requires normative judgment, even quantitative cost-benefit analysis is not value-free. The quantitative results of cost-benefit analyses must therefore be contextualized to the assumptions about what was measured and assessed. Further, the decision rule that guides cost-benefit analysis can appear to be more objective than it is because of its clear procedural structure (e.g., choose the option with the highest benefits and least costs). But underlying this decision rule is the valuing of efficiency (or whatever is being maximized or captured by the decision rule).

Finally, when cost-benefit analyses use willingness-to-pay as a metric in their calculations they may implicitly ignore considerations of equality and justice. This is especially true of wealth-maximizing versions of cost-benefit analysis because these leave out considerations of distributive justice and, as Posner says, “it treats a dollar as worth the same to everyone” (Posner 2001, p. 318). The problem is that gaining or losing a dollar has a much greater impact on a poor person’s welfare than on a wealthy person’s. If the preferences or utility of rich people or states are weighted more heavily in a cost-benefit analysis, the rich are likely to also

benefit the most from any policy the analysis recommends. For example, if the policies being evaluated are about national park access fees and it is determined that the rich are willing to pay more than the poor, then the results of a cost-benefit analysis might show that it would maximize net benefits to charge entry fees that are prohibitively expensive for the poor. Such a policy, however, may violate principles of justice by essentially denying the poor access to a public good. Obviously there would be many factors to consider in a full cost-benefit analysis, but there is the potential here for distributive injustices to be exacerbated. Using willingness-to-pay may not only treat rich and poor people unequally but may also result in recommendations that exacerbate injustices between the rich and poor. Furthermore, when cost-benefit analyses are done on a global level, they can, as Amartya Sen says, “obscure an enormous issue of justice and fairness between different parts of the world” (Sen 1995, p. 32). More importantly for this discussion, using willingness-to-pay as a metric may fail to appropriately capture long-term value, which it seems we should be concerned about when considering intergenerational risks.

The second thing to note about cost-benefit analysis has to do with its methodology. Discounting is used in economics, and specifically in cost-benefit analysis, to account for changes in the value of different metrics over time. Using a positive discount rate in economic analyses assumes that wealth will continue to increase over time and that relative values decrease over time. There are two reasons we may want to privilege a low discount rate when assessing intergenerational risks. First, this enables all possible outcomes to be considered whenever they threaten to occur. Fully assessing intergenerational risks requires us to be temporally neutral in this respect, which means we should grant future people equal ethical standing with respect to the harmful outcomes they might experience. Second, discounting the future has the potential to mask potentially harmful outcomes. A complete assessment of intergenerational risks therefore may require assessing all possible future impacts and using a zero or near-zero discount rate. Discounting the future has the potential to mask the harmful effects of intergenerational risks that should, after all, be the focus of an analysis of such risks. These points could be understood as applying to the two aspects of the discount rate, the rate of pure time preference and the rate of consumption, respectively. Treating all generations as having equal ethical standing requires using a zero (or near zero) rate of pure time preference, while taking into account the possibility of thresholds and non-compensate-able harmful outcomes requires using a low rate of consumption (which otherwise assumes future people will be wealthier and therefore benefit less per unit of consumption). Considering what this means for an economic analysis of the intergenerational risks climate change presents will help make this point clear.

The *Stern Review* of the economics of climate change argues that the approach to discounting taken in an economic assessment of climate change must diverge from traditional approaches because such an approach “must meet the challenge of assessing and comparing paths that have very different trajectories and involve very long-term and large inter-generational impacts” (Stern 2007, p. 25). Different climate change policies (different emissions scenarios) could lead to drastically different outcomes. The difference between high-emission scenarios and the lowest possible emission scenarios is a difference of many degrees in terms of global average temperature. Because of this, the *Stern Review* takes into account ethical arguments in determining an appropriate discount rate. The most influential ethical assumption the *Stern Review* makes is that, “if a future generation will be present, we suppose that it has the same claim on our ethical attention as the current one” (Stern 2007, p. 35). The *Stern Review* argues that this implies that treating the welfare of future generations as on par with our own because the prospects of

future generations matter follow from “most standard ethical frameworks” (Stern 2007, p. 37). This follows from John Broome’s conclusion in his contribution paper that he sees “no convincing grounds for discounting future lives,” which seems appropriate in the context of the assessment of intergenerational risks (Broome 2006, p. 19). (See Caney 2008, 2009 for a related argument that a human rights-based account requires that we do not have any pure time preference.) This stance about the ethical standing of future people leads the *Stern Review* to use a very low rate of pure time preference of 0.1% (Stern 2007, p. 663). (The reason the *Stern Review* has a positive rate of pure time preference at all is to account for the possibility of human extinction. There is a genuine question as to whether the *Stern Review* is right to account for the possibility of human extinction, but exploring this issue is outside the scope of this chapter. The *Stern Review* therefore generally uses a discount rate of 1.1%, though the *Stern Review* says that it does not always use a consistent discount factor and thus discount rate, see Stern 2007, p. 60. See also Dietz et al. 2007 for a reiteration and further defense of the *Stern Review*’s treatment of discounting.)

William Nordhaus, on the other hand, consistently uses a relatively large discount rate in his analysis while admitting that the choice of the discount rate is especially important for climate change because it will significantly impact the future – including the far future. He says, “The approach in the DICE [Dynamic Integrated model of Climate and the Economy] model is to use the estimated market return on capital as the discount rate. The estimated discount rate in the model averages 4% per year over the next century” (Nordhaus 2008, p. 10). (See also Nordhaus 2008, Chap. 9.) Nordhaus illustrates that according to this rate this means that \$1,000 of climate damages 100 years from now is valued at \$20 today. It is therefore unsurprising that Nordhaus has criticized the *Stern Review*’s “extreme” assumptions economic discounting, which results in its “radical view of policy” (Nordhaus 2007a, p. 689). He says, “The *Review* seems to have become lost in the discounting trees and failed to see the capital market forest by overlooking the constraints on the two normative parameters” (Nordhaus 2007a, p. 700). Despite the fact that Nordhaus believes that economic analysis should not be the sole guide to decision making, he clearly has strong opinions about how economic analysis should be done – using a relatively high discount rate.

Nordhaus argues that the *Stern Review*’s results stem from its use of a low time-discount rate and low inequality aversion (Nordhaus 2007b, p. 202). He believes the near-zero pure rate of time preference and correspondingly low discount rate used in the *Stern Review* magnifies “large and speculative damages in the far-distant future” into a large current value (Nordhaus 2007a, p. 696). Nordhaus further demonstrates, through a series of basic calculations, that if the *Stern Review*’s parameterizations are corrected to match standard economic methods and assumptions, in part by using a higher discount rate, the results are in line with standard economic models (such as his own) (see Nordhaus 2007a: Section 4, 697–701). He calculates that more than half of the estimated damages “now and forever” cited by the *Stern Review* occur after the year 2800, which he implies should be taken as reason against the review’s use of an extremely low discount rate (Nordhaus 2007a, p. 696). Martin Weitzman also estimates that the difference between the *Stern Review*’s discount rate and more traditional discount rates changes the estimated damage costs of climate change 200 years from now by two orders of magnitude (Weitzman 2007, p. 708). The question we must ask is whether it is in fact problematic, as Nordhaus suggests, that the *Stern Review* incorporates climate change effects in the (relatively) far-distant future. In the context of thinking about intergenerational risks I think it is not.

There are at least two main problems with Nordhaus' arguments in favor of using a "standard" discount rate and making recommendations based on these calculations. First, Nordhaus does not sufficiently take into account the ethical standing of future people. When it comes to addressing uncertain threats of harm that have the potential to affect future generations, the *Stern Review* makes ethical assumptions that enable it to more fully assess and therefore make more appropriate recommendations about the intergenerational risks climate change poses. But while the *Stern Review* focuses its arguments in favor of using a low discount rate on this point, there is a second reason why Nordhaus' arguments are misguided and which maybe even the *Stern Review* does not sufficiently consider. This second problem is that climate change does not fit the assumptions made by standard economic approaches insofar as there might be thresholds after which we will not be able to avoid potentially harmful climate impacts and climate change threatens to have harmful effects that future people may not be able to compensate for. Eric Neumeyer (2007) makes a similar argument that even the *Stern Review* fails to adequately address the irreversible and nonsubstitutable damages and loss of natural capitol that climate change will incur, though he makes this argument in contrast to arguments about discounting. He argues that incorporating the importance of such damages would have provided an even more compelling case for drastic action to mitigate climate change. Traditional cost-benefit analysis fails to account for the possibility that preventing some threats of harm cannot be delayed and that some harmful outcomes cannot be compensated for once they occur or are initiated.

Atmospheric greenhouse gas concentrations take a long time to dissipate, which means that there will be a delay between our acting to reduce greenhouse gas emissions and the climatic impacts (e.g., temperature changes) that will occur. The longer we delay action to reduce greenhouse gas emissions, the higher global average temperatures are predicted to rise. The problem is that global average temperatures will not immediately decrease if we later decide we want to take action to reduce atmospheric greenhouse gas concentrations. For example, once the West Antarctic Ice Sheet melts, we will not be able to refreeze it or prevent sea level from rising, no matter how wealthy we are. There are therefore thresholds or points-of-no return for preventing certain climate impacts. Using a high (or even any positive) rate of consumption in the discount rate does not sufficiently account for this because it assumes that future people will be able to use their increased wealth to address any harmful climate impacts. But, future people will likely not be able to compensate for the five or more meters of sea level rise that is predicted to occur if the West Antarctic Ice Sheet melts (IPCC 2007, p. 819), no matter how wealthy they are because the extent and magnitude of the impacts would simply be too great. We will not always be able to compensate for harmful outcomes, since, for example, some harmful outcomes could undermine our economic system or be so costly as to be beyond compensation.

These and other reasons may lead us to believe that we should use a very low discount rate, if we should discount at all. However, as Gardiner points out, rejecting discounting need not mean that we use a uniform zero discount rate (2011). We need to understand what the implications of our policy options are both now and in the future so that we can decide what the most appropriate course of action is. While I do not deny that future people will sometimes be able to compensate for some climate impacts, for example, by developing technologies to prevent such impacts from being harmful, we cannot *assume* that this will always be the case when we are talking about widespread, irreversible changes. In trying to understand how to address intergenerational risks we must understand in what ways future people will be affected

and whether or not they will be able to compensate for potentially harmful effects. We will not understand the implications of intergenerational risks unless we draw on analyses that significantly discount the future when assessing such risks. If economics is to guide decision making about intergenerational risks, cost-benefit analyses assessing such risks should use a very low discount rate, if they discount at all. Careful consideration of the normative assumptions guiding the quantification of the inputs to such cost-benefit analyses is also needed. Intergenerational risks raise ethical challenges that standard economic approaches may fail to account for.

## Precautionary Principles

---

An entirely different approach to addressing intergenerational risks would be to apply the precautionary principle. The precautionary principle has been used in many contexts and has many formulations. The general idea behind this principle is that it is better to be safe than sorry and/or that we sometimes ought to act in advance of scientific certainty. One way of understanding the precautionary principle is as guiding us toward caution in the face of risks, including intergenerational risks. As such it is at least implicitly one of the most discussed principles for addressing intergenerational risks. Nevertheless, there is no consensus as to how the precautionary principle should be formulated or interpreted. And if the precautionary principle is to guide decision making about intergenerational risks, we must be clear as to what this principle requires.

The first set of challenges the precautionary principle faces is that its components are often not clearly defined or delineated. These challenges concern the content of the precautionary principle. Derek Turner and I argue that the precautionary principle is inherently unclear in five ways: first, the precautionary principle is often formulated such that it is unclear who must take responsibility for and bear the cost of precaution; second, the precautionary principle is unclear and even internally contradictory when it applies simultaneously to threats of harm to human health and the environment; third, it is often unclear what are to be counted as threats of harm; fourth, it is also unclear what are to be counted as precautionary measures (see also Sandin 2004, 2007); fifth, it is often unclear how much precaution is required (Turner and Hartzell 2004). Of particular importance is a variant of the third issue: risks abound on all sides yet we cannot possibly be precautionary about everything (Sunstein 2005 and Posner 2004 also state versions of this objection). I identify this as the paralysis objection; the precautionary principle would be paralyzing if it were to require precautionary measures against any and all threats of harm.

Another set of challenges facing the precautionary principle stems from confusion about just what this principle is supposed to be. Not only does the precautionary principle appear to have many formulations, but also its very nature seems to vary depending on the author and situation. First, the precautionary principle is sometimes understood as a family of principles that share a common structure (see, e.g., Sandin 2007; Manson 2002; Hickey and Walter 1995). Individual formulations of the precautionary principle, according to this view, may be tailored to specific applications. Several authors have suggested features that such specific formulations of the precautionary principle must share (see, e.g., Manson 2002; Hickey and Walter 1995; see also O'Riordan and Jordan 1995). Other authors who ascribe to this view have emphasized

that there are some particularly plausible versions of the precautionary principle (see, e.g., Gardiner 2006b). Second, the precautionary principle has been interpreted as an approach to risk management such that it is more of a decision-making procedure or framework than a principle (see, e.g., Goklany 2001; Resnik 2003). On this view, the precautionary principle is seen as a guide to rational decision making in the face of uncertain threats of harm. A third view of the precautionary principle is captured by Kerry Whiteside's conclusion that "the precautionary principle shades off into precautionary politics" (Whiteside 2006, p. 150). On this view, the precautionary principle is understood as a banner for a new way of thinking about risk management in the face of uncertainty. Along these lines Turner and I note that the precautionary principle has come to serve as a banner signifying a shared commitment to the welfare of the environment and future persons, and in addition shared reservations about the effectiveness and applicability of economic cost-benefit analysis (Turner and Hartzell 2004; O'Riordan and Jordan 1995 make a similar point). Whiteside understands the precautionary principle as guiding us where standard assumptions about risk management do not hold by shifting the default position toward action rather than business as usual in the face of uncertain threats of harm. But he argues that there can be no 20- or 30-word juridical formulation of the precautionary principle because what is meant by "the precautionary principle" is this shift in the way we approach decision making.

Elsewhere I have brought attention to the apparent dual roles of the precautionary principle; it appears to call for precaution in the face of uncertainty as well as a new way of thinking about decision making (Hartzell 2009). I argue that rather than thinking of the precautionary principle as a loose family of principles or as a decision-making procedure, we should require all precautionary principles to be understood as individual moral principles capturing particular *prima facie* moral duties. This means there may be other moral duties that will sometimes supersede precautionary principles, but we have strong moral reasons to follow precautionary principles. We should require that all precautionary principles bear some connection to the intuition that it is better to be safe than sorry and/or to the idea that we should sometimes act in advance of scientific certainty, but this alone is not enough. If a precautionary principle is to have any real normative force it must pick out a unique *prima facie* moral obligation. All things being equal, in some (but certainly not all) cases we *ought* to take a better safe than sorry approach and act in advance of scientific certainty. There is thus a family of precautionary principles, but each precautionary principle is an independent moral principle that must be independently identified and justified. This understanding of precautionary principles clarifies that "the" precautionary principle cannot be used to justify any and all precautionary action. It returns meaning and normative force to precaution in the limited cases in which precaution is morally called for.

Precautionary principles then may guide decision making about intergenerational risks, but it is misguided to think that "the precautionary principle" can be helpful as there is no such single principle. One of the looming questions about intergenerational risks, after all, is how to determine when they are morally acceptable and when they are morally impermissible. A simple notion of "better safe than sorry" or "act in advance of scientific certainty" would push us to be extraordinarily averse to intergenerational risks since there will almost always be uncertainty about the possible outcomes of our actions. But limited precautionary principles may be able to guide us in the face of such uncertainty and help us sort out when we may and when we ought not to impose threats of harm upon future generations.

## Intergenerational Justice

---

The third established body of work that may help us understand how to address intergenerational risks comes from the study of intergenerational justice. Work on intergenerational justice applies to intergenerational risks insofar as such risks pose questions of justice. One question we may ask is, when it is permissible and impermissible to impose risks on future generations? Which intergenerational risks are morally acceptable and which are unjust? Few authors who have written on the topic of intergenerational justice have explicitly addressed intergenerational risks. But I see work on intergenerational justice as providing an insightful way of understanding the ethics of intergenerational risks. I do not have the space here to provide a thorough treatment of all work on intergenerational justice, but I hope that by offering a few examples from work on climate change this section will illustrate what the field of intergenerational justice has to offer to an understanding of intergenerational risk and why the significance and prevalence of the latter in many ways begs for more work on intergenerational risk. (A recent anthology, *Intergenerational Justice*, illustrates the breadth of work in this field that goes far beyond work on climate justice (Gosseries and Meyer 2009).)

If we understand climate change as involving intergenerational risks such that actions contributing to climate change pose time-delayed threats of (*de dicto*) harm, then we can see work on climate justice as trying to make sense of the ethics of intergenerational risks. And if we assume, as most justifiably do, that at least some of the intergenerational risks posed by climate change are morally unacceptable, thinking about what justice requires in terms of eliminating or reducing these risks, via mitigation and adaptation, can help us move from working to understand the nature of such risks to understanding how such risks should be addressed. Edward Page says, “The use of the language of entitlement and justice is important: although there is a range of alternative reasons for preserving environmental goods for present and future generations, justice appears to provide a more compelling and urgent defense of environmental and intergenerational duties than rival approaches” (Page 2006, p. 162). For all of these reasons intergenerational risks lend themselves to an intergenerational justice approach.

Darrel Moellendorf’s recent work on climate change and intergenerational justice is particularly relevant to this discussion because he implicitly responds to the challenge of Gardiner’s PIP (2009). Moellendorf defends a principle of Intergenerational Equality that states, “Present energy policy should produce foreseeable future (adaptation) costs of CO<sub>2</sub> emissions whose proportion to overall future economic output is equal to the proportion of (mitigation) costs to output of the present generation” (2009, p. 207). His argument appeals to a contractualist view of procedural justice that draws on John Rawls’s original position argument (Rawls 2001). Moellendorf’s key claim is that in order to achieve impartiality in our deliberations about intergenerational justice, we must bind ourselves “only to principles that we would find it acceptable for previous generations to have bound themselves” (2009, p 211). Moellendorf believes this may alleviate Gardiner’s worries about the implications of PIP insofar as committing to procedural justice may enable us to make moral commitments that extend us beyond a generationally self-interested perspective. (Gardiner himself, however, identifies several problems with contractualist views in intergenerational settings (2009).) With respect to intergenerational risks, Moellendorf’s view suggests we ought to take a perspective that will be fair across generations with respect to the costs of climate change. Of note, however, is that Moellendorf includes a “foreseeability” clause that limits the principle of Intergenerational Equality to known (or knowable) climate impacts. This implies

that policies condoning greenhouse gas emissions before the consequences of such emissions were known were not unfair or unjust. In order to be unjust on this view, a risky activity must be understood as such.

Another perspective comes from Henry Shue, who has written extensively on intergenerational justice with an emphasis on climate change and other environmental issues (e.g., 1980, 1981, 1993, 1999, 2010). His work on basic rights has influenced many writing on climate justice in particular. The intuition grounding his work on basic rights is that “human beings ought to enjoy control over avoidable damage to their own bodies” (Shue 1981, p. 593). Basic rights then, “are the morality of the depths. They specify the line beneath which no one is to be allowed to sink” (Shue 1996, p. 18). Basic rights specify “everyone’s minimum reasonable demands upon the rest of humanity” (Shue 1996, p. 19). Implicitly drawing on his work on basic rights, Shue (1993) makes an influential distinction between subsistence emissions and luxury emissions. Shue argues that we have to ensure the poor are entitled to those emissions that enable them to meet their basic needs, namely, to subsistence emissions. Part of what this implies is that if there is to be a system of emission allowances, justice requires that we not allow the wealthy to buy up the poor’s emission allowances. (In his 1999 paper, Shue similarly makes a multi-pronged argument, drawing on three distinct principles of justice, that wealthy industrialized states that should at least initially bear the costs of addressing global environmental problems.) We can apply this to the present discussion of intergenerational risks by understanding Shue as suggesting that whatever our obligations to minimize the extent of intergenerational risks are, we must ensure people’s basic needs are met. Extending his view may suggest that our priority in addressing intergenerational risks is to ensure both present and future people’s basic needs are met. Risky activities that threaten present or future people’s ability to satisfy their basic needs are morally unacceptable on this view.

Simon Caney draws heavily on Shue’s work in defending a human rights-based approach to climate change policy (2010a, b). Caney proposes that we understand dangerous climate change as climate change that systematically undermines the widespread enjoyment of human rights. He understands human rights as representing moral thresholds that have, to use John Rawls’ terminology, lexical priority over other moral values (Caney 2010a; see Rawls 1999, pp. 37–38 for a discussion of “lexical priority”). Caney concentrates on three key human rights: the human rights to life, health, and subsistence, focusing on what he takes to be the least contentious formulations of these rights to show that on even the most minimal conception of human rights it is clear that climate change jeopardizes these rights. He phrases each of these rights in such a way that individuals have a right not to have their ability or access to life, health and subsistence taken away or interfered with by other people. Caney thus frames human rights in terms of what people owe to each other, which allows him to conclude that whoever is contributing to climate change is violating the rights of individuals whose health, subsistence, and/or existence is threatened by the effects of climate change. We may apply Caney’s view to intergenerational risks when we conceive of some such risks as threatening to violate future people’s human rights. On this view we ought not create or contribute to intergenerational risks that threaten present or future people’s rights to life, health, and subsistence.

Caney defends two principles, which are revised versions of principles first defended by Shue (1999), as a starting point for thinking about climate change policy. These are, first the Poverty-Sensitive Polluter Pays Principle, which says that whoever contributes to dangerous climate change should bear the burden of combating it, unless this would push him/her below a decent minimal standard of living. And second, the History-Sensitive Ability to Pay Principle

which says that any remaining burden (not covered by the first principle – e.g., past emissions, nonhuman induced emissions, and legitimate emissions of the poor) should be borne by the wealthy, proportionally to their wealth and to whether they acquired this wealth in climate endangering or other unjust ways (Caney 2010b). One important implication of Caney's "hybrid model" that he points out is that the least advantaged have a duty to develop in non-carbon-intensive ways, if they can do so without great cost to themselves (2010b). (Caney admits that his view does not specify the appropriate duty-bearing entities, which would be necessary in order to formulate climate change policy. He notes that most discussions focus primarily on states as the bearers of responsibility in climate change policy, but points out that this focus might ignore important differences between people within states and other entities such as firms.) More generally, these principles may be applied to intergenerational risks that threaten human rights such that those contributing to intergenerational risks ought to combat potential human rights violations and if this is insufficient the wealthy ought to help protect future people's human rights.

Steve Vanderheiden (2008) defends a different view of what justice requires of us in climate change policy. His most distinctive move is to differentiate what justice requires for mitigation vs. adaptation policy because, he argues, these represent different distributive issues. Vanderheiden argues that mitigation policy, or emissions abatement policy, as he describes it, should be guided by an equity model. This model assumes that all people are moral equals and therefore have equal claims to the atmosphere's absorptive capacities, suggesting a default position of equal per-capita emissions shares. An unequal distribution of the atmosphere's absorptive capacity would have to be justified based on benefits accrued to the least advantaged. Adaptation and compensation policy, on the other hand, should be guided, argues Vanderheiden, by considerations of responsibility (for contributing to climate change). So while mitigation policy should look forward toward equal distributions of emissions, adaptation policy should look backward toward liability for creating threats of harm.

Vanderheiden, also following Shue, distinguishes between survival and luxury emissions such that he argues people have a basic right to survival (but not luxury) emissions. Thus while he too takes a rights-based approach in at least this sense, he comes to much different conclusions about what this implies than Caney. Vanderheiden brings rights into his account in part to highlight that the right to survival emissions is but one such right and that there is also a right to develop. He stresses the importance of thinking about the relationship between climate change and development policies. This implies that Vanderheiden may argue that how we address intergenerational risks cannot be separated from other justice issues. Yet he does not seem to address or acknowledge the contributions to climate change that pose intergenerational risks. On the other hand, failing to respect the right to develop could be interpreted as posing intergenerational risks such that Vanderheiden is actually taking a wide view of intergenerational risks.

What this very brief discussion of climate justice is meant to illustrate is that work on intergenerational justice has a lot to offer toward understanding the ethics of intergenerational risks. Caney and Vanderheiden's theories, for example, illustrate the way in which theories of climate justice (or intergenerational justice more generally) can guide decision making about intergenerational risks. Often, though not always, we can frame the question of whether or not a risky activity or behavior that will have long-term consequences (and hence poses an intergenerational risk) is morally acceptable or not as a question about whether such an activity or behavior is unjust or not. Not all of the ethical issues raised by intergenerational risks may turn out to be justice issues, but intergenerational risks certainly pose at least some justice questions.

## Further Research

---

That the very meaning of “intergenerational risks” requires expanding our existing concepts is illustrative of the complexity of such risks. Once we realize the far-reaching implications of our actions and we recognize that many risky activities will affect who will live in the future, we are forced to recognize that intergenerational risks may be more common and pervasive than we may have at first thought. And once we further realize the temptations of ignoring or avoiding the ethical issues intergenerational risks present, as Gardiner highlights, that intergenerational risks merit much greater attention, study, and consideration becomes clear. There are existing bodies of literature that inform how we should think about and address intergenerational risks, but we need to be much more explicit about this task if we are to do so effectively and appropriately. Considering how much, if any, knowledge an actor must have of the potentially harmful nature of her actions in order to be held responsible for the risky nature of such actions, for example, is an important consideration that merits greater attention than I (and some of the authors I have considered) have given it here. Much more work needs to be done in intergenerational ethics in order for us to be able to understand how we should think about the challenges intergenerational risks pose and how we should address them. What we think we owe future people, after all, most certainly will affect what (intergenerationally) risky activities we deem to be morally acceptable.

Another important issue that I have yet to so much as touch on is that of nonanthropocentric ethics. So far the entire discussion has assumed that intergenerational risks threaten future humans with no reference to the potential noninstrumental value of the nonhuman world. But we can imagine some risks as posing threats of harm to nonhuman animals and/or nature if we expand our interpretation of what constitutes “harm.” There are many theories in environmental ethics that attribute value to various aspects of the nonhuman world (which may or may not conflict with anthropocentric values) and which would worry about activities or events that threaten the future integrity of natural ecosystems, species, and/or ability of particular organisms to thrive and survive. As discussed here, threats to the environment may be bad because of the instrumental value of the nonhuman world, but many environmentalists and environmental ethicists would see deeper wrongs in environmental degradation or damage. It may be that we should understand long-term risks (as opposed to intergenerational risks) as *de dicto* threats of harm to the environment; such an interpretation would very much change how we should address such risks. There is a much larger, highly relevant debate about what has (intrinsic) moral value that is relevant to how we think about long-term risks. One’s moral perspective will inform one’s understanding of how we should think about and address intergenerational (or maybe more appropriately long-term) risks.

The lack of much direct work on the ethics of intergenerational risks should push us to question our most basic assumptions about how we should think about risks and the fact that so many risks are in fact intergenerational risks. I hope that understanding intergenerational risks will expose both the prevalence and moral complexity of such cases. This in turn will hopefully reveal the need for more thorough and deliberate contemplation of how we should think about intergenerational ethics. Future work should aim to better understand the nature of intergenerational risks and how these differ from intragenerational risks. This will hopefully enable us to more thoroughly consider what is at stake when we engage in intergenerational risky activities and to assess what principles and/or approaches should guide our actions that may create or contribute to intergenerational risks, which pose threats of *de dicto* harm on future generations.

## Acknowledgment

---

I began thinking about intergenerational risks during my undergraduate studies at Connecticut College. I am indebted to Derek Turner for his work with me on my undergraduate thesis as well as his continued support, guidance, and comments on an earlier draft of this chapter. I am also indebted to Stephen Gardiner who made this chapter possible and whose insightful comments added depth to my discussion. My graduate dissertation committee, Debra Satz, Joshua Cohen, Tamar Schapiro, and Stephen Schneider, also provided me with guidance and support that greatly influenced my work in this chapter. I am grateful for having had such amazing and inspiring mentors.

**Abstract:** The precautionary principle has come to the fore in risk discourse. It calls for early measures to avoid and mitigate environmental damage and health hazards in the face of uncertainty. This paper reviews the history of and current research on the principle and suggests areas where further scrutiny is needed. The origin of the precautionary principle is traced back to three sources: (1) the general idea of precaution, (2) specific nonjudicial codes of conduct and arguments from precaution, and (3) law texts. Much of the current theoretical study has been concerned with analysis of different aspects of the precautionary principle and with assessment of specific versions of the principle in different regulatory contexts. Issues related to terminology, to basic structure shared by different formulations of the principle, and to the distinction between strong and weak interpretations are considered. Discussion on different versions of the precautionary principle as (1) rules of choice, (2) procedural requirements, and (3) epistemic rules or principles is briefly revisited. General arguments leveled at the principle are spelled out. Despite the attention the precautionary principle has received in academic literature, there remain areas of research which deserve more thorough scrutiny. Formal methods of inquiry have been insufficiently utilized. Topics which deserve further study include the normative underpinnings of the principle, the status of the principle in scientific risk analysis, and the principle's relationship with stakeholder/public engagement.

## Introduction

---

The precautionary principle embodies the idea that *in dubio pro natura*. If in doubt, decide in favor of the environment. Over the past two and half decades, this seemingly simple precept has found its way to the center of environmental law and policy. The precautionary principle is mentioned in domestic laws (e.g., in Australia, France, Germany, Sweden, and UK) and international treaties (e.g., CPB 2000). Numerous declarations and other soft law instruments include the principle in their objectives or articles/general principles (e.g., UNCED 1992). Common examples come from the contexts of marine protection and disposal of hazardous wastes, fisheries management, protection of the ozone layer and chemicals regulation, conservation of the natural environment and biological diversity, climate change and global warming policies, regulation of genetically modified organisms (GMOs), and public health policy.

Arguably, the most noted formulation of the precautionary principle is the one adopted at the *United Nations Conference on Environment and Development* in Rio de Janeiro.

- ▶ Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation (UNCED 1992, Principle 15).

Another well-known formulation was introduced at a conference organized by the Science and Environment Health Network (SEHN) in 1998. According to it,

- ▶ [w]hen an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause and effect relationships are not fully established scientifically (*Wingspread Statement on the Precautionary Principle* 1998).

Besides the Rio formulation and the *Wingspread Statement*, many other formulations of the precautionary principle can be found in laws, treaties, protocols, declarations, communications, and other legal and policy documents (for legal analyses of the principle see Fitzmaurice 2009;

Hohmann 1994; de Sadeleer 2002; Trouwborst 2002). Several definitions or analyses have been put forth by academic scholars in the relevant theoretical literature (see Adams 2002; Gardiner 2006; Manson 2002; Morris 2000; Sandin 1999, 2004b; von Schomberg 2006; Soule 2002; Sunstein 2005).

Not only does the precautionary principle take many forms, but it remains a matter of ongoing controversy. Academic scholars from various disciplines (e.g., risk analysts, legal theorists, economists, political scientists, and ethicists), decision-makers, industry representatives, environmental organizations, and the lay people continuously argue about the principle. The debate is centered mainly on two interrelated issues. First, despite academic efforts to clarify the principle and established policy documents, consensus has not been reached concerning the exact definition of the principle. Second, the way in which the precautionary principle should be put into practice has remained controversial. No commonly accepted guidelines for the implementation of the principle exist. This holds even in the European Union (EU), where the precautionary principle has gained the most attention and popularity. In spite of the *Communication on the Precautionary Principle* (CEC 2000), which was introduced by the Commission of the European Communities in order to standardize the use of the principle, the adopted national precautionary policies within the EU have varied in a wide range (see e.g., Levidow et al. 2005).

Furthermore, the precautionary principle has been criticized by some scholars such as political scientist Aaron Wildavsky (1996), legal scholar Cass R. Sunstein (2005), economist Julian Morris (2000), physicist Chauncey Starr (2003), and bioethicists John Harris and Søren Holm (e.g., Holm and Harris 1999; Harris and Holm 2002). Most commonly, the principle is claimed to be too vague, incoherent, unscientific, and/or counterproductive. Theoretical differences are deep-seated. Some authors do not even seem to consider the precautionary principle an action-guiding precept, but purely an epistemic (i.e., belief-guiding) or a procedural principle. Although the precautionary principle is predominantly a legal principle, it has been regarded as a decision rule (Hansson 1997), epistemic principle (Peterson 2007), a risk management tool (CEC 2000, pp. 3, 13), an ethical principle (Carr 2002), a methodological rule for risk research (Tickner 2003), and an organizing concept for various contemporary ideas that challenge the regulatory *status quo* (Jordan and O'Riordan 1999; for discussion see Gardiner 2006; Harris and Holm 2002; Sandin 2007).

In what follows, we will review the history of and current research on the precautionary principle and suggests areas where further scrutiny is needed.

## History

Various views have been proposed concerning the origin of the precautionary principle. There is also a disagreement over the first appearance of the principle in official documents (see e.g., Adams 2002). Different accounts that trace back the origin of the precautionary principle may be subsumed under three classes. These include (1) the general idea of precaution, (2) specific nonjudicial codes of conduct and arguments from precaution, and (3) official documents.

### General Idea of Precaution

It has been argued that the origin of the precautionary principle can be found in the general and everyday idea of precaution. Philippe H. Martin from the European Commission Joint Research Centre claims that

- ▶ [t]he precautionary principle is an age-old concept. Unambiguous reference to precaution as a management guideline is found in the millennial oral tradition of Indigenous People of Eurasia, Africa, the Americas, Oceania, and Australia (Martin 1997, p. 276).

This view reflects a very wide understanding of the precautionary principle not restricted to environmental and health concerns. Precaution has played a role in oral traditions around the globe. It guides us not to inflict harm with our actions. The core of the principle is seen as a rule of thumb.

Taking precautions is no doubt in accordance with common sense. “The idea that care and foresight are required in the face of (...) uncertain future is universal and of all times” (Trouwborst 2002, p. 7). As a number of scholars have noted, the essence of precaution is captured by several English sayings such as “better safe than sorry,” “look before you leap,” “a stitch in time saves nine,” and “an ounce of prevention is worth a pound of cure” (e.g., Randall 2011; Resnik 2003; Sandin 2004b; Trouwborst 2002; VanderZwaag 2002). Despite the apparent similarities, it should however be noted that these sayings and aphorisms are general in nature. They do not provide specific guidance for concrete situations. The sayings emphasize the avoidance of harm and preparing for the uncertain future, but they seem to do it in a wider sense than does the precautionary principle. Unlike the general idea of precaution, the principle is triggered only by inadequate and/or disputed scientific knowledge concerning certain types of environmental threats and health hazards.

Even if we sidestep the obvious differences in content between precaution and the precautionary principle, we might still end up with a more theoretical problem. Even if someone takes precautions in a particular situation, this does not necessarily mean that the agent in question subscribes to a precautionary principle. In order to infer that there is a precautionary principle present, we should at least demand that the agent holds that precaution should be taken in the particular situation and in situations that are relevantly similar, with criteria for relevant similarity further specified in some way (Sandin 2004a, p. 4). This minimum condition is not fulfilled in the case of sayings or the other writings mentioned above because the similar cases in which precaution should be applied are not specified.

Instead of regarding precaution to be equivalent to the precautionary principle, it can still be considered an origin or a predecessor. The general idea of precaution might also be used to explain the remarkable attention that the precautionary principle has received. According to legal scholar David VanderZwaag (2002, p. 166), “[a] prime reason for the international popularity of precaution is its reflection of common sense notions evident in numerous cultures.” The principle provides a practical implementation to several wisdoms or sayings. VanderZwaag is right in that part of the evident “magnetism” of the precautionary principle springs from the intuitiveness of the general idea of precaution. Yet, other factors may have played a greater role.

First, owing to a number of factors (such as the growth in the world’s population; the increasing change, complexity, and interdependencies of societies; and the new possibilities provided by rapid technological development), the stakes have become higher than before. Human action can lead – and has already contributed – to serious and irreversible environmental damage. We may be facing a changed situation with regard to the inducement and management of environmental threats and health hazards. Second, a growing recognition of ecosystems’ sensitivity as well as of their intra- and interdependencies is not without significance. Our limited understanding of several natural processes and related risks has increasingly

been admitted and emphasized. Third, the prevailing institutionalized risk governance methodology (especially quantitative risk assessment) has been subjected to criticism. In particular, the strict divisions between science and value and between risk assessment and risk management have been called into question.

In sum, various forms of precaution have been taken as long as human beings have existed. It would however be problematic to argue that the precautionary principle has actually been invoked in the above-mentioned cases. The general idea of precaution has most probably played a role in the formation of the precautionary principle, and it can be employed to partly explain the wide endorsement of the principle. (For an analysis of the concept “taking precautions” see Sandin 2004b).

### Specific Codes of Conduct and Arguments from Precaution

---

The origin of the precautionary principle has sometimes been traced to specific nonjudicial codes of conduct and arguments from precaution. According to the former view, the basic idea of the principle has been present in ethical codes and policies, e.g., in public health policy. Some scholars have even argued that the first reference to it can be found in the Hippocratic Oath *primum non nocere* (first, do no harm) (Ozonoff 1999, p. 100; Graham and Hsia 2002, p. 374). We agree that certain ethical codes and policies might be correctly attributed as being precautionary in nature. Nevertheless, these codes and policies typically seem to resemble more closely the general idea of precaution than the precautionary principle itself (as the latter is usually understood).

The second strategy is to trace the history of the precautionary principle to certain arguments from precaution which have been presented in various contexts, e.g., in energy policy criticism. This is the case when Morris asserts that

- ▶ PP-like arguments have been used in the USA since the 1950s; at that time, groups of political conservatives opposed fluoridation of water on the grounds that fluoride was used as rat poison and that involuntary fluoridation amounted to mass medication, a step on the road to socialism. In the 1960s, left-wing radicals similarly used PP-like arguments against nuclear power. (...) By highlighting th[e] possibility of catastrophe, regardless of the probability of its occurrence, campaigners were able to instill fear of the technology as such (Morris 2000, p. 2; see also Goodin 1980, pp. 418–419; Pearce et al. 1980, p. 58).

This strategy is also put forward by philosophers Derek Turner and Lauren Hartzell. They contend that German philosopher Hans Jonas gave an early version of the precautionary principle in his book *The Imperative of Responsibility* (Turner and Hartzell 2004, p. 452). In Jonas' words, “[i]t is the rule, stated primitively, that the prophecy of doom is to be given greater heed than the prophecy of bliss” (Jonas 1984, p. 31). Although Jonas' vision is general in nature, it has clear similarity to the very basic idea of the precautionary principle. First, the principle implies that when considering the introduction of an activity, certain environmental and health risks outweigh the possible (economic) benefits of that activity. Second, Jonas is concerned about the possible irrevocable consequences of technological developments, and this also reflects the common understanding of the principle.

In addition to the cited examples, there have been several other claims about the origin of the precautionary principle which can be subsumed under this class (see, e.g., EEA 2001;

Martin 1997, p. 264). Given the apparent similarities and lines of development of ideas, these arguments from precaution deserve to be notified when the history of the precautionary principle is under study.

## Judicial Documents

---

The most common strategy to search for the origin of the precautionary principle is to look for instances of it in law texts and policy documents. This may take two forms. The first option is to identify early explicit use of the term “precautionary principle” or other equivalent terms. The problem with this strategy arises from the facts that the first references to the principle were often brief and that the principle was not defined. Moreover, several phrases have been employed, such as the terms “precautionary measures” and “precautionary approach.”

A commonly agreed predecessor of the precautionary principle is the *Vorsorgeprinzip* which was introduced to German environmental law and policy in the 1970s (for discussion see Boehmer-Christiansen 1994). The *Vorsorgeprinzip* emphasizes identification of early warnings of environmental threats and preparing beforehand for the uncertain future and for its risks. It was first incorporated into air and water protection act in West Germany, but it soon became a fundamental principle of German environmental law.

The first explicit mention of the precautionary principle (or more precisely, a precautionary approach) in an international environmental declaration was in 1987. The Ministerial Declaration of the *Second International Conference on the Protection of the North Sea* states that

- ▶ [a]ccepting that in order to protect the North Sea from possibly damaging effects of the most dangerous substances, a *precautionary approach* is necessary which may require action to control inputs of such substances even before a causal link has been established by absolutely clear scientific evidence (Paragraph 7; Italics added).

The second option to search for the origin of the precautionary principle is to identify cases in which the principle is thought to be present even if it has not been explicitly mentioned. Accordingly, the first instance in an official text may be found in the *World Charter for Nature*, adopted by the United Nations General Assembly, as early as in 1982.

- ▶ Activities that are likely to pose a significant risk to nature shall be preceded by an exhaustive examination; their proponents shall demonstrate that expected benefits outweigh potential damage to nature, and where potential adverse effects are not fully understood, the activities should not proceed (Principle 11b; Italics added).

Principle 11b includes the basic constituents of the precautionary principle: a reference to an unacceptable threat of environmental damage and/or health hazard, to scientific uncertainty, and to precautionary measures in the form of inactions.

Other cases have also been suggested. Legal scholar Daniel Bodansky (1991) argues for the early use of the precautionary principle in law and policy. In his view, although the principle is not explicitly mentioned in the environmental law of the USA, the precautionary principle has been the basis of much of it for several years. The “no-discharge” requirement of the 1972 *Federal Water Pollution Control Act Amendments* is provided as an example of this. The act

presumed that discharges of pollutants are harmful to the water quality in the first place even without any scientific predictions, and it included the so-called ALARA (as low as reasonably achievable) approach as the required response. Early examples of the precautionary principle can also be found at international level. In the 1970s, a moratorium on commercial whaling “was justified on the basis of uncertainty about the impacts of continued whaling (...) rather than on the basis of scientific evidence” (Bodansky 1991, p. 5). According to Mikael Karlsson, president of European Environmental Bureau (EEB), the precautionary principle was included in the *Swedish Environmental Protection Act* of 1969 (Karlsson 2006; for other examples of this strategy, see also EEA 2001; Myers 2006, pp. 4–6; Whiteside 2006, pp. 66–70).

The further development of the precautionary principle in environmental law and policy is not reviewed here. Several such analyses are available (Fitzmaurice 2009; Freestone and Hey 1996; O’Riordan et al. 2002; de Sadeleer 2006; de Sadeleer 2002; Trouwborst 2002; for a comparison of precaution in the USA and Europe see Whiteside 2006, Chap. 3; Wiener and Rogers 2002).

## Current Research

---

Much of the current theoretical research on the precautionary principle has been concerned with clarification of its different aspects, with analysis of its relevance in different regulatory contexts, and with arguments for and against its different interpretations. Next, discussion on terminological issues, basic structure, weak/strong distinction, three types of the precautionary principle, and main arguments against the principle will be briefly revisited.

## Terminology

---

Terminological issues present a source of confusion and disagreement. Most authors speak about one definite principle (e.g., Rogers 2001), but others use the indefinite plural form (e.g., Löfstedt et al. 2002). Furthermore, several terms have been employed. In official documents, phrases such as “precautionary measures,” “precautionary principle,” “principle of precautionary action,” and “precautionary approach” can be found. An even more diverse set of phrases has been used in the commentary literature pertaining to the principle. Besides the aforementioned terms, the examples include “precaution” (Levidow et al. 2005), “precautionary thinking” (Trouwborst 2002), “precautionary assessment” (Tickner 2003), “precautionary science” (Cranor 2003), and “precautionary principle/approach” (see e.g., VanderZwaag 2002; cf. Peterson 2007).

The following points make it understandable that some legal scholars (e.g., Hohmann 1994) use the plural form, i.e., *precautionary principles*, when they refer to the precautionary principle. As noted, there are several formulations of the principle in official documents. The formulations differ from each other. Although differences are to be expected between different regulatory contexts given the different situations in regard to risk imposition, knowledge about risks and manageability of risks, formulations differ considerably also within a regulatory context. Consider an example of this found in marine environmental protection. The Ministerial Declaration of the *Second International Conference on the Protection of the North Sea states*

that precautions can be taken in the absence of absolutely clear scientific evidence. In the corresponding statement of the third conference, no evidence to prove the causal connection is required.

- ▶ [A] precautionary approach is necessary which may require action to control inputs of such substances even before a causal link has been established by absolutely clear scientific evidence (*Second International Conference on the Protection of the North Sea 1987*, Paragraph 7).
- ▶ [P]recautionary principle, that is to take action to avoid potentially damaging impacts of substances that are persistent, toxic and liable to bioaccumulate even when there is no scientific evidence to prove a causal link between emissions and effects (*Third International Conference on the Protection of the North Sea 1990*, Preamble).

Bodansky (1991, p. 5) has phrased an obvious worry lying in the background: because different formulations of the precautionary principle state the trigger for taking precautions and the appropriate precautionary measures in radically differing ways, “it is difficult to speak of a single principle at all.” Nevertheless, instead of speaking about several principles, (at least, apart from judicial studies) it seems to be more fruitful to say that there is only one principle which is formulated (or understood) in various ways. The use of singular and plural may just indicate the fact that the precautionary principle is thought of at different levels of generality.

In the academic literature, different terms have been employed to point out slight differences between theoretical positions. As an example of this, environmental health scholar Joel Tickner (2003) has introduced precautionary assessment in which the principle has implications for the risk assessment phase. This goes against the typical view of the precautionary principle as merely a risk management tool. That one concept has sometimes been used in several meanings is also worth noticing. The term “precaution” has been employed to refer to the precautionary principle (e.g., Levidow et al. 2005), to the prescribed precautionary measures, and to the general idea of precaution (Sandin 2004b).

The most debated terminological issue is the possible disparity between the terms “precautionary principle” and “precautionary approach.” It is not straightforwardly clear as to whether there is a difference in meaning between the precautionary principle and the precautionary approach (see e.g., Conko 2003, pp. 642–643; Trouwborst 2002, pp. 3–5; VanderZwaag 2002, pp. 166–167). It has been thought that the precautionary approach represents a less stringent version of the precautionary principle and that it thus avoids theoretically implausible forms of absolutism such as total reversal of the burden of proof (see e.g., Conko 2003, p. 642). One context in which the terms are commonly distinguished from each other is fisheries management (see e.g., Mace and Sissenwine 2002, pp. 14–15; Ortega Vicuña 1999). Several authors nevertheless hold the opposite view that the terms “precautionary principle” and “precautionary approach” can be used interchangeably (e.g., Mascher 1997, p. 70; Trouwborst 2002, p. 4). It is noteworthy that some official documents treat the terms as equivalents (e.g., *Wingspread Statement 1998*). The formulation of Principle 15 of the Rio Declaration (UNCED 1992) which is typically considered a paradigm example of the precautionary principle actually includes the term “precautionary approach” in the English versions of the text, while translations into several other languages (e.g., Swedish) use terms corresponding to “precautionary principle.”

We employ the term “precautionary principle” as a uniting term for the various phrases found in official documents and in the relevant academic commentary literature.

The disparities that the use of different terms sometimes implies are taken into consideration by means of speaking about different understandings (or interpretations/formulations) of the principle.

## Basic Structure

---

Many scholars have argued that (several) different formulations of the precautionary principle share common elements and a common structure. It has been spelled out in slightly different ways and terms by different authors adopting what might be called an analytical approach to the precautionary principle (e.g., Sandin 1999; Manson 2002). These structural schemata can be used to explicate, compare, and evaluate different formulations of the precautionary principle. An early attempt is Sandin who considers the dimensions of the principle and provides the following characterization:

- If there is (1) a threat, which is (2) uncertain, then (3) some kind of action (4) is mandatory (Sandin 1999, p. 891).

Accordingly, there are four basic dimensions of the principle:

1. The *threat dimension* that refers to one or other undesired possible state of the world
2. The *uncertainty dimension* that expresses our (lack of) knowledge of these possible states of the world
3. The *action dimension* that concerns what response to the threat is prescribed
4. The *command dimension* that states what the status of the action is (Sandin 1999, pp. 890–895).

The content of these dimensions vary considerably between different versions of the precautionary principle. But arguably, many disputes concerning the exact meaning of the principle could be reduced to disagreements on the proper range of the variables (1)–(4) in this structural schema.

A slight modification of the above is to think different formulations of the precautionary principle as a function of a trigger condition and precautionary response. When a situation fulfills the prerequisites described by the trigger condition, the stated precautionary response should be taken (or taking the precautionary response is justified). The trigger is twofold. It consists of *damage* and *knowledge thresholds* which determine the necessary and jointly sufficient preconditions for the application of precaution. A damage threshold specifies the relevant harmful or otherwise undesirable outcomes. They typically include serious and/or irreversible environmental damage and health hazards. A knowledge threshold defines the required level of scientific understanding of an identified threat. According to a common view based on a decision-theoretic classification, the principle can be applied when the (objective) probability of a threat cannot be established or when its magnitude or severity is uncertain or contested. If the probability of a threat is known and/or relatively high, it is common to talk about taking preventions rather than precautions. (The distinction between the prevention principle and the precautionary principle is more complicated in legal practice.) A broader view, which rests on the level of scientific understanding, states that taking precautionary measures is well-founded when a threat is poorly understood in scientific terms, or when there are scientific discrepancies and/or disagreements on the risk in question.

Precautionary response means taking preemptive measures. These may take the form of outright bans or phaseouts, moratoria, premarket testing, labeling, and requests for extra scientific information before proceeding. Another kind of precautionary response might be establishing new precautionary risk assessment methodologies. The focus is then not only on how to deal with the identified threats, but also on the methods to anticipate and assess threats in the first place. (When these methodologies are in use, they may be considered to belong to the trigger side as they change the trigger condition for taking precautions. As an example of precautionary risk assessment methodologies see Tickner 2003. For an analysis of the narrow and broad precautionary policies implemented within the EU see Levidow et al. 2005. For discussion on different kinds of precautionary measures see, e.g., Whiteside 2006, pp. 52–55).

## The Weak/Strong Distinction

---

It has become common to distinguish between weak and strong interpretations of the precautionary principle. Scholars have employed the distinction in order to evaluate different understandings/formulations of the precautionary principle (e.g., Harris and Holm 2002; Hughes 2006; Morris 2000; Soule 2002; Sunstein 2005, Chap. 1). It is frequently referred to in academic literature, environmental policy reports, and the public discussion on the principle.

Morris defines the strong form as follows: “take no action unless you are certain that it will do no harm.” According to its weak counterpart, lack of certainty is not a justification for preventing an action that might be harmful (Morris 2000, p. 1). Business ethicist Edward Soule argues that the weak form provides regulators with the authority to override other factors and make environmental risk the deciding concern. This is however optional because it does not obligate regulators to treat environmental risk in this way. The strong interpretation, in its turn, restricts regulators to consider environmental risk in isolation from possible benefits. Taking precautions is not optional but mandatory (Soule 2002, pp. 18–19, 22, 24).

While the Rio formulation (UNCED 1992) is typically thought to represent a paradigm example of the weak form of the precautionary principle, the *Wingspread Statement* (1998) is the most frequently provided example of the strong form. Other examples which are commonly subsumed under the weak form include formulations of the precautionary principle found in the *Ministerial Declaration on Sustainable Development in the ECE Region* (1990), the *Communication on the Precautionary Principle* (CEC 2000, p. 4), the *Cartagena Protocol on Biosafety to the Convention on Biological Diversity* (CPB 2000, Article 10), and the *Second North Sea Declaration* (1987, Preamble, Paragraph VII). In contrast, the *Third North Sea Declaration* (1990, Preamble) and the *World Charter for Nature* (1982, Principle 11b) are frequently considered to represent the strong form.

Some authors find both interpretations to be well-grounded. According to Soule (2002, pp. 18, 30), “in domestic contexts the weak formulations are unobjectionable (...) [t]he strong PP [precautionary principle] might seem to require some repairs and not rejection.” Others claim that neither the weak nor the strong form is credible (e.g., Harris and Holm 2002; Morris 2000). Yet, most often, the weak form is argued to be a valid tool of environmental and health risk governance, and it is contrasted with the strong one, which is considered unacceptably extreme, incoherent, or otherwise implausible (e.g., Hughes 2006; Sunstein 2005).

Interestingly, the weak/strong distinction has been employed (or “defined”) in several ways. It is made on the basis of different, sometimes several, criteria instead of one and the same or generally agreed ones. First, the weak/strong distinction is often associated with placement of the burden of proof (e.g., Wiener and Rogers 2002; see also Hohmann 1994). Accordingly, the strong interpretation (S1) says that the proponent of an activity should demonstrate that the activity in question does not lead to an environmental disaster. On the other hand, the weak interpretation (W1) reduces the evidence threshold of a government to interfere in actions of the scientific community, industry, etc. The precautionary principle is a policy instrument which is used to justify restrictions when policymakers have no scientific proof that the action(s) in question would cause harm (Manson 1999).

At other times, the decisive criterion which distinguishes the strong interpretation from the weak one is taken to be the normative status of the prescribed precautionary measures (e.g., Conko 2003; Cameron and Wade-Gery 1995). According to the strong interpretation (S2), there is an obligation to take precautionary measures, whereas the weak counterpart (W2) states merely that precautionary measures are justified (Godard 1997, p. 25). Sometimes the strong form and weak form are also distinguished by referring to the status of cost-benefit analysis (e.g., Myhr and Traavik 2003; see also Soule 2002). The strong interpretation (S3) then implies that non-environmental consequences of taking precautions – e.g., possible economic losses – should not be taken into consideration or that they are always overridden by environmental and health considerations. The prohibition is categorical (Nollkaemper 1996). In contrast, the weak interpretation (W3) requires that the chosen precautionary measures are cost-effective. The known and predicted costs and benefits of different measures and the option of having no measures should be considered (see, e.g., CEC 2000; *Wingspread Statement* 1998). Instead of straightforward bans and moratoria, taking precautionary measures can also mean increased monitoring of an activity, etc.

It has also been thought that the criterion which distinguishes the strong form from the weak one is the status of scientific evidence. The weak interpretation (W4) says that any implementation of precautionary measures presupposes scientific evidence for a hazard which has been identified and assessed in the preceding risk assessment (see Foster et al. 2000; Morris 2000). The strong counterpart (S4) states that scientific proof is not a necessary condition for the application of precautionary measures. Lastly, worth noticing is that some scholars do not employ the strong form and weak form as sharply distinguished groups but as a continuum (e.g., Hughes 2006; Sunstein 2005; Tinker 1996).

## Types of Precautionary Principles

---

Another way of classifying different versions of the precautionary principle is according to what type of rule they express (Sandin 2007). According to this approach, versions of the precautionary principle can express (1) rules of choice, (2) procedural requirements, and (3) epistemic rules or principles.

In some cases, the precautionary principle is formulated as a *rule of choice*. The outcome of such a rule is an action or set of actions that should be chosen, or not chosen (cf. Peterson 2003). The *Wingspread Statement* (1998) version of the precautionary principle is an example of this. It states that some courses of action are not permissible. Those commentators who identify the precautionary principle with the maximin decision rule (Hansson 1997) also see

the principle as a rule of choice. Maximin is a proposed decision rule for decisions under ignorance stating that you should choose the action where the worst outcome is least bad, i.e., maximize the minimum.

In other cases, the precautionary principle is a *procedural requirement*. They do not prescribe what action should be chosen but state conditions for how such a choice should be made. The most widely cited version of the precautionary principle of this kind is the Rio formulation stating that under conditions of scientific uncertainty, “lack of full scientific certainty *shall not be used as a reason* for postponing cost-effective measures to prevent environmental degradation” (UNCED 1992, emphasis added). In this category, we also find burden-of-proof requirements, stating that proponents of a potentially risky activity should bear the burden of proof: This means that those proponents should be required to show that the activity is safe, rather than that the authorities should be required to show that the activity is proven to be hazardous before prohibiting it. Incidentally, such a requirement is also found in the *Wingspread Statement* (1998) which sets out criteria for application of the principle in the paragraphs following the definition.

In the last type of cases, the precautionary principle is an *epistemic rule or principle*. These versions are not about how we should act or how decisions should be made, but about what we should believe. In risk management terminology, this would in practice mean moving precaution from the risk management to risk assessment. Several commentators have been critical of the precautionary principle as an epistemic rule (Harris and Holm 2002; Peterson 2007; Sandin 2007). The main objection is that such a principle would lead us to incorporate a number of false beliefs in our belief system, which would undermine our epistemic basis for decision-making, leading us to bad decisions.

## Arguments Against the Precautionary Principle

---

Several criticisms have been leveled at the precautionary principle. The *argument from vagueness* is one of the most common. It says that the precautionary principle is ill-defined and thus too vacuous to offer any useful guidance for decision-making. Consequently, the principle should be abandoned. Bodansky (1991, p. 5), for example, has argued that the precautionary principle cannot serve as a regulatory standard because it does not specify how much (pre)caution should be taken. Yet he concludes that the principle may play a role in environmental policy as a general goal and stresses the use of discretion in its implementation (Bodansky 1991, p. 43). A more pessimistic conclusion is drawn by Turner and Hartzell (2004, pp. 449, 451, 459) when they claim that “the precautionary principle, in all of its forms, is fraught with vagueness and ambiguity,” that “there is no way of gaining precision and conceptual clarity without sacrificing plausibility,” and that the precautionary principle can serve us neither as a moral principle nor as a decision-making principle (see also Sunstein 2005, pp. 54–55).

The *argument from incoherence* has the following basic logic: incoherent principles should not be used as a basis for societal risk decision-making; the precautionary principle is incoherent; thus, it should be abandoned. Philosopher Gary Comstock (2000) has argued that “[t]he precautionary principle commits us to each of the following propositions: (1) We must not develop GM crops. (2) We must develop GM crops.” In their paper “Extending Human Lifespan and the Precautionary Paradox,” Harris and Holm (2002, see also 1999) similarly claim that the precautionary principle is incoherent and consequently does not provide

the kind of justification (for a precautionary “pause” from proceeding with new technologies) that it is often presumed to offer. Their main argument is that the principle cannot coherently be employed as a decision rule, an epistemic rule, or a moral principle (cf. Sandin 2006). The argument from incoherence is also found in Sunstein (2005) and Peterson (2006).

It has also been argued that the implementation of the precautionary principle would lead to serious and commonly unwanted consequences, and thus that the principle should be abandoned as a policymaking tool. The *argument from adverse effects* says that, instead of decreasing it, the precautionary principle increases our risk imposition in total. This argument takes several forms. The use of the principle may result in different kinds of adverse effects – directly or indirectly. Precautionary measures taken may in themselves impose a new environmental threat or a health hazard. In his book entitled *The Precautionary Principle: A Critical Appraisal of Environment Risk Assessment*, engineer and policy analyst Indur Goklany (2001, see also 2000) provides us with a detailed analysis as to why the application of the precautionary principle to various contentious environmental issues may result in undesirable effects and increased risk taking. A similar kind of an argument is put forward by policy analysts Henry I. Miller and Gregory Conko who argue that “[i]f the precautionary principle had been applied decades ago to innovations like polio vaccines, and antibiotics, regulators might have prevented occasionally serious, and sometimes fatal, side effects by delaying or denying approval of those products, but that precaution would have come at the expense of millions of lives lost to infectious diseases” (Miller and Conko 2000, p. 100).

Lastly, to argue that the precautionary principle is a value judgment or an “ideology,” that it is unscientific, or that it blurs the boundary between science and policy in an unacceptable way is not uncommon (e.g., Morris 2000; Wildavsky 1996; Gray and Bewers 1996) (For analyses of general arguments against the precautionary principle, see Sandin et al. 2002; Ahteesuu 2007).

## Further Research

---

The precautionary principle has recently received much attention in academic discourse, and this body of literature has virtually exploded over the last decade. Yet there remain areas of research which deserve more thorough scrutiny. First, there are methods of inquiry which have hitherto been insufficiently utilized. In particular, this applies to formal methods. Second, certain topics deserve further study. These include the normative underpinnings of the principle, the status of the principle in scientific risk analysis, and the principle’s relationship with stakeholder/public engagement.

## Formal Methods

---

Comparatively, few works approach the precautionary principle using formal methods (see, e.g., Ready and Bishop 1991; Perrings 1991; Peterson 2006). Some of economics and decision theory’s developments come close to its basic idea. Economist Frank Knight (1921, p. 11, Part III Chaps. VII & VIII) distinguished between quantifiable risks (i.e., uncertainties which can be represented as statistical odds or probabilities) and “true” uncertainties which cannot be quantified (i.e., assessed in this way). The precautionary principle is typically considered to be applicable to situations in which the probability of a risk cannot be assigned. Irrevocability

as a qualification of the damage threshold of the precautionary principle has earlier counterparts. Irreversible consequences in terms of restricting tomorrow's set of opportunities (or decision possibilities) with today's choices have been a subject of close scrutiny and debate in decision-theoretic literature since the early seventies. Similarities can also be found between the precautionary principle and the maximin decision rule, and some early commentaries treat them as amounting to the same thing (Hansson 1997). Others have interpreted the precautionary principle as minimax regret (Chisholm and Clarke 1993). This is certainly an area in which considerable work remains to be done.

## Normative Underpinnings

---

As a principle of practical decision-making, the precautionary principle may be justified on the basis of ethical and sociopolitical grounds and/or as a form of rational action. The application of the principle is fundamentally a normative (and political) choice. The degree to which we are prepared to take precautions is related to the values which we attach to the nature and human well-being. Notwithstanding, normative underpinnings of the precautionary principle have received only little attention. Although the importance of ethical discussion has been underlined in several occasions, there are only a few published papers on the issue. Susan Carr (2002) at the Open University in the UK has criticized the EU's negligence of the value-based aspects of the principle. The Commission of the European Communities has emphasized the scientific aspects of precautionary decision-making and ignored almost totally the justification of its basic values. Environmental scientist and ethicist Marc A. Saner (2002) relates the precautionary principle to the main approaches in the Western ethical traditions, in particular to those of virtue ethics, deontology, and utilitarianism (On normative underpinnings, see also Jensen 2002; Munthe 2011; Parker 1998; von Schomberg 2006). In policymaking, the precautionary principle has been invoked to justify a wide range of policies – sometimes even mutually contradictory ones (see Levidow et al. 2005). This has often been done without an explicitly stated normative framework.

## Risk Analysis

---

The precautionary principle has typically been thought to present a risk management principle or tool (e.g., CEC 2000, pp. 3, 13). This is reflected, for example, by the following statements: "Precautionary principles have been proposed as a fundamental element of sound risk management" (Löfstedt et al. 2002, p. 381), and the principle "is invoked in the process of risk management" (Rogers 2001, p. 1). In practice, this means that the precautionary principle can be applied when a risk has been identified in the preceding risk assessment, but a considerable amount of uncertainty remains (i.e., the probability of the risk cannot be quantified and/or the magnitude of the risk is unknown). Yet other standpoints have also been suggested. Some authors argue that the precautionary principle should already be taken into consideration at the level of risk assessment. According to this position, the principle works not only as a risk management principle/tool, but it also affects the way in which risk assessment is conducted (Goldstein and Carruth 2004, pp. 491–493; see also Levidow et al. 2005, pp. 268–269). New notions such as "precautionary appraisal" (Klinke et al. 2009) and "precautionary assessment" (Tickner 2003) have been introduced. The relevance of the precautionary principle to risk assessment deserves more study.

## Participatory Decision-Making Practices

Participatory decision-making is frequently connected with the precautionary principle. In their report *Late Lessons from Early Warnings*, European Environment Agency (EEA 2001, p. 17) argues that implementing the principle calls for interest groups participation which “should be at an early stage, broadly drawn, and carried down to the appropriate local level” (See also Fisher and Harding 1999, p. 290; Funtowicz and Ravetz 1993). Yet, what is the exact nature of this link between precaution and stakeholder/public engagement remains unclear. The question in itself has been somewhat neglected in the related theoretical literature. Biologist John Lemons, philosopher Kristin Shrader-Frechette, and philosopher Carl Cranor suggest that a “fundamental dilemma surrounding (...) the use of a precautionary approach is how to balance the need for expert scientific knowledge with the need to involve the public in the decision-making process” (Lemons et al. 1997, pp. 233–234). According to environmental law scholar Elizabeth Fisher (2001, p. 320), “while there is little agreement over what the nature of that participation should be it is clearly an important part of a precautionary decision-making process.” Even though several comments and some proposals for inclusive precautionary risk governance frameworks have been put forward, relatively few analyses of the relationship between precaution and engagement is available (see, e.g., Fisher and Harding 1999; Raffensberger and Barrett 2001; see also Ravetz 2004; for an analysis of precaution and democratic deliberation see Whiteside 2006, Chap. 5).

**Abstract:** The standard meaning of risk adopted by risk analysts from a broad range of fields is that risk is the probability that a certain set of consequences will occur given a hazardous scenario. Risk analysis is the process of determining the probability of occurrence and consequences as well as evaluating the determined risks. Capability refers to the genuine opportunity that an individual has to do and become things of value, such as being educated and maintaining bodily integrity. Such doings and beings are called functionings. A capability approach provides a distinct evaluative space for conceptualizing and judging states of affairs on the basis of how the capabilities of individuals are affected. This chapter examines the reciprocal contributions of a capability approach and risk theory. A capability approach has been used to enrich risk theory in three ways. First, it has been argued that the consequences component of risk should be conceptualized and assessed in terms of the impact of a hazardous scenario on capabilities, instead of either resources or utility. Second, instead of evaluating risks on the basis of either public or expert judgment, risks should be judged acceptable or tolerable on the basis of whether certain threshold levels of capabilities are maintained. Third, a capability approach provides a distinct alternative to a prominent way of managing risks, cost-benefit analysis. Instead of comparing alternative policies on the basis of their relative advantages and disadvantages, policies should be evaluated on the basis of whether they address unacceptable or intolerable risks and on the basis of their likely affectability. Likely affectability considers the dollar per unit change in the expected impact of a hazardous scenario on capabilities. Risk theory has enriched the capability approach in two ways. First, considering risk has highlighted an important dimension of capability, security, not previously recognized. Second, attempts to operationalize a capability approach to risk have led to the development of a novel way to assess capabilities, and not simply actual functioning achievements.

## Introduction

---

In this chapter we discuss a capability approach in risk analysis and discuss how risk analysis has enriched theorizing about capabilities. The standard meaning of risk adopted by risk analysts from a broad range of fields is that risk is the probability that a certain set of consequences will occur given a hazardous scenario (Kaplan and Garrick 1981; Hansson 2007b). This definition is more specific than the broader definition of risk found in the philosophical literature according to which risk is “a possible scenario in which adverse events take place” (Hansson 2007b). Risk analysis is the process of determining the probability of occurrence and consequences as well as evaluating the specified risks. There are three different components of risk analysis: risk determination, risk evaluation, and risk management. Capability refers to the genuine opportunity that an individual has to do and become things of value, such as being educated and maintaining bodily integrity. The capability approach provides a distinct evaluative space for conceptualizing and judging states of affairs on the basis of how the capabilities of individuals are affected.

There are four sections in this chapter. The first defines capability and a capability approach and discusses how capabilities are assessed. The second provides an overview of how the capability approach has been applied to risk analysis as well as how ideas from risk analysis have been used to deepen our understanding of capabilities. The third outlines two main areas for further research in a capability approach to risk.

## History

### Defining Capability

There are many valuable states and activities, such as being adequately nourished, being educated, and participating in the political life of a community, which a given individual may or may not be in a position to achieve. In the capability approach pioneered by Amartya Sen (1989, 1992, 1993, 1999a, b) and Martha Nussbaum (2000a, b, 2001) such states and activities are called functionings. An individual enjoys a particular capability if he or she has a genuine opportunity to achieve a specific valuable functioning. In practice, capabilities are interdependent. An individual might have a genuine opportunity to have a rewarding career and a large family, but not have an opportunity to achieve both at the same time. An individual's general capability captures this interconnectedness. An individual's general capability is a function of the various combinations or vectors of functionings that he or she has a genuine opportunity to achieve (Sen 1992).

Two general factors influence the capability of an individual: what he or she has and what he or she can do with what he or she has (Wolff and de-Shalit 2007). The resources of an individual provide information about what he or she has. Internal resources refer to the assets an individual possesses, including skills, talents, and psychological well-being. External resources encompass the other means available to him or her, including income, wealth, and the support of family. For example, whether an individual has a genuine opportunity to be educated depends on her mental resources and talents. However, it may also depend on income, insofar as there is tuition or costs for lodging, meals, and books associated with schooling; moreover, schooling often reduces an individual's ability to earn income in the short term. Family support for education is also critical; families must be willing, for example, to allow a child to attend school instead of working inside or outside of the home. The resources of an individual are not the only factor that influences what genuine opportunities are available to him or her. There are variations in what individuals can achieve with a given set of resources (Sen 1993, 1999b). Equally salient for determining the genuine opportunities of an individual is the social and material structure within which he or she acts. Customs and traditions, laws, the physical infrastructure of a community, and language are all examples of some of the dimensions of this social and material structure. It is this structure that influences what an individual can do or become with the resources at his or her disposal. An individual may have a set of talents and skills. However, whether an individual can become educated given his or her talents and skills depends on the condition of the physical infrastructure (e.g., whether there are roads or paths through which he or she can access a school), social norms, and laws (e.g., whether there are formal or informal restrictions on him or her attending school). Such factors impact whether and how resources contribute to achieved functionings (Robeyns 2005, p. 99).

An individual's capability is morally significant because of its connection with individual well-being. According to Sen (2009), well-being can refer to either the "promotion of an individual's well-being" or the promotion of an individual's agency goals. Agency goals are a broader category of goals, encompassing everything an individual has reason to pursue. Some of the goals of an individual may include his or her own well-being, and so an increase in well-being will be an increase in agency achievement. However, some agency goals may not be connected to an individual's well-being; indeed the achievement of some agency goals can

be at the expense of individual well-being. Using the freedom/achievement distinction, an individual's well-being might relate to well-being achievement or well-being freedom. Keeping these distinctions in mind, Sen claims that capability, broadly understood as the dimension of freedom concerned with substantive opportunities, can include both well-being freedom and agency freedom. He argues that more capability often enhances well-being, when well-being is defined in terms of agency. However, because that same agency freedom can be in tension with, or indeed go against, individual well-being freedom depending on the goals a particular agent has, capability may not always enhance well-being understood as well-being freedom. Capabilities provide information about the opportunity individuals have (or lack) to exercise their agency in shaping their lives.

Conceptualizing and assessing individual well-being in terms of capabilities differs importantly from two common metrics for assessing well-being: resources and utility. Consider resources, or evaluating well-being on the basis of the market commodities (e.g., income, resources) or primary goods (e.g., wealth, income, social bases of self-respect) an individual enjoys. Resources are one necessary condition for the well-being of individuals. As we saw earlier, resources influence the capabilities of individuals. An increase in resources can also be the consequence of certain functioning achievements. However, one problem with the resource framework is that it mistakes means for ends. Resources are taken to be intrinsically good, instead of instruments for the achievement of what is intrinsically good, namely, capabilities. Typically, we care about income not for its own sake but because of what it allows us to do and become. A second problem with the resource-based framework is that it ignores interpersonal variability, or the different rates at which diverse individuals can use resources to achieve a particular functioning. As David Crocker (2008, p. 114) writes, "Due to variations among individuals, the same commodity either may help some and harm others or may promote the well-being of some a lot and of others only a little. Although food intake normally will enhance human functioning, it will kill the person choking on a fish bone. To function well, Milo the wrestler needs on the one hand, more food than the infant and the disabled and, on the other hand, less food than a wrestler of a similar size but stricken with parasites."

Another method for assessing individual well-being is in terms of utility. Welfare economics is the discipline devoted to the assessment of the goodness of states of affairs and policies in terms of their impact on well-being. Well-being/advantage is usually defined in terms of utility. Utility is defined as happiness, where happiness is often understood as desire fulfillment (Sen 2009). The utility approach avoids one weakness with the resource framework: it does not fetishize goods but makes individuals the fundamental unit of concern (Crocker 2008). However it has important limitations. First, happiness and desire fulfillment are necessary but not sufficient for well-being. Individuals who are persistently deprived may adapt to their circumstances to make life tolerable, learning to "take pleasure in small mercies" and refusing to desire or hope for change in their circumstances. If we assess the well-being/advantage of such individuals on the basis of their happiness alone, then we would fail to get an accurate picture of their actual disadvantage. Conversely, "people may have well-being and even opulence (be 'well off') and yet be unhappy and frustrated; their unfulfilled desires may be for rare Rioja wine and top-of-the-line Mercedes" (Crocker 2008). As these examples illustrate, the informational basis of well-being/advantage in welfare economics is incomplete. It should be broadened to include factors such as substantive opportunities, negative freedoms, and

human rights. Omitting this information prevents us from making important distinctions in our judgments of the relative advantage of individuals who enjoy the same level of happiness, but differ dramatically along these other dimensions. Omitting this information also leads to distorted assessments.

## The Capability Approach and Gaging Capabilities

---

The capability approach offers an evaluative space in terms of which judgments about states of affairs should be made. For example, in a capability approach to development, “[T]he purpose of development is to improve human lives by expanding the range of things that a person can be and do, such as to be healthy and well nourished, to be knowledgeable, and to participate in community life” (Fukuda-Parr and Kumar 2003). Societies are assessed as more or less developed from this perspective, then, not on the basis of their wealth but rather on the basis of the degree to which they ensure the ability of individuals to be healthy, knowledgeable, and a participant in their community. The capability approach is used in a wide variety of fields including social choice theory, welfare economics, development ethics and economics, moral and political theory, disaster studies, and education (Robeyns 2006; Gardoni and Murphy 2010).

To be able to use the approach to evaluate different states of affairs, it must be possible to assess the capabilities of individuals. The earliest attempt to operationalize the capability approach was in development economics. The United Nations and development agencies now assess development on the basis of the functionings achievement of members of a country. The Human Development Report (*HDR*), published annually since 1990, uses the Human Development Index (*HDI*) to assess development. The *HDI* continues to provide a prominent model for assessing functionings achievements in other fields. In the *HDI*, the functionings used for assessing development include the ability to live a long and healthy life, the opportunity to be knowledgeable, and the ability to have a decent standard of living. Capabilities are not directly observable or quantifiable. In practice, indicators are used to try to indirectly gage either actual functionings achievements and/or capability, the freedom to achieve functionings (Raworth and Stewart 2003; United Nations Development Program 2007). Indicators are used to quantify each functioning. To illustrate, one indicator for the ability to live a long and healthy life is life expectancy at birth. For the opportunity to be knowledgeable the adult literacy rate is used. Gross Domestic Product (*GDP*) per capita is an indicator selected for the ability to have a decent standard of living. The data collected for each indicator is compared to a scale of minimum and maximum values (goalposts). In the case of life expectancy, the average life expectancy rate for individuals in a given country is compared to the minimum value of 25 years and the maximum value of 85 years (United Nations Development Program 2000). This comparison, also called normalization or scaling, gives some context and meaning for the specific life expectancy rate of a given country, providing a picture of what the level of functioning achievement for that indicator is (Jahan 2003). The goalposts represent reasonable minimum and maximum values based on an analysis of historical data (Raworth and Stewart 2003). Finally the normalized or scaled values of the individual indicators are combined in an unweighted average. No weights are typically used because each functioning is taken to be equally important.

## Current Research

---

In this section we first consider how the capability approach has been applied to risk analysis. We then discuss two important ways in which the concept of capability has been enriched by risk studies.

### Use of the Capability Approach in Risk Theory

---

The study of risk is highly interdisciplinary. A diverse range of risks are the subject of examination, including those associated to environmental, technological, man-made, and natural hazards. This section describes the contributions that the Capability Approach has made to risk analysis. We consider in particular the contributions to the three components of risk analysis: risk determination, risk evaluation, and risk management.

#### Risk Determination

Risk determination refers to the quantification of the probability of occurrence of a particular hazard and its associated consequences. Our focus in this section is not on the probability component of risk, for which there are a wide variety of methods of quantification available. For a description of such approaches see Paté-Cornell (1996), Haimes (2004), and Cullen and Small (2004). Rather, our interest is in how the consequence components of risk are often characterized and assessed. The first contribution of the capability approach to risk theory is in our understanding of how the consequences from hazardous scenarios should be conceptualized and assessed. Below we first describe two common approaches to conceptualizing and quantifying the consequence components of risk and their limitations. We then discuss how the capability approach has been proposed as an alternative, and how this approach avoids the limitations with existent approaches.

#### Limitations with Common Frameworks to Risk Determination

Risk analysts and those who provide the inputs for a risk analysis, including engineers and social scientists, have historically adopted a broad resource-based approach to the consequence component of risk (Rowe 1980; Vose 2000; Bedford and Cooke 2001; Haimes 2004). In one framework, the numbers of resources of various kinds that are lost, including structures, money, time (in terms of delays in construction), and/or individuals are counted. Counting the consequences of risks in this manner has a number of limitations. First, a concentration on resources lost does not provide information about how the lives of individuals are affected. As we noted in the discussion in the previous section, there are different rates at which a given resource can generate an opportunity to achieve a valuable functioning. Thus, identifying the number of structures damaged does not alone tell us what that loss means for the individuals in the community affected. Losses of a given structure can have a greater or lesser impact depending on whether the structure is a hospital, an empty building, or an apartment complex, for example. Second, defining consequences in terms of resources implicitly treats what are important means to achieving well-being as ends in themselves. Third, risk analysts, engineers, and social scientists increasingly recognize the need to consider consequences beyond those traditionally taken into account in risk analysis. However, the resource framework does not provide a principled way to demarcate what losses should count or are salient for purposes of

risk analysis. Indeed, consequences are often selected in practice on the basis of their ease of quantification (Murphy and Gardoni 2006; Gardoni and Murphy 2009).

A second alternative framework evaluates consequences on the basis of the utility lost in a given hazardous scenario. Utility is commonly determined by examining the preferences or choices of individuals. An underlying assumption is that the satisfaction of preferences increases welfare. Preferences or choices are assessed in monetary terms. Thus, all consequences of interest (e.g., the loss of a human life, harms to the environment) are converted into a monetary figure. This figure is determined on the basis of individual “willingness to pay” (Sunstein 2005). That is, the cost associated with a risk is based on an examination of what individuals would need to be paid to be willing to be exposed to a certain risks. These figures are characteristically based on actual market activity. As Cass Sunstein (2005) describes it, “Suppose that people must be paid \$600, on average, to eliminate risks of 1/10,000; suppose, for example, that workers who face risks of that magnitude generally receive \$600 in additional wages each year. If so, the VSL [Value of a Statistical Life] would be said to be \$6 million.” Contingent valuation surveys are used in cases where there is no market evidence on which to make an assessment. For example, to assess the loss of a coral reef, individuals may be asked what they are willing to pay to salvage coral reefs (Sunstein 2005; Hansson 2007a).

A number of objections have been raised to conceptualizing consequences in terms of utility. Most fundamentally, assigning costs to certain consequences on the basis of market choices and preferences does not accurately convey the costs of certain consequences, either over- or under-estimating their significance. This is so for a number of reasons. First, individuals may have misperceptions about or be indifferent toward risks they face. One common case of misperception of risks is that rare, dramatic risks might be feared more than ordinary risks. In the workplace, individuals may not be fully knowledgeable about the occupational risks they face when accepting a position; when they do learn of certain risks the costs to leave may be grave, including loss of seniority or pension if they seek employment elsewhere (Anderson 1988). Environmental costs may not be a source of grave concern, in part based on a failure to understand the significance of the environment to us. As a result, the costs assigned may lead to a corresponding over- or under-valuation of certain kinds of losses (Slovic 1987; May 2001; Murphy and Gardoni 2006).

Second, even when individuals have an accurate perception of the risks they face and are not indifferent to their consequences, the willingness to pay amount may not capture the way individuals value certain costs, such as the loss of their lives. Risks that are job-related may not be voluntarily accepted, but rather chosen because they were the only form of employment available (Wolff and de-Shalit 2007). As Elizabeth Anderson (1988) writes, “Workers with families commonly do not regard their choices about risks to their lives as acts of consumers out to maximize their personal utilities. Rather, they see their choices as attempts to discharge their responsibilities to their families. Bound by their responsibilities to others, they do not feel free to risk their lives at will for pay, as they sometimes acknowledge having done in their youth. But neither do they feel free to jeopardize their families’ means of livelihood and future prospects by simply quitting their hazardous jobs and risking long-term unemployment.” Thus, choices to accept certain wages may not reflect an individual’s judgment about the value of his/her life, but rather the judgment about how it is necessary to fulfill certain responsibilities.

An additional limitation is that the utilitarian framework does not focus attention on what should be of fundamental interest, namely, how the genuine opportunities of individuals will

change if certain hazards are realized. Instead of valuing and prioritizing the promotion of the agency of individuals, the utilitarian framework treats the losses of human lives as a market commodity. Furthermore, information about the monetary costs of consequences does not translate into information about how the freedom of individuals to do and become things of value will be restricted. That is, what are the implications of certain forms of environmental damage for the lives of individuals? Concentrating on what individuals may be willing to pay to avoid certain losses does not provide information about the ways in which the genuine opportunities open to individuals may change should certain hazards be realized.

### A Capability Approach to Risk Determination

In a capability approach, the consequences of hazardous scenarios are conceptualized and assessed in terms of changes in capabilities. Risk is then defined as the probability that capabilities will be reduced (Murphy and Gardoni 2006). Conceptualizing the consequences component of risk from a capability approach overcomes the limitations with both the resource and utilitarian framework. It focuses the attention of risk analysts directly on how a hazardous scenario will affect the welfare of individuals within a community, insofar as consequences are defined in terms of the change in the genuine opportunities of individuals to achieve valuable states and activities. It thus avoids the mistake of focusing on commodities, which are instrumental means but not valuable ends in themselves. Furthermore, the capability approach can account for differences in interpersonal conversion rates in using resources to achieve valuable functionings; the capability approach focuses directly on the freedom to achieve valuable functionings itself. The capability approach also does not define the consequences of hazards in terms of what individuals would be willing to pay. It thus avoids the commodification of costs like the loss of a human life and problems with the lack of information about, concern for, or ability to avoid certain risks plaguing the utilitarian analysis. What individuals would be willing to pay to avoid certain consequences plays no role in determining what the consequences of a hazardous scenario might be. Instead, the impact of a hazard on the genuine opportunities of individuals is the focal point of concern. The capability approach can account for the broader indirect impact that a hazard might have, because built into the framework is the recognition of the fact that both resources and the social and material structure of a community profoundly affect the opportunities open to individuals. Concern with the freedom of individuals to achieve valuable functionings invites questions about whether and in what ways the resources of individuals or the social and material structure of a community have changed. Finally, concentrating on capabilities, rather than achieved functionings, reflects a respect for the commitment of liberal governments to ensure that a range of options of ways of living are open to individuals, instead of promoting a particular way of living itself.

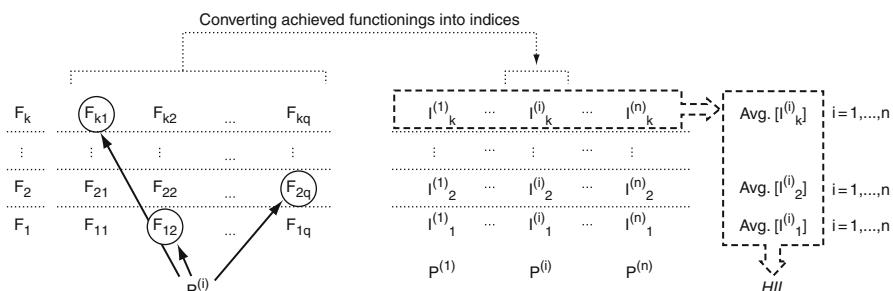

To assess the impact of a hazard, it is necessary to operationalize the capability approach to risk. Initial efforts to operationalize the capability approach built on the framework are provided by the *HDI* for development, which assesses achieved functionings (Gardoni and Murphy 2009). For the purposes of quantifying the consequences of risk, a Hazard Impact Index *HII* was developed (Gardoni and Murphy 2009). The *HII* is constructed in four steps. The first step involves selecting the capabilities relevant for the kind of risk in question; that is, it is necessary to identify which capabilities will provide an accurate picture of the impact of a hazard. Gardoni and Murphy (2009) have argued for a set of criteria that any argument for the capabilities to be used in risk analysis must satisfy. Briefly, a given capability is relevant for risk analysis insofar as it reflects the underlying values and concerns with risk. To ensure that a capability risk analysis is

both comprehensive and, at the same time, practically possible to perform, the minimum number of capabilities should be selected and the capabilities chosen should provide information not available from given capabilities (e.g., because there is a correlation between the enjoyment of two capabilities). Gardoni and Murphy also proposed a preliminary list of capabilities to be used in risk analysis conducted with respect to natural hazards.

Indicators must then be chosen for the selected capabilities. In the context of risk, appropriate indicators must be shown to track the impact on the capability of interest of a hazardous scenario (Gardoni and Murphy 2010). Such indicators will allow risk analysts to assess the impact of a hazardous scenario on capabilities, and so assess the consequence component of risk. Following the model provided by the *HDI* indicators were taken to track the change in the level of achievement of each associated functioning. Each indicator must be converted into an index that ranges from 0 (minimum achievement) and 1 (maximum achievement) through a process of scaling analogous to that used in the *HDI*. Finally, all indices are combined through an averaging process to create an aggregate measure of achievement. It is also noted that in the context of risk analysis the values of the indicators cannot be simply measured but need to be predicted since the subject of risk analysis is future events. The *HII* gives a snapshot of the predicted well-being after a hazard. A comparison between the *HII* and the actual well-being before a hazard (also measured using a capability approach) provides a measure of the impact of the hazard.

Figure 39.1 illustrates this formulation of the *HII*.  $F_1, F_2, \dots, F_k$  on the left column are the functionings under consideration. Each functioning can be achieved at different levels 1 through  $q$ . For example, functioning  $F_k$  might be achieved at levels  $F_{k1}, F_{k2}, \dots, F_{kq}$ . As shown in Fig. 39.1, an individual  $P^{(i)}$  might achieve  $F_1$  at level  $F_{12}$ ,  $F_2$  at level  $F_{2q}$  and so on, up to  $F_k$  at level  $F_{k1}$ . Each level of achieved functioning for individual  $P^{(i)}$  is then converted into a corresponding index, for a total of  $k$  indices:  $I_1^{(i)}, I_2^{(i)}, \dots, I_k^{(i)}$ . The same process is repeated for all the considered individuals  $P^{(1)}, \dots, P^{(n)}$ . An average of the indices over all individuals is then computed ( $\text{Avg.}[I_k^{(i)}]$ ,  $i = 1, \dots, n$ ) for each functioning. Finally the *HII* is computed by combining all the averages.

One limitation with this construction of the *HII* is that it assesses the level of achievement of functionings, not capabilities. For assessing the least advantaged in society and for assessing the impact of a natural hazard (e.g., flood, earthquake, or hurricane) in the emergency phase

**Fig. 39.1**

Illustration of the current formulation of the *HII* and *HDI* (Published previously as Fig. 1, in Murphy and Gardoni 2010, with kind permission from Taylor & Francis Ltd., <http://www.informaworld.com>)

(the time that immediately follows a medium or large disaster) information about achieved functionings may be sufficient for assessing capabilities. This is because we can typically assume that the functionings frequently used in these contexts, which are basic functionings, will be automatically chosen if individuals have the genuine opportunity to do so. Examples of basic capabilities in Murphy and Gardoni's (2010) sense include the capability to have adequate shelter, avoid injuries, and be adequately nourished. Murphy and Gardoni's use of the notion 'basic capabilities' departs from both Nussbaum and Sen. Nussbaum defines basic capabilities as "the innate equipment of individuals that is the necessary basis for developing the more advanced capabilities, and a ground of moral concern." (2000b, p. 84). Sen defines basic capabilities as capturing "the ability to satisfy certain crucially important functionings up to certain minimally adequate levels." (1993, p. 40). By contrast, we delimit basic capabilities in terms of those functionings that, with rare exceptions, individuals will choose to achieve if they have a genuine opportunity to do so. In the case of basic capabilities, the levels of achieved functionings thus provide an accurate picture of the capabilities. For example, we can reasonably assume that if some individuals in the emergency phase in the aftermath of a hazard are not sheltered this is because they lack the capability to be so. However, when we gage the medium- and long-term impacts of a hazard on capabilities, an assessment of functionings achievement is typically an inaccurate proxy. This is because the medium- and long-term impacts of large hazards, or the impact of smaller hazards, affect non-basic functionings (or basic capabilities in a more subtle manner) that we cannot safely assume will be chosen given an opportunity to do so.

In addition, as discussed earlier, in practice only vectors of functionings are open to an individual and choosing to achieve one functioning level might preclude the opportunity to chose a certain level of a different functioning. That is, only certain combinations of functionings are open to an individual to achieve. However, the original formulation treated each functioning in isolation and did not account for how different functionings might interact in fact. (Murphy and Gardoni 2010). Furthermore, the original formulation assessed the average impact on levels of functionings achievement across a population. However, an average impact can mask important variations among a population. The same average may reflect a case in which all individuals had roughly the same impact, or a case in which some individuals were not impacted but a portion of the population was severely impacted. The variation in impact may correlate with certain subgroups within a population, though it need not do so. Finally, in evaluating the capability of an individual we need to consider two dimensions captured by this approach: the *quality of the possible vectors*, and the *extent of the freedom* that an individual has in choosing different vectors. In evaluating capability, we need to capture both the quality of the options open to an individual as well as the quantity, or range of vectors, he or she has a genuine opportunity to achieve. The quality of the possible vectors provides information about the levels and kinds of functionings that can be achieved, and, more generally, of the available opportunities. The range of vectors provides information about the scope of freedom.

For this reason, Murphy and Gardoni (2010) proposed a method for determining vectors of capabilities of an individual. The fundamental idea is that functioning achievements of other people says something about the choices that are genuinely open to an individual in the same group. Knowing that other individuals have chosen to realize a certain opportunity is an indication that such opportunity actually exists and allows us to distinguish between a situation where an individual chooses not to actually take advantage of an opportunity versus a situation in which such an opportunity does not exist. This method also accounts for

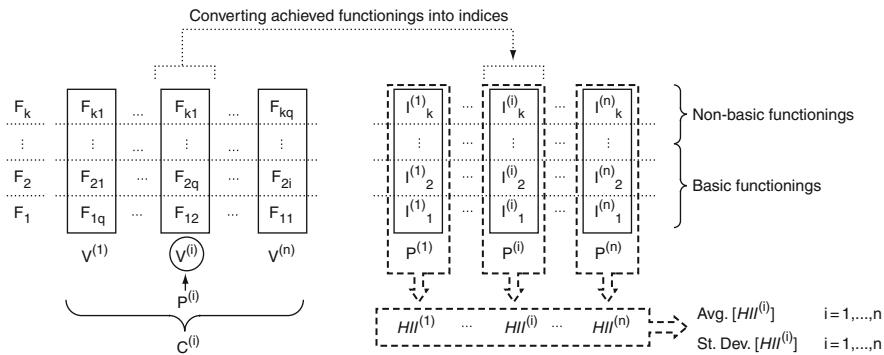

Fig. 39.2

Illustration of the new formulation of the  $HII$  (Published previously as Fig. 2, in Murphy and Gardoni 2010, with kind permission from Taylor & Francis Ltd., <http://www.informaworld.com>)

vectors, rather than isolated functionings, by computing the impact of a hazard at the individual level and then determining the achieved functionings across individuals.

Figure 39.2 illustrates the formulation proposed by Murphy and Gardoni (2010). An individual  $P^{(i)}$  can only choose among a set of vectors of achieved functionings,  $V^{(1)}, \dots, V^{(n)}$ . For example,  $P^{(i)}$  can choose  $V^{(i)}$  which means choosing  $F_{12}, F_{2q}, \dots, F_{k1}$ . After transforming the achieved functionings into indices, we need to compute the  $HII^{(i)}$  (or the  $HDI^{(i)}$  if this approach is applied to human development) for individual  $P^{(i)}$  and only then determine the statistics (average and standard deviation) of the  $HII^{(i)}$  across all individuals, indicated in Fig. 39.2 as  $\text{Avg.}[HII^{(i)}]$  and  $\text{St. Dev.}[HII^{(i)}]$ , respectively. In this formulation,  $\text{Avg.}[HII^{(i)}]$  tells us about the quality of the possible options, while the  $\text{St. Dev.}[HII^{(i)}]$  captures the extent of freedom.

## Risk Evaluation

As its name implies, risk evaluation is the process of assessing the information provided through a risk determination. Of particular interest is whether a risk is acceptable or not. Below we survey two common methods for judging the acceptability of risks and their corresponding limitations. A third approach, cost-benefit analysis, is considered in the next section on risk management. We then present the capability approach to acceptable risk.

### Limitations with Common Frameworks to Risk Evaluation

One approach to determining the acceptability of a risk is to consider whether the public finds a given risk acceptable (Hunter and Fewtrell 2001). Underlying this approach is a commitment to democratic governance, where democracy is taken to imply a form of majority rule. In a democracy, policies and decisions are justified insofar as they express the will of the people. However, there are two important limitations with using public judgment as the basis for determining the acceptability of risks. First, as noted earlier, the public often has limited, and sometimes inaccurate, knowledge about risks; thus judgments will not be based on correct assessments. Furthermore, the public may be indifferent about risks they face. All of these factors undermine the confidence we can have in the assessments of the acceptability of a given

risk the public may make. Second, the public judgment standard for acceptable risk mistakenly equates democracy with majority rule. However, it is widely acknowledged by liberal democratic theorists that individual rights are at the core of democracy and constrain what the majority may want to do. Furthermore, democratic processes should not take preferences or views of citizens as a given, but rather aim to help develop an informed citizenry. Thus, democracy does not require that the initial, often uninformed, preferences of citizens be the basis for evaluating risks a community faces.

An alternative approach is to leave judgments about the acceptability of risks to experts. Professional risk analysts have the most complete information about the character of risks and the knowledge to understand how to interpret the results from a risk analysis. Often risk analysts use as the basis for their judgments their past experience, the standards of their profession, or the preferences and desires of their client (Fischhoff et al. 1981). However, in practice experts may be biased in their evaluation of the acceptability of risks, failing to take into consideration aspects of risk that matter to the general public or how risks impact society as a whole, as opposed to their client in particular. Finally, the criteria experts use to judge a risk as acceptable are frequently implicit, making it difficult to scrutinize or evaluate the justifiability of a particular decision.

### A Capability Approach to Risk Evaluation

In addition to providing an alternative characterization of the consequences of a hazardous scenario, the capability approach provides resources for a novel way of conceptualizing the criteria in terms of which a risk should be judged acceptable. Motivating this approach is the key claim that justice requires that individuals enjoy a certain threshold level of capability (Nussbaum 2000b). Judgments about the acceptability of a risk, then, should take into account whether or not individuals will continue to enjoy threshold levels of capabilities in the aftermath of a hazard (Murphy and Gardoni 2008).

There are two thresholds that are relevant in this context. The first is the acceptable threshold. This threshold specifies what minimum level of capabilities it is acceptable for individuals to enjoy over any period of time; this is the level below which capabilities should not fall ideally. In the aftermath of a hazard, especially the immediate aftermath, it may not be practically possible for all individuals to enjoy the acceptable level of capabilities. A framework for risk evaluation should recognize this possibility, while at the same time setting limits on what is permissible even in the immediate aftermath of a hazard. This is where the second threshold comes in. The tolerability threshold is lower than the acceptable threshold. It specifies what level of capabilities is tolerable in the immediate aftermath of a hazard, provided this lower level is temporary, reversible, and does not fall below a lower tolerable limit. The tolerability threshold reflects the moral necessity of avoiding permanent damage to the well-being of individuals (Murphy and Gardoni 2008).

To account for the role of public deliberation, Nussbaum (2000b) and Sen (2009) rightly note, is an important component of the capability approach. In a capability approach to acceptable risk (Murphy and Gardoni 2008), the precise specification of the acceptable and tolerable threshold can be the product of internal democratic processes. The goal of such public processes is to articulate standards that establish realistically ambitious levels of acceptable and tolerable capabilities, given a society's actual conditions. Because we are dealing with risks, in which the precise consequences of a hazard are unknown, the specification of the thresholds of acceptable risk must also take into account probability. That is, in addition to specifying the

level of capabilities judged acceptable, the acceptable threshold must also specify the probability that capabilities will not fall below the acceptable threshold which must be minimally met for a risk to be judged acceptable. The same consideration is true of the tolerability threshold.

In risk evaluation, then, we assess the probability that the level of capabilities across a population is below the thresholds of acceptable and tolerable risk. To take into consideration questions of justice in the distribution of risks, a process of disaggregation may be used. This involves determining the probability distribution (as a measure of the likelihood) of the capabilities of subgroups within a population. The probability that the level of capabilities for various subgroups is below the thresholds of acceptable and tolerable risk may then be assessed.

The capability approach to acceptable risk avoids the limitations with relying either only on public judgment or on expert judgment. It finds a central role for the public to play in shaping the criteria of acceptable risk in setting the thresholds of acceptability. At the same time, judgments about the acceptability of particular risks can be done by experts, whose evaluation will be shaped by the standards the public sets.

## Risk Management

Communities and individuals want to know what risks they face, and to make judgments about whether such risks are acceptable, in part so that they can effectively manage risks. The information provided by risk determination and risk evaluation provides a foundation for ensuring that policies about risk are formulated in a well-informed manner. Such policies must take into account the limited resources available to governments and agencies as well as the other competing priorities that governments must address. Risk management strategies provide a framework for aiding policy makers, who are generally not experts in risk analysis, in deciding which risks should be prioritized for mitigation action and which mitigation strategies should be taken. Below we first discuss one prominent risk management framework, cost-benefit analysis and its limitations. We then consider a capability approach to risk management.

### Limitations with Common Frameworks to Risk Management

A common method of evaluating and managing risks is cost-benefit analysis (CBA). CBA is a broadly utilitarian approach in which two or more options for public policy decision making are compared on the basis of their respective advantages and disadvantages. The advantages and disadvantages are defined in terms of the consequences. All consequences (which may include economic costs, risks of death, environmental harm) are assigned a numerical, typically monetary, value. The monetary value is assessed based on the preferences of individuals, where such preferences are measured based on the amount of money an individual would be willing to pay to avoid certain risks or the amount of money he or she would agree to be paid to be exposed to certain risks. Market information or valuation surveys provide the basis for monetary figures. After quantifying the relative advantages and disadvantages, advantages are weighed against the disadvantages numerically. The option with the greatest net benefit (taking into account benefits minus costs) is then selected (Sunstein 2005; Hansson 2007a). There are two strengths of CBA, which explains in part why it is favored by policy makers. First, it provides a straightforward decision-making strategy for determining which risks to address and in what way to address them. Second, it takes as a priority the efficient allocation of scarce resources.

However, CBA has also been the subject of a number of criticisms, which parallel those raised to a utility approach to risk determination. To briefly review, first, as noted earlier, many critics of cost-benefit analysis object to allowing the market to establish a distribution of risks on the basis of what individuals are willing to pay or be paid. For critics, this does not recognize and cannot guarantee the obligations that both employers and communities have to guard against exposing employees or individuals to certain kinds of risks. Second, relying on market mechanisms to quantify risks is problematic because it assumes that individuals have full knowledge about the risks they face when they determine what they would be willing to be paid to be exposed to certain risks and that they base their decision on their assessment of how they value what will be put at risk, such as their lives. However, neither assumption is warranted in practice. As noted above, individuals are often not fully knowledgeable about the risks they face. Furthermore, choices about risk exposure are often a function of factors, such as limited income or employment opportunities, that do not reflect how individuals value certain goods. Third, CBA fails to sufficiently recognize that the protection of life is not simply a question to which a certain cost should be assigned, but reflects a principle or ideal to which societies should be committed. Relatedly, it is problematic to assess a monetary value to the loss of human life or a monetary value to other noneconomic goods. Fourth, there are important issues of fairness and equality in the distribution of risks which the CBA cannot take into account, given its emphasis on the aggregate costs and benefits (Asveld and Roeser 2009, esp. the chapters by Hansson, Cranor, and MacLean).

### A Capability Approach to Risk Management

In a Capability Approach to risk management, the overarching aim is to protect and promote individuals' capabilities (Murphy and Gardoni 2007). Given this aim, the first step in evaluating which risks to address is to determine whether a given risk is acceptable or tolerable. Priority should be given to risks judged intolerable, followed by a consideration of risks judged unacceptable.

When evaluating a range of policy options to address and mitigate unacceptable or intolerable risks, policy makers should determine which policies are viable options. Viable options should be reasonably anticipated to bring the predicted level of capabilities above the tolerable or acceptable thresholds, respectively. This can be achieved by reducing the probability of occurrence of a given hazard and/or its expected impact. Because resources are limited and risk management is not the only objective to pursue, choices among viable options need to be made. In a Capability Approach, we select from among viable options on the basis of the likely affectability of relative policies. That is, from among policies considered, we can select a policy to pursue based on the expected dollar per unit change in the impact of a hazard. Monetary quantification can be used as a measure of the cost of a given policy; its effectiveness is then conceptualized in terms of the increase or decrease in capability levels.

The capability approach to risk management avoids some of the main criticisms leveled against CBA. In a capability approach the thresholds that set the criteria for acceptable and tolerable risk reflect the judgment that justice requires that individuals not be exposed to certain kinds of risks and that society has an obligation to ensure that individuals are protected from such risks. Because the quantification of the impact of risks and of mitigation strategies is defined and assessed in terms of capabilities, the Capability Approach does not involve quantifying the value of a human life or commodifying diverse kinds of goods. At the same

time, assessing policies on the basis of their likely affectability ensures that consideration is given to the fact that resources are scarce and that it is important to ensure that public resources are used in an efficient manner.

## Use of Risk Theory in the Capability Approach

---

The concept of risk has been used to enrich our understanding of capability. In their work on assessing advantage and disadvantage from a capability approach, philosophers Jonathan Wolff and Avner de-Shalit (2007) have argued that it is important to consider the security of any functioning achievement when assessing the capability of an individual. An individual has a genuine opportunity to achieve a given functioning only if that achievement is one that can be sustained; it is not an achievement that is at undue risk. A functioning achievement is at undue risk, in their view, insofar as its achievement is temporarily and involuntarily put in jeopardy by the pursuit of other functionings achievement. In other words, a functioning achievement is insecure when an individual is “forced to take risks that in one way or another are bigger than others are being exposed to or take” (Wolff and de-Shalit 2007). To illustrate, the achievement of being sheltered may be insecure and at risk insofar as an individual has an uncertain income stream stemming from irregular employment that results in unstable ability to pay rent. Alternately, an individual may be forced to constantly put her bodily integrity at risk, insofar as the only available sources of employment are dangerous occupations (Wolff and de-Shalit 2007).

The inclusion of the idea of secure functionings achievement is becoming widely accepted and adopted in capability analyses. Capability is now understood to represent the genuine opportunity an individual has to achieve a particular functioning in a secure manner. Thus, concern with the functionings achievements being put at risk in an involuntary or disproportionate manner is a central issue. Wolff and de-Shalit suggest statistical information can provide some insight into the security of functionings achievement. In their view, we can assess the security of functionings achievement by looking at trends over time for specified subgroups. In their words, (2007, pp. 116–117),

- ▶ The fact that I have a job today says nothing about whether it is a day's casual work or a sinecure for life. However, taking a wider view and looking at the individual's social circumstances or context immediately provides more information. Indeed, statistics will provide much of what we need. Imagine that among certain groups – perhaps the young, recent immigrants, or the low paid – there is a high degree of mobility in employment or housing, with those moving jobs or homes also experiencing periods of unemployment or homelessness. This, then, gives a *prima facie* reason to believe these functionings are not achieved securely by people within these groups... In general, then, although individual functioning is not an indicator for the degree of security, statistics often can be.

There is a second contribution that risk theory makes to the capability approach. The method developed to assess capabilities in the context of risk analysis (Murphy and Gardoni 2010) and illustrated in Fig. 39.2 can also be applied to assess capabilities in its original context of development economics and in other applications. As noted above, initial efforts to operationalize the capability approach built on the model provided by the *HDI* for development, which concentrated on assessing achieved functionings. Furthermore, the

original formulation treated each functioning achievement in isolation, while in practice an individual  $P^{(i)}$  can only choose among a set of vectors of achieved functionings.

## Further Research

---

There are two main areas of further research for a capability approach to risk analysis that we concentrate on in this section. The first centers on the issues to address to operationalize the capability approach to risk. The second centers on the place of a concern with capabilities in an overall perspective on risk evaluation and management.

The capability approach developed by Sen is deliberately underspecified. Sen (1992, 1993) refrains from identifying the capabilities that should be used in any given evaluative exercise for two reasons. The first is that the capabilities that should be considered will always be to some extent evaluative exercise specific; that is, the capabilities of interest when considering development are not necessarily the capabilities of interest when assessing risk. The second reflects Sen's commitment to identifying valuable capabilities via democratic procedures, and in particular democratic deliberation. These two commitments of Sen's give rise to a series of theoretical questions for a capability approach to risk. First, there is the issue of how evaluative exercise specific the selection of capabilities should be. For example, should the capabilities selected vary according to the kind of risk being assessed? The work done to date developing a capability approach to risk has been conducted in the context of the risks posed by natural hazards. Are the capabilities relevant for technological risks, for example, the same as those relevant for natural hazards? On what basis do we answer this question? Second, if Sen is correct about the role of public deliberation, in the context of risk there is a need to incorporate a place for public deliberation in the selection or evaluation of capabilities and a method for such deliberation to become possible.

Making the capability approach operationalizable also requires further research into a cluster of questions surrounding the quantification of consequences. Indicators must fulfill at least two criteria (Gardoni and Murphy 2010). They must be representative of a given capability and be intuitively plausible. The latter criterion is required to facilitate the adoption and successful application of a capability approach in public policy discussion and decision making about risk. Indicators in the context of risk are designed to track changes in capabilities, so that we can understand the impact of a given hazardous scenario on a community. One question concerns which indicators will be both representative of a capability and provide information about the change in capabilities due to a hazard.

Another issue is that, unlike many current applications of the capability approach, indicators in the context of risk must be *predicted*. With risks we are always dealing with future possible states, not analyzing existing states as is the case with many current applications of the capability approach. The basis on which an accurate and credible prediction of changes in capabilities can be made must be determined and, in particular, whether current methods for quantifying risks can be used for this purpose or whether novel methods for prediction must be developed. One method (Gardoni and Murphy 2010; Murphy and Gardoni 2010) is to forecast the impact of future hazards by first assessing the impact of past disasters using available data. The impacts of past disasters can then be used to estimate the likelihood of each potential outcome of  $HII$  for a given hazard type,  $H$ , of magnitude,  $M$ . Mathematically, such likelihood is expressed as the conditional Probability Density Function (*PDF*),  $P(HII|H, M)$ , of  $HII$  for given  $H$  and  $M$ . Using the Total Probability Rule (Ang and Tang 2007), we can then estimate the

probability of future societal impacts accounting for their likelihood of occurrence integrating out  $H$  and  $M$ , as

$$P(HII) = \int P(HII|H, M)P(H, M)dHdM$$

where  $P(H, M)$  is the joint PDF of  $(H, M)$ , which can be estimated for typical natural hazards based on for example meteorological or seismological considerations for hurricanes and earthquakes, respectively.

Further research is also required to determine whether, and to what extent, indicators for selected capabilities must be either time-dependent or risk-dependent. With respect to time-dependence, the issue is whether in trying to understand the long-term versus immediate impact of a hazard the indicators must change.

The second general topic for further research concerns the place of capabilities within a comprehensive framework of risk evaluation and risk management. One specific question for further research is the place of a consideration of capabilities among the additional, diverse moral considerations that a judgment of the acceptability of a risk must take into account. The capability approach to risk developed to date provides an account of how the capabilities dimension of risk should be evaluated, which reflects the fact that capabilities are constitutive dimensions of individual well-being and that justice requires a minimum level of capabilities be guaranteed for all individuals. However, the consequences of a hazardous scenario are not the only factor that is relevant for risk evaluation purposes. It is well-established that the public is concerned about and distinguishes among risks on the basis of the source of a risk, that is, how a risk was brought about or created (Wolff 2006; Murphy and Gardoni 2011). The public distinguishes among risks on the basis of whether they were created through negligence, recklessness, and non-culpable behavior. Risks are also evaluated differently depending on whether they were voluntarily taken or not. The distribution of benefits associated with taking risks and the potential harm that may be realized should a hazardous scenario occur is morally salient (Fischhoff et al. 1981; Slovic 2000; Asveld and Roeser 2009). One question for further research then is: when evaluating a risk, on what basis should we weigh or take into consideration the expected impact of a given risk on capabilities relative to the other moral factors that matter? A second question centers on the broader implications of a capability approach for issues in risk management. That is, if we conceptualize risks from a capability perspective, how should that inform the principles that should guide the creation and regulation of risk? Consider technological risks. Should, for example, new technologies be permitted only insofar as it can be shown that such technologies will enhance human capabilities? Should the design of technologies be guided by a concern for capabilities? There are a number of authors working on extending the capability approach to areas like design ethics (Oosterlaken 2009), information technology (Johnstone 2007; Wresch 2007; Zheng 2007; Coeckelbergh 2010b) and AI technology in health care (Coeckelbergh 2010a). Another question is whether it is necessary to adopt a capability approach to design or to technology insofar as one adopts a capability approach to risk.

## Conclusion

This chapter has provided an overview of the reciprocal contributions of a capability approach and risk theory. A capability approach can enrich risk theory in three ways: (1) The consequences component of risk can be conceptualized and assessed in terms of the impact of

a hazardous scenario on capabilities; (2) Judgments of the acceptability of risks can be made on the basis of whether certain threshold levels of capabilities are maintained; (3) The primary aim of risk management can be to protect and promote individuals' capabilities, by prioritizing unacceptable or intolerable risks and by selecting policy options on the basis of expected dollar per unit change in the impact on capabilities. On the other hand, risk theory has enriched the capability approach by (1) drawing attention to an important dimension of capability, namely security; and (2) providing resources for developing a novel way to assess capabilities instead of functioning. Further work is needed to make the capability approach to risk theory operationalizable and to clarify the place of a concern for capabilities in an overall perspective on risk evaluation and management.

**Abstract:** Risk is a relatively new object of sociological research, but this research field has grown rapidly over the last three decades. This chapter argues that the task of sociology is to contribute to risk research by emphasizing that risks are always situated in a social context and are necessarily connected to actors' activities. Thus, sociology opposes the reification of risks, where risks are lifted out their social context and are dealt with as something uninfluenced by activities, technologies, and instruments that serve to map them. The chapter comprises four sections, the first being a general introduction. The next section presents a historical perspective on sociology and risk. It starts by briefly describing what sociology is, followed by a discussion of how the concept of risk becomes an object of sociological thought. The section ends by presenting and discussing three different sociological perspectives on risk, all providing different contributions. The third section focuses on current strands of sociological risk research. It starts by giving an overview of three different sociological approaches to risk: Mary Douglas's cultural theory of social order, Ulrich Beck's theory of reflexive modernization and the risk society, and Niklas Luhmann's system theory. All three approaches conceptualize risk differently and make different contributions to the sociological study of risk. The review of these theories is followed by a presentation of five central discussions within the sociology of risk: risk governance, public trust, democracy and risk, the realism–constructivism debate, and governmentality and risk. Finally, the fourth section briefly presents some areas in need of further sociological research.

## Introduction

---

Over the last few decades, we have witnessed an explosion of risk management practices across a wide range of organizational contexts, such as environment, health, food, crime, media, and traffic (Lupton 1999; Tulloch 1999; Hutter and Power 2005; Hughes et al. 2006; Kemshall 2006; Taylor-Gooby and Zinn 2006; Renn 2008; Reith 2009). All organizations have to relate to risks in their environment. These risks are not only connected with industrial activities, such as harmful substances or technical artifacts. Instead, a growing number of risks concern how actors act upon what they see as risks associated with an organization. Public relations, risk communication, and participatory approaches to risk management have emerged as means to handle diverging interests in society; not least public perceptions could be a source of risk in the sense that these perceptions could pose a threat to the legitimacy and stability of existing ways of managing risk (Power 2007, p. 21). Thus, risk management focuses on how organizations deal not only with the technical calculation of risks, but also with the actors they perceive as possible threats and potential risks to the stability of the organization. Managing such processes is a matter not only of rules for how we should mitigate or accept certain environmental hazards or health risks, but also of rules regarding the process itself, and of activities that target the understanding of risk and deal with public opinion and perceptions concerning it.

This development implies that risk management is no longer limited to a specific sector dealing with certain kinds of risks (such as nuclear power, the chemical industry, and road transport). Risk management has instead become an integral part of managerial language and organizational activities, and all organizations – private companies, governmental agencies, interest organizations, and nongovernmental organizations – have to deal with risks and have made risk management an important rationale for their activities. Not only organizations, but also citizens must include risk thinking when organizing their social world

(Tulloch and Lupton 2003; Höijer et al. 2006). Previous certainties – social forms such as nation state, class, ethnicity, traditional family structures, and gender roles – which people use to map out their future are now eroding and citizens have to navigate their lives without them (Beck 2002, p. 22). There is not only public concern about new technologies, but also about how to organize social life and who and what to trust in an uncertain world. This has led researchers to claim that we today face a grand narrative of risk and risk management at the global level (Power 2007, p. viii). Thus, society has no option but to organize itself in the face of risk (Lidskog et al. 2005). Assessing, managing, and communicating risk has become a veritable industry.

This progression from risks associated with certain industrial activities to risks associated with individual and organizational behavior has led to a strong call for sociological analysis. However, scientific development is not only a reflection of changing societal conditions; it is also a driving force of this change. Social theorists have claimed that we today live in a risk society (Beck 1992), a culture of fear (Furedi 2002), and in a social climate that fosters insecurity, fear, and risk (Giddens 1990; Bauman 2006; Furedi 2008). Citizens and organizations have been provided with a new risk language, causing them to evaluate different phenomena and activities in terms of risk. Thus, there is a dynamic relation between societal development and our understanding of and reflection on this development and society at large.

Within science we have witnessed a development from technical risk analysis – populated by philosophers, statisticians, and economists – to the broader field of risk governance, in which social scientists ponder how actors understand risks as well as how they handle them. Risks are put in specific contexts, which implies a call for social science in general and sociology in particular to develop knowledge on risk. This is the reason why we today can see an explosion of social scientific literature on risk; in particular how to analyze and manage risk.

The contribution of sociology to the field of risk research is mainly that society is differentiated, which means that also cognitions, understandings, and feelings of risk are differentiated. Actors have various cultural belongings and structural positions which make them understand reality differently, and therefore also act differently. Thus, to develop sociological knowledge on risks implies to contextualize risks; they are not the result of a calculation made beyond society, but instead the result of how actors, located in specific social settings, understand and manage certain phenomena. Risk is for sociology always a particular risk situated in a specific context.

Risk is a relative new object of sociological research, and even if this field has grown rapidly over the last three decades, it has not yet fully been institutionalized as a self-evident subfield of sociology (Krimsky and Golding 1992; Zinn 2008, p. 200). In addition, the sociological discipline covers a broad range of perspective and traditions, which is reflected in its research on risks; there are a number of sociological ways to conceptualize, understand, and conduct research on risk. Sociological thought spans from rational choice approaches to cultural theory; it encompasses micro-sociological theories on the construction of self-identities as well as macro-sociological theories on world systems. Thus, it is not an easy task to map out the sociology of risk. We will do so, however, by starting from some central assumptions of sociology, reviewing some of its most well-known approaches to risk, and finally by presenting a few important ongoing discussions and pointing out important areas in need of further research.

The aim of this chapter is to construe a sociology of risk that does not take technical risk analysis as a point of departure, to prevent sociology from being given a too restricted role in researching risk. Instead, we argue that the task of sociology is to contribute to an

understanding of the risk field in which risks always are situated in a social context and are necessarily connected to actors' activities. Thus, sociology opposes any kind of reification of risks, in which risks are lifted out of their social context and dealt with as something uninfluenced by the activities, technologies, and instruments that serve to map them.

The essay comprises four sections, this introduction being the first. The next and second section presents a historical perspective on sociology and risk. It starts by briefly describing what sociology is, followed by how the concept of risk gradually becomes an object of sociological thought. The section ends by presenting and discussing three different sociological perspectives on risk, all providing different contributions to the risk research field. The third section focuses on current strands of sociological risk research. It starts by giving an overview of three different sociological approaches to risk: Mary Douglas's cultural theory of social order, Ulrich Beck's theory of reflexive modernization and the risk society, and Niklas Luhmann's system theory. All three approaches conceptualize risk differently and make different contributions to the sociological study of risk. The review of these theories is followed by a presentation of five central, partly overlapping and ongoing discussions within the sociology of risk: risk governance, public trust, democracy and risk, the realism–constructivism debate, and governmentality and risk. Finally, the fourth section, based on these current discussions, briefly presents some areas in need of further sociological research.

## History

---

### What Is Sociology?

---

The origin of sociological thought can be traced to the end of the eighteenth century in Western Europe (Eriksson 1993). At this time, questions arose about the social order, the division of labor, social hierarchies, social cohesion, and individualization. A concept of society emerged that did not correspond with the sum of its population, but instead was a social phenomenon *sui generis*, a phenomenon with its own characteristics.

This understanding does not mean that society was external to human beings, but rather was something constitutive of them. The history of human beings and the history of society are two sides of the same coin. This perspective on society emerged with thinkers such as Adam Ferguson (1767), John Millar (1771), and Adam Smith (1776). Whereas Thomas Hobbes (1651) understood man as a “rational wolf” in need of external pressure from outside (in form of norms, laws, and force) to enable social life, these social thinkers understood human beings and society as interdependent. In their view, society was more than an external environment; it was also something inside us. Our words and deeds were not only individual acts; they were also social products. These thinkers were the predecessors of sociology, and 100 years later, the discipline of sociology first saw the light of day.

The growth of sociology is intertwined with the development of empirical data collection and social statistics (Calhoun et al. 2007, pp. 13–18). In a number of European countries, governments had begun to regularly collect information about their populations. Statistical analysis grew strongly, and the national census – originally a way to keep track of adult males’ availability for military service – emerged as a regular activity of the state, taking its modern form in the nineteenth century. British Parliamentary investigations of industrial conditions provided the empirical basis for Karl Marx’s initial theorizing, empirical

data on deaths collected by governments and churches for Émile Durkheim's study of suicide, and publicly gathered data for Max Weber's investigation of German peasants and "junker capitalism."

Sociology was constituted as an empirically based social science, with an emphasis on the importance of context (social, material, economic, cultural) for understanding social life. It also emphasized that society was a social phenomenon in its own right; it was not just an aggregate of individuals. Social practices and collective understandings were not possible to explain by referring to individual human beings.

Phenomena and activities should be understood and explained in relation to their social contexts. And this applies not only to norms and artifacts, but also to actors and knowledge. Hence, sociology is critical of individualistic explanations, though without rejecting the importance of actors. Individual human beings are always situated in social settings, which have to be considered when explaining their cognitions, feelings, and practices.

## Risk in Sociology: From Social Problems to Risk

---

The relationship between individuals and society has been central to sociological thought since its origin (Giddens 1984). There have been – and still are – many ways for sociology to explore and explain this relationship. Even if everyone agreed that there was no such thing as "pure individuals" – human beings unaffected by society whose thoughts, emotions, and wills developed apart from society – they all emphasized that this relationship was not a harmonious one. People find themselves limited by social positions and cultural belongings and struggle to transform structural barriers and cultural restrictions. At the same time, sociologists emphasized that human beings' aspirations and ideals come not only from inside, but also from outside – from social norms and ideals that surround them and which they gradually have internalized. They do not develop their own goals, values, and preferences apart from those that exist in society, but instead develop them in relation to these. Thus, the human being is neither a puppet, nor her own master. Social structures and cultural belongings not only serve as barriers to social action, they also enable it.

In classical sociology, social problems and not risks were the focal point. Its classical thinkers – Karl Marx, Max Weber, Émile Durkheim, and Georg Simmel – were preoccupied with the emergence of modern society, not least the development of industrialization, urbanization, and rationalization and their degrading effects on human beings. Different kind of social problems were put to the fore in the sociological analysis, and different angles were tried in exploring these problems. Risk was not incorporated as a conceptual lens through which these problems were understood and analyzed. Instead, risk research emerged and developed without any relation to sociological thought. The reasons for this were dual: disciplines dealing with risks did not see any relevance of sociological analysis, and sociology did not see risk as a relevant object for sociological research.

Traditional risk concepts have been developed within a framework where risk is technically defined. For *technical risk analysis*, risk means to anticipate potential harm to human beings, cultural artifacts and ecosystems, to average these events over time and space, and to use relative frequencies (observed or modeled) as a means to specify probabilities (Renn 1998, p. 53). Thus, risk concerns a situation or event in which something that human beings value is at stake and where the outcome is uncertain (Jaeger et al. 2001, p. 17).

This kind of analysis implies that one set of experts establishes the probability and magnitude of the hazards and another set of experts evaluates the costs and benefits of various options. Thereafter, political priorities are invoked in order to make decisions on regulating (forbidding, controlling, permitting) certain risks (Amendola 2001). Science is pivotal in measuring and assessing risks, and therefore experts should guide the risk management processes.

Thus, technical risk analysis is an un-sociological understanding of risk; it does not consider the broader social, cultural, and historical context from which risk as a concept derives its meaning (Lupton 1999, p. 1). In response to this kind of analysis, three different sociological perspectives have emerged, all making different sociological contributions to the field of risk research: the social construction of misperception of risk, the social amplification of risk, and the social construction of risk. With this development, important ideas from classical sociology have gradually been taken advantage of and made to influence risk research.

## Sociology Explaining Public Misperceptions of Risk

---

Risk researchers and risk managers gradually recognized that the public's perception of risk was different from the view held by the experts. The nuclear researcher Chauncey Starr's seminal article "Social benefit versus technological risk," published in *Science* in 1969, emphasized the importance of considering public acceptability of risk (Starr 1969). He found that risk tolerance was correlated with a number of social components. For example, the public more easily accepted voluntary and familiar risks than involuntary risks (comparing risks associated with the same level of social benefit).

Social and behavioral scientists have devoted themselves to finding out how different groups and individuals perceive risks (Gutteling and Wiegman 1996; Breakwell 2007). Their point of departure – most explicitly within the *psychometric school of risk analysis* – is that for laypersons risk is a subjective assessment in which contextual factors play an important role. This does not mean that citizens' reasoning is irrational or haphazard. On the contrary, it is possible to find cognitive patterns and trace causal factors that explain citizens' risk perceptions. It is found that factors such as novelty (how new a risk is), dread (how feared the risk is), and if the cause of the risk is seen as tampering with nature, are significant factors shaping risk perception (Slovic 1987; Sjöberg 2000). Perceived influence and power are also important factors, as is cultural belonging (Finucane et al. 2000; Zinn and Taylor-Gooby 2006). Also of importance is the social and spatial context in which people make judgments (Lidskog 1996; Wester-Herber 2004). Much research has also been concerned with how different social groups access, interpret, understand, and respond to different forms of information in diverse contexts (Slovic and Peters 1998; Bickerstaff and Walker 2001; Howel et al. 2002).

Thus, there are a number of contextual and social factors that explain why the public does not assess risk in a similar way as the experts. This perspective considers citizens' perception and understanding of risk, and does not give any attention to the perception of experts and how they understand and measure risks. Instead, the technically defined risk is taken for granted; it is seen as an objective phenomenon in which scientific measurements and statistical calculations give correct, or at least the most valid, knowledge on the character of the risk.

When technically defined risks are not seen as contextually generated, the public's risk understanding is portrayed as biased or incorrect compared to the experts' more accurate

assessment. The difference between expert and citizen understanding is interpreted as caused by public ignorance or misunderstanding of science (Irwin and Wynne 1996; Levinson and Thomas 1997). By informing – and sometimes even educating – laypeople about the “real risk,” it is believed that the public would correct its judgment and accept risks that experts and regulators have found to be acceptable (Gouldson et al. 2007). According to this view – commonly labeled as *the deficit model of public understanding of science* (Irwin and Wynne 1996) – knowledge is first produced in a closed circle of scientists, after which it should be disseminated to the public (who in many cases are unable to understand science properly). This view is a variant of the “sociology of error,” which explains what is seen as error and falsehood in science with reference to contextual factors (such as traditions, ideology, conventions, authority, and interests) and what is seen as true and valid knowledge with reference to observations and reasons. The role of sociology, however, is to explain error, not truth (Bloor 1976).

An implication of this perspective is that risk assessment concerns objective analysis aiming to produce factual knowledge about specific risks, while risk communication is about the distribution/transmission of this factual knowledge to the public. To make risk communication effective, it is important to understand how different segments of the public understand risks, and assess the sources of information, to be able to effectively inform them about risks in different circumstances. The sociological task is to provide knowledge about these factors that result in public misperception of risks.

## Sociology Explaining Amplifications of Risk

---

The deficit model draws a sharp line between risk as defined and assessed by experts and as understood by the public. However, many sociologists seek a more sophisticated way to understand the clash between experts’ and the public’s understanding of risk. In the late 1980s, the *Social amplification of risk* approach was developed (Kasperson et al. 1988; Pidgeon et al. 2003). This is a communication model according to which an original physical event generates a signal that passes different social stations that amplify or attenuate the signal. The model explains why risks evaluated by technical risk analysis as being similar may receive different levels of attention in society at large.

The basic assumption is that a risk event has certain physical characteristics, such as material damage, injuries, and deaths. These characteristics provide an original signal that is then transformed in the communication process. The risk event itself has no meaning, but the social stations of amplification charge it with meanings and messages. The social amplification of risk explains how risks and risk events interact with psychological, social, institutional, and cultural processes in ways that amplify or attenuate risk perceptions and public concern, and thereby shape risk behavior.

It also explains the development of secondary effects of risk events, that is, risks caused by the amplification processes and not by the signal itself (Kasperson et al. 1988). Social amplification of a risk event associates it with meaning that may result in changed policy regulation, new conditions for insurance, consumer boycotts of a product, decreased institutional confidence, and social stigma. Thus, the amplification may result in social or economic consequences that go far beyond the direct consequences of the risk event.

Thus, technical risk analysis cannot provide information about how risks are amplified in society, because understanding and explaining processes of amplification is solely a task for

social and behavioral science. The social amplification approach proposes a division of labor in which technical risk analysis is concerned with investigating the original signal whereas social science in general and sociology in particular analyze how this signal is transformed by society.

The social amplification of risk approach is symmetric in the sense that both the attenuation and intensification of the original risk signal are taken into account. Both technical risk analysis and sociological analysis are needed in order to gain knowledge on risk and its consequences for society. The approach contributes an understanding of why certain hazards and events that experts assess as low risk may receive public attention, whereas other hazards that experts consider more severe receive less attention (Kaspelson et al. 2003). By encompassing different factors on different levels, it presents a dynamic and multilayered view on how risk understanding develops. It also aims to link the three leading schools of risk analysis – technical risk analysis, psychometric studies of risk perceptions, and sociocultural studies on risk understandings – into a single framework (Pidgeon et al. 2003).

This bridging effort is ultimately based upon a clear division between a physical world of events and a social world of meanings. The amplification process starts with a physical signal, either in the form of an event (e.g., an earthquake) or the recognition of an adverse effect (such as the discovery of climate change). Thereafter, social factors attribute meaning to it. Risk is thereby conceptualized partly as an objective property of a hazard or risk event, and partly as a social construct (Kaspelson 1992, p. 158). According to its proponents, this position avoids the two problems of conceptualizing risk in a totally objectivistic or in a relativistic manner (Renn 2008, p. 39).

The approach links different ways to understand and analyze risk. It is, however, a synthesis based on a linear model in which something external to society is channeled through amplifying stations, resulting in different consequences, and where feedback mechanisms and processes of iteration only take place between the social stations of amplification. The hazard itself and experts' calculation of risk (not least through technical risk analysis) are left outside the approach and are not included in the analysis. In this way, risks – or at least risk events and hazards – are positioned as external to society. Fact finding and sense making are seen as different and discrete spheres of activity, the former populated by technical risk analysts and the latter by various segments of the public. This model does not discuss how the risk (in form of risk events, hazards, or the technical calculation of risk) is constructed, but only how it is amplified. Hence, the bridging ambition also results in a reproduction of the divide between expert and public understandings of risk. Not only risks are amplified in this approach, but also the divide between risk and understandings of risk.

## Sociology Explaining Risk

In contrast to sociological studies of the misperception of risk and the amplification of risks, the *social construction of risk* approach includes the role of science and technical risk analysis as topics to investigate. Its starting point is that all risks are socially constructed in the sense that risks always exist in contexts (Wynne 1992a). This means that technical risk analysis and experts' assessments of risks have no privileged position; they are only one of many possible ways to frame, define, and understand risks. Thus, knowledge is intimately related to meaning and actors, which means that no kind of knowledge and no kind of actors should be excluded from sociological analysis. Instead, a symmetrical approach is put forward, where all

risks – irrespective of how they are assessed and by whom – are seen as socially constructed. Risks, hazards, and risk events are all sociocultural phenomena in their own right, and should not be seen as unproblematic facts that generate specific signals which laypeople then misunderstand or social stations amplify.

This understanding – that also science's assessment of risk should be seen as construction of risk – has been fuelled by recent developments in society. Science was initially applied to a “given” world of nature, people and society, and scientific skepticism demystified the social and natural worlds. Science's own claim of rationality was itself spared from the application of scientific skepticism. According to Ulrich Beck (1992), a process of “reflexive scientization” is gradually taking place, whereby scientific skepticism is extended to consider the inherent foundations and external consequences of science itself. This demystification opens up new possibilities for questioning science and technical risk analysis. This extension of the scope of rational skepticism means that no scientific statement is “true” in the old sense of there being an unquestionable, eternal truth, where “to know” means to be certain (cf. also Giddens 1990, p. 40; 1994).

The implications of this perspective – risk as a product of social processes – are far reaching. Not only does it mean that the task of sociology is to analyze how actors – including science and risk experts – frame, define, understand, and manage risks. It also implies that the separation of risk regulation into distinct areas – risk assessment, risk management, risk communication – is incorrect. Values are not solely invoked in the initial process of defining risks that then should be analyzed, evaluated, and regulated by technical risk analysis. Instead, they are an intrinsic part of the risk regulation process, as in the process of developing and validating knowledge. Thus, even if they are presented as separate spheres, they are not discrete activities ordered in a linear process aiming to regulate risk, but instead are dynamically related to each other. The problem is that technical risk analysis' definition of risk is preceded by an implicit framing, which is rarely the subject of discussion, either by citizens or by the risk researchers themselves. This framing provides a very restricted understanding of risks and of actors, behaviors, and processes (Wynne 1992a, 2005). When this framing is naturalized – taken as a pre-given way to understand and conceptualize risk – it restricts the role of sociology to investigate and explains why actors' perceptions and understandings of risk differ from those put forward by technical risk analysts.

The social construction of risk approach has been criticized, not only by technical risk analysts, but also by social scientists. To consider risk as a social construct implies, according to its opponents, a far-reaching relativism where risk bears no relation to a reality beyond human consciousness and cultural values. The social amplification of risk was explicitly developed with the aim of transcending the division between naïve empiricism and far-reaching relativism, as an approach that includes both the need for technical risk analysis and the need for cultural theory (Kasperson et al. 1988). Some researchers, such as Ortwin Renn (2008), argue that it is possible to take advantage of both a more contextual understanding of risk and a more traditional analytical and context-less approach to risk. This is done by defining risk as constituted by both physical/material and social/cultural elements (Kasperson 1992, p. 158; Renn 2008, p. 2). This argumentation rests on the general assumption that it is possible to analytically separate values and evidence, social norms and factual knowledge, deliberation and analysis, but that in practice there is a need for better integration of these analytically distinct entities.

As will be shown below, to understand and analyze risk as a social construct does not necessarily imply a strong relativism, but is based on the assertion that risks are social facts that

are irreducible to technical measures. Similarly, its view of knowledge – as contextual, unstable, and sociocultural – does not imply a relativism where all standpoints are given the same cognitive value.

## Current Research

---

A number of sociologists, from somewhat differing standpoints, have emphasised that risk has largely replaced the previous notions of fortune and fate (Beck 1992; Bauman 1993; Luhmann 1993; Giddens 1999). In the past, a lack of certainty was attributed to powers (God, nature, magic) beyond human control, whereas today it is attributed to organizations (such as scientific communities, companies, and nation states). Risk is a factor in human decision making because we cannot gain sufficient knowledge about which possible future will result from our decisions. Furthermore, risk is constituted by the distinction between present reality and future possibilities. Thus, it presupposes that the future is not determined, and that human action shapes the future. As Anthony Giddens (1990, p. 3) puts it:

- ▶ Modernity is a risk culture... The concept becomes fundamental to the way both lay actors and technical specialists organise the social world. Under conditions of modernity, the future is continually drawn into the present by means of the reflexive organisation of knowledge environments.

However, to reflect on future consequences of human action is nothing new in history. The decisive difference is that in modern societies almost all aspects of social life are included in these reflections and have become objects of decisions and deliberations; hence thinking in terms of risk assessments is a more or less ubiquitous exercise in everyday life (Callon et al. 2009).

In the following, we will present three important sociological contributions to risk research, all of which treat risk as central for society at large. They take into account the broader historical, social, and cultural contexts from within which risk derives its meaning and resonance. Thereafter, we present five thematic areas that are objects of lively discussion in contemporary risk sociology.

## Important Theories

---

### Mary Douglas: Purity and Danger

The British anthropologist Mary Douglas (1921–2007), who has inspired many social scientists in the field of risk research, argues in her book *Purity and Danger* that risks should be understood with reference to the social organization (Douglas 1966). The assessments of risks are responses to problems in the social organization of a specific society, but are also resources for building social order and defending social boundaries. The way risks are viewed reflects the organization of society, including its borders to other societies. What we usually understand as threats coming from outside of society are in fact problems within society.

More specifically, Douglas is interested in how societies assess purity and pollution, which she connects with the overarching concept pair of order and disorder. Purity supports order

(both cognitive and social) and pollution is what deviates from and threatens order, and should therefore be condemned. According to Douglas, the separation between purity and pollution, the latter signifying danger, is one of the most fundamental conceptual distinctions in our thinking. This division is, however, relative: "There is no such thing as absolute dirt: it exists in the eye of the beholder" (Douglas 1966, p. 2).

It is important to stress that these definitions are not chosen individually, but in a collective process which is compelling for individuals. Demands for purity are simultaneously requirements for social order, for the survival of society. Douglas argues that we all have norms of order and an associated type of purity to defend, but that these orders and types vary between groups and societies.

In every defense against risks, there is a wish to protect a social order that is considered endangered. Discussions about risks include a desirable norm – a norm of purity – from which the seriousness of the risks can be established. This norm makes it possible to require risk reduction and thereby increases purity. Demands for better risk management imply demands for societal change. A norm of purity contains a vision of a societal order that better corresponds to this norm. Therefore, for sociology, risk should never be seen as something out there, separate from society, but as something produced in and by society.

One implication of this perspective is that our use of the concept of risk reveals who we are. Values and beliefs (including preferences and knowledge) – what Douglas calls *cosmologies* – are viewed as coherent and endogenously derived systems (cultural biases), generated from specific patterns of social relations (Douglas 1978). Such cosmologies support and legitimate social relations. Actions, organizations, and knowledge interact to generate and legitimate social relations. This interplay should not be understood as a unidirectional causal relation but as a reciprocal interaction in which knowledge and society are co-produced (cf. Jasenoff 2004).

One well-known tool for interpreting and explaining such co-production is the *grid–group typology* originally developed by Mary Douglas and her coworkers (Douglas 1982, 1996; cf. Thompson et al. 1990). "Grid" describes the internal structure, how roles and activities are positioned, and "group" the external borders, how the boundary between insiders and outsiders is defined. These two dimensions are fundamental to all cultures, and imply four different cultures: hierarchical, individualistic, egalitarian, and fatalistic.

*The hierarchical culture* is characterized by a stable and regulated internal social order (high grid). Group membership is strong (high group); it is clear to everyone who is a member and who is not. This culture is characterized by formal procedures, rules, routines, timetables, and trust in authorities. *The individualistic culture* is the opposite of the hierarchical. Group membership as well as hierarchy are low (low grid and low group). This is a culture of enterprise characterized by uncertainty and change. Decision making is performed with a minimum of formal procedures, and is based on trust in individual competence. *The egalitarian culture* has a strong boundary to other groups and the outside world (high group). Purity is strived for and outsiders are viewed as threats. The internal differentiation is low (low grid); equality is strived for between positions. *The fatalistic culture* is a residual culture. It is neither individualistic nor collectivistic, but rather cut off (low group). It includes individuals who do what they are told, though without the protection of either social privileges or individual skills (high grid). Those who govern activities and formulate plans for what will happen are always someone else.

Douglas has used this typology to explain the existence and distribution of different risk perceptions (Douglas and Wildavsky 1982; Douglas 1992). The way individuals and groups

react to risks reveals their cultural belongings. Is the reaction about *embracing*, *ignoring*, *rejecting*, or *adapting* (Douglas 1978)? In an uncertain situation of risk, are the possibilities emphasized or the negative consequences? These questions are relevant for all kinds of issues that people see as risks and dangers; they can concern things like nuclear power and biotechnology, but also EU membership and immigration.

In terms of the grid–group typology, Individualists tend to focus on the possibilities, *embracing* risks as opportunities to exploit for personal profit. Fatalists do not know how to react and tend to *ignore* the risks. Egalitarians mobilize resistance in order to *reject* and eliminate the risks. Hierarchical people try to assimilate and *adapt* to the risks through regulation and control of risk activities.

## **Ulrich Beck: The Risk Society and Reflexive Modernization**

Ulrich Beck's (1992) *Risk Society: Towards a New Modernity* – originally published in German in 1986 – is one of the most influential works of social analysis in recent decades. This book is about the reflexive modernization of industrial society. Beck's underlying thesis is that we are not witnessing the end but the beginning of modernity, a modernity beyond its classical industrial design. This guiding idea is developed from two angles. First Beck focuses on the social transformation from an industrial society with its production of wealth to a risk society with its production of risks and social hazards. The other side comes into view when Beck places the immanent contradictions between modernity and postmodernity within the industrial society at the center of discussion. Thus, risk and reflexive modernization are the two – intrinsically interrelated – themes of this book. Beck explicitly states that the aim is to seek “to understand and conceptualize in sociologically inspired and informed thought these insecurities of the contemporary spirit, which it would be both ideologically cynical to deny and dangerous to yield to uncritically” (Beck 1992, p. 10).

Just as modernization in the nineteenth century dissolved the structure of feudal society and produced the industrial society, modernization today is dissolving industrial society and another society is coming into being. This new and coming society is “the risk society,” which is a distinct social formation just as the industrial society was. The risk society differs very clearly from the industrial class society in that it focuses on the environmental question and the distribution of risks instead of the social question and the distribution of wealth. In both types of societies, risks are socialized, that is perceived as a product of political decisions and human action; but in contrast to the risk society, the classical industrial society saw risks as manageable side effects of the production of wealth. These risks were legitimated partly with reference to the production of wealth and partly through society’s development of precautions and compensation systems.

Risk is defined by Beck (1992, p. 21) as “a systematic way of dealing with hazards and insecurities induced and introduced by modernization itself”. The risks and hazards of the risk society are different than in the industrialized society, as they are more widespread and serious. For the first time in history, society involves the political potential for global catastrophes. In the risk society, the relation between wealth production and risk production is reversed. The production of wealth is now overshadowed by the production of risks. The risks produced have lost their delimitations in time and space and consequently can no longer be seen as “latent side effects” afflicting limited localities or groups.

At one level, the distribution of risks adheres to the class pattern, but it does so inversely: wealth accumulates at the top, while risks accumulate at the bottom. Therefore, the risk society could be seen as simply strengthening the class society. However, on another level, this is not true. Today's diffusion and globalization of risks entails "an end of the other"; that is private escape routes shrink (it is impossible to buy yourself free from risks) as do the possibilities for compensation. Thus, risk positions are no longer pure reflection of class positions, but instead they transform and replace class positions. One example of this is that property (such as forests) today is being devaluated; it is undergoing a creeping "ecological expropriation" which implies the emergence of new conflicts between the different interests of profit and property. This means that the central conflicts in the future will be not between East and West, between communism and capitalism, but between countries, regions, and groups involved in primary and in reflexive modernization, the latter being those that are striving to relativize and reform the project of modernity.

Global risks – mega-hazards, to use Beck's term – overlap with social, biographical and cultural risks, as well as insecurities. Today, these latter forms of risk have reshaped the inner social structure of industrial society and its fundamental certainties of life: social classes, familial forms, gender status, marriage, parenthood, and occupations. This comprises the other part of Beck's discussion of reflexive modernization.

The theory of modernization is formulated by Beck as the unleashed process of modernization overrunning and overcoming its own "coordinate system". This coordinate system has fixed the understanding of the separation of nature and society, the understanding of science and technology, and the cultural reality of social class. It features a stable mapping of the axes between which the life of its people is suspended – family and occupation. It assumes a certain distribution and separation of democratically legitimated politics on the one hand, and the "subpolitics" of business, science, and technology on the other.

Today, a social transformation is underway within modernity, in the course of which people will be set free from the social forms of industrial society. This reflexive modernization dissolves the traditional parameters of the industrial society (such as class and gender). This "detraditionalization" occurs in a social surge of individualization, through which a capitalism with individualized social inequality is developing. Here the family is replaced by the individual as the reproductive unit of the social in the life world.

Having discussed this theory of individualization, Beck turns to the role of science and politics in the era of reflexive modernization. He argues that when encountering the conditions of a highly developed democracy and well-established scientification, reflexive modernization leads to an unbinding of science and politics. Earlier monopolies of knowledge and political action are then differentiated.

In discussing science, Beck makes a distinction between primary and reflexive scientification, with the former meaning that science is applied to a "given" world of nature, people and society, and the latter that the scope of scientific skepticism is extended to encompass the inherent foundations and external consequences of science itself. Reflexive scientification thus entails a demystification and demonopolization of scientific knowledge claims. At the same time, the role of science in the risk society is growing. Today's threats are beyond human perception and experience and it is through science that risks become known. Science thus comprises the "sensory organs" for the perception of today's risks. Taken together, these two parallel and different developments do not mean that science has come to an end; on the contrary, it pervades all areas of modern life. Today's science is undergoing a situation of being

dethroned similar to that which happened to (institutionalized) religion. In Beck's secularization model of modern science, the future will bring about a pluralization and a marketization of science.

Beck has been of pivotal importance for sociology, not least by paving the way to make risk a central concern for general sociology. In the wake of *Risk Society*, he has published a number of books in which he further develops his perspective: *Ecological Politics in an Age of Risk* (1995), *Ecological Enlightenment* (1995), and *World Risk Society* (1999). In his later writings – such as *What Is Globalization?* (2000), *Individualization* (2002, with Elisabeth Beck-Gernsheim), *Cosmopolitan Vision* (2006), *Power in the Global Age* (2006), *The Brave New World of Work* (2010), and *A God of One's Own* (2010) – Beck puts more emphasis on reflexive modernization and its importance for all aspects of society such as family, work, religion, and global politics. However, in all his books, irrespective of their subject, the main theme is reflexive modernization and the future development of society.

### Niklas Luhmann: System Theory and Risk

Drawing on Talcott Parsons's social theory, the German sociologist Niklas Luhmann (1927–98) developed a general theory of modern society. The starting point is that there is a fundamental distinction between system and environment and communication is the basic social operation (Luhmann 1984, p. 47). A higher complexity in the environment entails a greater importance for the system to reduce this complexity, otherwise the system will not be operational.

This reduction of complexity is accomplished through functional differentiation, which means that different subsystems develop, each with distinct forms of communication (programs and binary codes). These subsystems are self-referential and autopoetic, which means that their internal orders guide their observations and interpretations and that they are not formed and structured by any external factors.

A subsystem is cognitively open; it is receptive to signals from its environment. At the same time, it is operationally closed. Signals are always transformed into communication through a particular binary code of the subsystem. These codes are abstract and universally applicable distinctions. Science codes a signal in terms of truth/untruth; economy in terms of property/no property; law in terms of legal-illegal; religion in terms of transcendent/immanent; and politics in terms of political power or lack of power and so forth. Luhmann (1989, p. 18) states that:

- ▶ The system introduces *its own distinctions* and, with their help, grasps the states and events that appear to it as *information*. Information is thus a purely system-internal quality. There is no transference of information from the environment into the system. The environment remains what it is.

This does not mean that nothing else exists than social systems and their communicative processes. What it says is that external facts can only be taken into account as part of the system's environment and only be understood through communication. There is no position available outside the system; these facts can only be understood from within (Luhmann 1993, p. 5). It is, however, possible to observe the border of a system, and this is done through "second-order observation" (Luhmann 1993, p. 223). First-order observations identify facts and objects as givens, and do not reflect on the distinction used in the observation. Second-order observation is an observation of the distinction implicitly used in the first-order

observation; it recognizes which distinction is applied in observing a fact or object. Luhmann (1993, p. 227) stresses that second-order observation is not more true or objective than first-order observation. What second-order observation reveals is that there are no objective facts outside the operation of each subsystem. What may seem like an objective fact in the first-order observation (which takes for granted its own distinction), is a product of a particular distinction made in the observation process. Thus, the same event is coded differently by different subsystems.

For instance, the signal from the Tohoku earthquake in Japan, March 11, 2011, that resulted in more than 15,000 deaths and a nuclear disaster at Fukushima nuclear power plant is coded radically differently by different subsystems. The economic subsystem focuses on price mechanisms, economic compensation, and falling prices of shares; the political subsystem on political legitimacy of decisions concerning the location of the nuclear power plants and how the disasters were handled by authorities, but also on the legitimacy of the political representatives that had permitted this activity; the legal subsystems on violations against the given permissions for the plant and the liability of the company as well as political institutions; science on health consequences of radiation exposure for workers and the local population. It is what is communicated that counts. A phenomenon, an event, or an activity can never in itself create a response; it needs to be subject of communication.

- ▶ But as physical, chemical, or biological facts, they create no social resonance as long as they are not the subject of communication. Fish or humans may die because swimming in the seas and rivers has become unhealthy. The oil pumps may run dry and the average climatic temperature may rise or fall. As long as this is not the subject of communication, it has no social effect. Society is an environmentally sensitive (open) but operatively closed system. Its sole mode of observation is communication. It is limited to communicating meaningfully and regulating this communication through communication (Luhmann 1989, pp. 28–29).

Risk is inherently linked to a functionally differentiated society. In contrast to many other theories, Luhmann does not see risk as a result of detrimental activities or as caused by industrial society. Instead, risk is attributed to decision making that may result in negative consequences. Contingency is a central concept for Luhmann, which means that a situation includes a large number of possibilities. To be able to act, it is necessary to choose among these possibilities, but there is no fundamental point – external authority – that tells what to select among the various alternatives. This has to do with the development of the functionally differentiated society.

In contrast to earlier societies, there is no privileged function system in society, which means that a functionally differentiated society has no center. Each subsystem can only refer to its own communication, and only internally can it refer to its environment. Through internal differentiation, the system develops a richer way to manage the complexity of the environment. At the same time, this differentiation results in a higher internal complexity, with different functional subsystems existing side by side and communicating with their own specific codes and with no external authority. Earlier societies' external references (such as religion) are replaced by the social system's self-references in the form of subsystems.

Luhmann defines *risk* as an attribution of an undesired event or possible future loss. Thus, risk is an intrinsic part of a functionally differentiated society. Decisions have to be made without any certainty about what consequences they will lead to. The cause of the damage could either be attributed to the system itself (risk) or something external to the system

(danger) (Luhmann 1993, pp. 101–102). This means that risks concern attribution, which becomes even more clear when Luhmann discusses another distinction, namely, between those who take the decision and those who are exposed to its consequences (Luhmann 1993, pp. 105). Those who take the decision face a risk; whereas those who are victims face a danger, that is, those who perceive themselves as exposed to something that they cannot control. Uncertainty is intrinsic to both risk and danger; the difference lies in who is seen to be a decision maker.

Luhmann (1993, p. 109) stresses that “one man’s risk is another man’s danger” and claims that there is a growing gap between those who participate in decision making and those who are excluded from decision-making processes but have to bear the consequences of these decisions.

Luhmann’s system theory provides an alternative understanding, not only of risk but also of society at large. It sees risk as a matter of attribution and communication, associates it with decision making, sees it as inherently linked with a functionally differentiated society, and strongly emphasizes the distinction between risk and dangers and between decision makers and those affected; and in doing so the theory has both received support and met with criticism (Japp and Kusche 2008, pp. 101–103).

## Thematic Areas

---

There is today an ongoing and lively discussion within the sociology of risk. In what follows, we present five partly overlapping areas of central importance in contemporary risk sociology: risk governance, public trust, democracy and risk, the realism–constructivism debate, and governmentality and risk.

### Organizational Risk: From Risk Analysis to Risk Governance

To conceptualize an object as a risk entails seeing it as manageable and governable (Baldwin and Cave 1999; Hood et al. 2001; Hutter 2001; Lidskog et al. 2009). Risk creates space for action as it opens the future for calculation, deliberation, and decision making. In this sense, regulation “enrolls” futures and shapes policy formulations (Wynne 1996).

Risk regulation is not only about how to govern an existing reality, it also concerns the transformation of this reality, for instance, by dealing with novel forms of knowledge that have not yet been put into industrial practice (cf. Stehr 2005). Regulation does not only concern how to regulate an existing activity, but also how novel knowledge should be deployed and employed.

As shown above, there has been far-reaching criticism of technical definitions of risk, not least concerning the difficulty of upholding a sharp separation between an objective measure of risk and a sociocultural understanding of risk (Hilgartner 1992; Rosa 1998; Amendola 2001; Todt 2003). The critique was initially directed at problems *within* risk analysis, and consequently public perception of risk was seen as a challenge to how risk was defined and approached by technical and calculative means. In the 1990s, however, there was a shift from this internal focus to the broader question of the legitimacy of government. Organizations must ponder not only how to deal with technically defined risks, but also how to deal with

actors who may question both the legitimacy of current methods for regulating risk and the trustworthiness of organizations responsible for this regulation. Prompted by several regulatory failures, authorities and companies have started to account for and deal with public opinion and public perceptions of risks, not only to handle criticism but also to forestall it (Löfstedt 2005). Programs for risk communication, public relations, stakeholder dialogue, and public involvement are today integral to both public and corporative governance (Gouldson et al. 2007). Calls for more inclusive and transparent processes, public dialogue, and democratic engagement are widespread in society (Irwin 2006). A heightened concern for stakeholder involvement and public inclusion can be seen as a strategy to influence perception, shape understandings, and produce legitimacy.

Michael Power describes this shift as a move from risk analysis to risk governance. The “governing gaze” has shifted from how risk is defined, analyzed, and calculated to the governance of the organizations that analyze risk (Power 2007, p. 19). Even though the call for a more inclusive risk analysis and risk management may have evoked some response from regulatory agencies, it has not directly led to more inclusive and deliberative risk regulation processes. Rather, the shift from risk analysis to risk governance has increased the awareness of how organizations deal with public opinion and public perceptions as a source of risk in the sense that such perceptions could pose a threat to the legitimacy and stability of existing ways of governing risk (Power 2007, p. 21). This justifies research on how organizations deal not only with technically defined risks but also with the actors they perceive as possible threats and potential risks to the stability of the organization.

Risk regulation does not only concern what is acceptable in terms of how we should mitigate or accept certain risks and hazards, but also rules regarding the process itself and activities that target the understanding of risk and deal with public opinion and perceptions concerning it. Thus, risk governance is not limited to technical calculation of risk, but also includes the evaluation of organizational aspects in regulation of risk.

With a focus on risk governance, that is how uncertainties are organized in order to transform them into governable risk, the questions of who should be involved or excluded in risk regulation processes, on what grounds, and what aspects should be made open and transparent to others, gain greater relevance due to the legitimacy gains and losses such decisions may generate. A heightened concern for public involvement in regulation can thus be seen as “a strategy to govern unruly perceptions and to maintain the production of legitimacy in the face of these perceptions” (Power 2007, p. 21).

## **Public Trust: The Relation Between Experts and Laypeople**

Technical risk analysis builds on a sharp boundary between experts and laypeople. Laypeople do not have access to all the knowledge possessed by experts and therefore draw different conclusions about risks, their ordinariness, magnitudes, and impact. In technical risk analysis, scientific knowledge is the norm and this is what experts have but laypeople lack. This difference is what motivates the concept of lay knowledge, of not being an expert. Focusing on what laypeople lack constitutes the basis for *the deficit model* mentioned earlier in this essay (Irwin and Wynne 1996). According to this model, the solution is to inform and educate laypeople in order to give them the capacity to gain correct knowledge and thereby arrive at the same conclusions as experts. Risk psychology and risk communication originally developed as

academic fields with the aim to understand how laypeople reason about and assess risks in order to learn how to effectively communicate correct knowledge to this group.

The deficit model has been heavily criticized, not least by researchers in the field of science and technology studies (STS) (Wynne 1995; Irwin and Wynne 1996). These scholars argue that the most important problem is not that the public is unaware of research results and scientific facts, but that scientific experts are unaware of and disinterested in lay knowledge and how laypeople assess the situation when decisions are to be taken on complicated risk issues. Consequently, the problem is not that laypeople lack knowledge or lack trust in expertise, but that experts in technical risk analysis do not trust laypeople. Laypeople have the competence to contribute to discussions and decisions on risks, since these concern much more than scientific facts. If grasping scientific details becomes the most important requirement for participation in risk discussions, the relevance of scientific knowledge becomes heavily exaggerated (Irwin and Michael 2003, pp. 22–28). Despite their lack of scientific knowledge, laypeople are competent actors with developed abilities to reflect on what types and sources of knowledge are of relevance to both risk analysis and risk assessment and why some experts should be more trusted than others.

Today, public involvement is often devoted much attention, but there is a tendency to frame this involvement from a technocratic understanding based on the deficit model (Irwin 2006; Lidskog 2008). In this way, broadened participation gives experts further possibilities to inform the public with the aim of winning acceptance for already proposed decisions. This instrumental ambition can be found in every participatory project, because there are always groups who strive for a specific outcome of the process. Studies have found that when laypeople are not considered competent to influence the decisions – when they are taught instead of listened to – the result is often one of alienation rather than engagement amongst the public (Wynne 2001).

Problems arise when such an overconfident and self-sufficient expert culture tries to communicate the benefits of a risk project. This culture is not interested in reflecting on its own shortcomings, and criticisms from laypeople are understood as based on their not understanding what is best for them (Wynne 2001, p. 447). If expert cultures wish to increase their legitimacy and appear as trustworthy to the public, they should instead be less confident about their own results and open to acknowledging their own limitations.

It is, however, not only uncertainties to which attention should be given attention, but also ignorance. Scientific knowledge is strongly specialized with a narrow focus, which implies that complexities are reduced and alternatives are actively deleted. In order to increase the trustworthiness of scientific knowledge, it is important to make visible the conditions of scientific knowledge production and risk assessment. The implication here is that scientific knowledge alone is not enough when deciding about complicated risk issues. It must therefore be enriched by other types of knowledge, as well as by other perspectives in order to give a more complete and nuanced view of the risks at stake.

The alternative to the deficit model and a technocratic framing of risks is to include a broader understanding of participatory processes, one which acknowledges that other actors than scientific ones can contribute knowledge on risk and therefore should be given possibilities to influence the regulation of risks (Funtowicz and Ravetz 1990; Lidskog and Sundqvist 2011). Hence, questions concerning who formulates the issue, sets the agenda, and exercises power become important. However, this does not mean to replace blind trust in experts with blind trust in laypeople. To draw clear boundaries between experts and lay people and grant

one of these priority over the other is not the right way to proceed. Instead it means that the public *always* has important contributions to make in technical discussions on risk issues. These contributions should never be evaluated from the deficit model for the reason that they are not about scientific facts, but about how to assess the relevance, trustworthiness, and ignorance of scientific facts. This kind of public competence, which emphasizes the contextual dimension of science, can always enrich scientific knowledge (Wynne 1993, p. 328).

The public can also contribute knowledge and insights about what they are worried about (Marres 2007; Sundqvist and Elam 2010; Lidskog 2011). This knowledge as well as the assessments made by members of the public are anchored in their livelihoods. Experts and authorities are often completely unaware of the reasons for ordinary people's worries, and it is therefore of great importance to involve concerned groups in decision processes in order to include relevant experiences. Experts and decision makers need to improve their awareness of how worries are the driving force of public engagement and that scientific knowledge rarely is an adequate response to these worries.

## Risk and Democracy: The Importance of Framing

How risks are defined is a central topic for sociology to study. The reason for this is that it determines what groups and what competences are considered relevant for taking a stand and making decisions (Lidskog et al. 2011). Sociology contributes to risk analysis by showing how definitions of risks shape social relations and distribute powers to groups, at the same time as other groups are excluded from decision making. In a risk context, a scientific definition of the issue at stake is often assumed. However, such a restriction may lead to reductionism, giving experts too much power, while rendering other important factors invisible. Laypeople are reduced to passive receivers of information who only can contribute their trust and consent regarding expert proposals (Wynne 1992b; Wynne 2001).

Sociological studies of expert work do not conclude that risk issues should be handled without experts. What is claimed is that experts alone should not define, investigate, and give answers to risk issues. Risks are too complicated to be delegated to experts. Sociological studies of the social dynamics in definition of risks are valuable for making risk management more relevant and robust. Not least to show how definitions and processes of framing are made and what consequences these processes have for different groups' possibilities to participate in and influence risk management.

Regulating a risk is not only about setting limits, but also about framing the risk as such, deciding what actors are of relevance and should be included in the decision process, what roles, mandates and responsibilities are given to them, and finally and most importantly what to make decisions about (Lidskog et al. 2009). Sociologists and other social scientists have critically scrutinized framing processes in public decision making, and a key finding is that frames concerning technical issues are usually dominated and influenced by experts in a technocratic way (Wynne 2001, 2005). By narrowing the issue, scientific experts exaggerate the scope, power, and importance of scientific knowledge in the public domain, neglecting cultural factors and ignoring citizen competence (Wynne 1992b; Wynne 2001; Jasianoff 2010). Paradoxically, science is often accorded the most prominent role even when public dialogue is striven for. A reason for this is that many issues are technically framed, with questions of risk, safety, and effectiveness placed at the center (Wynne 2005, 2010). Scientific expertise is needed

to answer such questions, since experts have the resources and competence to know the “true” nature of the issue at stake.

The result is that what is presented as a democratic risk decision process is often a technocratically framed process based on a scientific definition of the risk. The public are invited to participate in a process that is often presented as being about dialogue but the possibility to influence the process according to their own perspectives is often unclear, and in practice very restricted. These processes do not open up decision making to wider evaluation and influence, but instead function to gain legitimacy and acceptance for already defined – and many times in practice already decided – expert-based proposals.

A technocratic framing reduces the role of citizens to one of trusting or distrusting experts; to saying yes or no to already decided proposals and to being restricted to only discussing the local and concrete aspects of a project. Instead, they should be provided with opportunities to define and frame the project in their own way, putting forward what risks they see as relevant and worthy of attention. Sociologists have argued that the discussion should not only include the meaning of the project and its risk from the perspective of the experts and regulators, but also from the perspective of the public and other stakeholders (Gieryn 1999; Hilgartner 2000; Irwin and Michael 2003; Jasianoff 2005; Wynne 2005).

Since there is no correct framing of risk issues, risk management will always be surrounded by conflicts. Different groups frame problems differently and give them different priorities. Sometimes it is the case that what one group considers to be a solution to a problem, another group considers to be part of the problem. Some suggest that nuclear power is a sustainable energy solution, because it does not lead to carbon emissions, while others argue that the radioactive waste makes it anything but a sustainable and secure long-term source of energy. In this situation, the option of denying the existence of different frames is a dead end. Instead, the first step toward a robust solution is to acknowledge the existing frames and welcome different groups to contribute their own perspectives, using their own frames, knowledge, and values. Frequently, this opening up of the framing is met with criticism and opposition from those groups that are already handling the issue from a particular frame. They have invested time, money, and prestige in the project and are therefore reluctant to change the established framing of the issue and its particular way of handling it. But taking public involvement seriously entails a more democratic framing of issues, in the sense that issues have to be connected to public concerns (Marres 2007). If we are to find a way beyond pendulum swings between technocracy and populism – that either scientists or laypeople should decide – various groups of frames must meet on a more equal footing.

## Produced Risk: Beyond Realism and Constructivism

An ongoing controversy in risk research is between realism and social constructivism. Do risks possess physical characteristics that exist independently of cultural and social contexts, including actors' perceptions, or are they socially and culturally constructed attributes, produced and shaped by these contexts? Technical risk analysis is based on realism, and sees risks as independent of their context. As described earlier in this essay, many social scientists and sociologists accept technical risk analysis and its realism, but add studies on why the public accepts some risk analyses and rejects others. The public's risk assessments are understood as social constructs, whereas experts' risk assessments are seen as realistic descriptions. But among social scientists, we also find

those who question the realistic approach and consider it wrong. Instead, they want to go beyond this dichotomy in order to find a middle ground between realism and social constructivism. Many scholars claim that there is a third way between “naïve realism,” and “idealism” (Renn 2008), positivistic and constructivist paradigms (Rosa 1998), and “pure realism” and “radical constructivism” (Zinn 2008). The first implies the existence of an empirical and objective reality outside human perception, and the latter a subjective and cultural understanding shaped by humans and with no necessary connection to an objective reality.

However, the quest to find a middle way, or third way, between subjective and objective reality – between something internal and something external to human beings and society – reproduces what it tries to transcend. The first is based on causal laws of material reality, and the second, on a social world of opinions and norms. This point of departure is questioned by certain sociologists, claiming that the focus should instead be on the dynamic interplay between different factors that make up reality (Irwin and Michael 2003; Latour 1993, 2004, 2005). Reality is neither reducible to something out there, beyond human action, nor reducible to something in there, to human thoughts and actions. Instead it is co-produced by many factors.

However, social constructivism has been and still is an important tradition within the sociology of risk. Its historical roots go back to classical sociology, not least the work of Émile Durkheim (1858–1917). Durkheim elaborated a unique domain for sociology by demarcating a social reality totally different from that of biology and psychology. “The social” – or social facts, as he called it – is a reality in its own right, irreducible to other levels of reality (Durkheim 1982). The task of sociology was to explain social facts, and these explanations should not include any findings or factors from the psychological (individual) level or the biological level. The result was a specialization and division of labor among academic disciplines, where every discipline has its own domain and unique explanations. This understanding of sociology entailed that everything that exists outside the social domain was disregarded. The social domain was considered autonomous with regard to other domains.

The implication was that when analyzing risk, sociology should study people’s interpretations and experiences of these risks, and how these are bound to social structures that steer perceptions and actions. Material objects and technical artifacts were left outside the analysis, and seen as not having any power to influence what is taking place in the social domain. Experiences of risks should not be explained with reference to nature or artifacts, but only social factors. For example, when sociology explains people’s worries about nuclear waste, the focus should not be on the strength of the canisters as a technical barrier to protect the biosphere from radioactivity, but on people’s opinions about these barriers and how these influence their assessment of radioactive risks. Thus, the objects of sociological analysis are perceptions, interpretations, and socializations to social patterns of risk attitudes toward radioactivity and disposal of nuclear waste.

This sociological purification of a social dimension has been successful in so far as it has created a distinct niche for sociological thought and provided important knowledge concerning how people perceive, understand, and act upon risks. Nevertheless, its strong separation between nature and society, with sociology only investigating the latter, is problematic. This strong focus on the social dimension has led to a paradoxical understanding of nature and artifacts, which Bruno Latour (2004, p. 33) has aptly described as follows:

- ▶ Those who are proud of being social scientists because they are not naïve enough to believe in the existence of an “immediate access” to nature always recognize that there is the human history

of nature on the one hand, and on the other, the natural nonhistory of nature, made up of electrons, particles, raw, causal, objective things, completely indifferent to the first list.

The consequence of social constructivism is that we, on the one hand, find a society with a history and on the other a nature without history. Latour is critical of this kind of approach, which leaves important aspects of reality outside sociological analysis. According to him, the task of sociology is to transcend both realism and social constructivism, a task that necessarily entails that dichotomies – such as those between nature and culture, social and technical, actor and structure, science and society – be critically studied and not taken for granted. How and why these dichotomies are produced and reproduced should also be explained.

Latour's proposal for transcending the dichotomy between realism and social constructivism is to focus on the *production of risk*. Risks are produced by practices, by actors using instruments and technologies. It is therefore misleading as a sociologist to focus on perceptions, opinions, and experience. Instead, the focal point for sociology should be to explore how risks are produced, by what means, and with what effects. The focus on practices means that there is no “real risk” behind our perceptions and actions. There are no risks separate from actors and society, possible to observe by actors. Instead, there are a number of actors and activities where nature, technology, and culture interact, resulting in the production of risks. There are no risks beyond socially produced risks, that is, beyond the measuring and monitoring of risk. Through these practices not only knowledge about risks is produced but also the risks as such. Thus, practices are performative; they not only describe reality but also shape it. By studying these practices, sociology can transcend the dichotomy between realism and social constructivism.

## **Governmentality: Toward an Individualized Risk Management**

Ulrich Beck emphasizes that the current society is increasingly individualized, in the sense that individuals are seen as being responsible creators of their own lives and are therefore constantly required to make their own decisions. “The choosing, deciding, shaping human being who aspires to be the author of his or her own life, the creator of an individual identity, is the central character of our time,” as Beck (2002, p. 23) puts it.

This individualization, however, does not necessarily mean the achievement of greater personal freedom. Beck grasps this development with the term “institutionalized individualism” (Beck and Beck-Gernsheim 2002). At the same time, as nation-states have outsourced many of their functions and operations, there is an insourcing of functions to the individual level. What the nation-state, the employer, the union, or the family once provided is now presented as being the responsibility of the individual. Thus, individualization in this sense does not mean freedom of choice, but instead the compulsion to choose in a situation where no certainties exist. It is a “precarious freedom” centered on imperatives such as think, calculate, plan, adjust, negotiate, define, and revoke (Beck 2002). But even though we often lack knowledge of what choices are best, it is demanded of us to make individual decisions and be responsible for the consequences.

There is a tension between institutionalized individualism and the risk society thesis about mega-hazards beyond human control. According to Beck (2008), the government of incalculable risks and mega-hazards leads to the irony of putting an end to the free liberal society in the ambition of protecting citizens from risks. At the same time, individuals are continuously ascribed responsibility for risks that are impossible for them to manage.

However, a certain strand of sociological thought, following Michel Foucault's (1991) work on governmentality, cultivates a perspective that takes neither individualism nor the character of risks and the risk society for granted. Instead they argue that risks should be conceptualized and understood as a way of steering practice. The task of sociology is to study how, through technical apparatus and administrative institutions, incalculable dangers are made into knowable and governable risks. Risks become a way of ordering reality and making it calculable, and expert knowledge is decisive in this (Rose 1993; Dean 1999).

Instead of making use of coercive power, the government can steer through norms, knowledge, and individual self-discipline. The reason for this is that we have today an "advanced liberal society," based on a clear division between the state and the civil society (Rose 1996, 1999). Civil society has emerged as an autonomous sphere in which individuals can express themselves as free citizens. In protecting this autonomy, coercive means of governmental control are precluded, which means that more sophisticated instruments and mechanisms need to be developed, technologies for governing at a distance (Rose and Miller 1992).

This way of exercising power, in which those who are controlled feel autonomous, is based on tools for the self-development of those who are governed. The responsibility is placed on citizens to govern themselves, to act upon themselves, and be responsible "for the security of their property and their persons, and that of their families" (Rose 1999, p. 247). An almost paradoxical relationship is created between the state and the civil society, in which the exercise of power is conducted with the goal of not being visible. It is characterized more by bringing citizens to perform a regulated freedom than by imposing on them coercive measures (Rose and Miller 1992, p. 174).

The strong emphasis on individuals as being responsible governors of their own lives creates dilemmas. Increasingly, individuals have to face and make decisions on a range of issues characterized by uncertainty. An example of this is how genetic risks are governed with the aim to improve the quality of the population. During the development of the welfare state, it became an important task for the government and the public administration to guide, control, and intervene in the reproduction of the population, but today these decisions are delegated to individual citizens. The problem is no longer framed as improving the quality of the population but as a question of individual lifestyles. Today, reproduction is about promoting the self-governance of the client (Novas and Rose 2000). The responsibility to govern genetic risks – to decide about having children and informing others about one's own genetic risks – has been made into a lifestyle choice. However, plenty of experts are willing to give advice on how to make your own lifestyle possible, and guide your choice in certain directions.

Risks thereby constitute a strategy for disciplinary power to monitor and govern individuals and thereby whole populations (O'Malley 2008). Those individuals that deviate from what is presented as normal behavior are seen as "at risk," and need to be controlled with the aim of achieving behavioral modification. This control is primarily that of self-management, with individuals being urged to protect themselves from certain risks (Giddens 1991). Risks are thereby de-socialized, privatized, and individualized; they become a responsibility of the individual, and a way for government to govern the conduct of individuals. The sociology of risk should therefore be devoted to studying questions about how problems are defined, by whom and in relation to what goals, and through which practices, technologies and rationalities this governing is accomplished and authority exercised.

## Further Research

---

As emphasized in the introduction, the specific contribution of sociology of risk is to place risk in its social context. There are no risks “out there” in the sense of being independent of the society in which they emerge, are measured and monitored. Society is differentiated, which means that cognitions, understandings, and feelings of risks are differentiated. Actors – including scientific ones – have various structural positions and cultural belongings and therefore understand risks differently. To develop sociological knowledge on risks implies to contextualize risks; to associate them with specific actors, institutions, and settings. This means that no conceptualization, regulation, or research on risks is beyond sociological exploration; and furthermore, scientific definitions of risks and technical risk analysis should be proper study objects for sociological investigation.

This does not imply a reductionism and relativism, seeing different actors’ understandings of risks as all that exists. On the contrary, risks should be understood as produced through social activities where nature, technology, and culture interact. Sociology of risk should not be restricted to investigating risk perceptions, but should also study definitions and usage of risks, including how different actors deal with risky nature and unruly technologies; how these are framed and regulated, and as a consequence of these activities, produced.

The five thematic areas described above have by no means been given a final answer, but are in need of further research. As already emphasized, these areas are interrelated; organizational aspects of governing risks, public inclusion in risk regulation, framing and production of risks, and the monitoring of individuals’ risk behavior are interconnected. As with many other disciplines, sociology consists of different theoretical traditions, methodological assumptions, and analytical approaches. Therefore, it will never be able to give simple, single, and final answers to complex issues, and the sociology of risk is no exception of this. It is, however, able to gain knowledge on important topics, and while not producing final knowledge at least it may produce more and better knowledge – theoretically informed and empirically sensitive – on the function and place of risks in different social settings.

Studying processes of risk assessment and risk management, the sociology of risk could make important contributions to preparing and realizing a political and democratic discussion on risk issues, controversial as well as uncontroversial. By identifying and clarifying the political aspects of these objects, making frames and framing processes visible, and showing how technologies and political devices are embedded in social processes, it opens up risk regulatory processes for public scrutiny and evaluation. What may originally be framed as technical issues, only relevant for a specialized group of experts, will thereby become relevant for citizens. Risk regulation is about more than just choosing the best regulatory instruments and finding the best technical solutions to predefined risks. It concerns building society and choosing a future.

**Abstract:** Through history and in most cultures differences between men and women have been observed and expressed in various ways. Also in our society differences between men and women are evident and this becomes particularly clear in the context of risk perception. This chapter will present three models that are found in the research literature that aim at explaining these differences. The first model focuses on differences due to knowledge and familiarity with science, including trust. This model however, fails to take into consideration the distinction between estimated knowledge and factual knowledge, making it difficult to understand exactly what role knowledge plays in risk perception. Second, differences between men and women have also been explained by biological mechanisms or social roles. Here it is believed that women are more nurturing by nature and men are more driven toward growth and expansion. It is argued that it is of limited importance whether these differences are biological or social, as it will have little bearing on the management of risk. The third explanation focuses on cultural differences and uses examples from disaster management. Here it is concluded that women are by social processes most often excluded from the areas where risks are created and managed, and suffer the consequences from this lack of influence in disasters. The chapter concludes with three suggestions for future research.

## Introduction

---

How risks are perceived depend on a number of things: for example, how old we are, what experiences and education we have, and if the risk is taken voluntary or not. One way of looking at the perception of risk is to focus on specific characteristics of the risk itself: if it is a novel risk or a risk that is perceived as unfair. Also the consequences of the risk influence risk perception: if the consequences are irreversible rather than temporary, chances are measures to strictly regulate this risk will be taken. Our individual differences and preferences also affect how we perceive risks: which risks are worth taking, which are not, and how risks should be managed are all affected by individual differences. These variations in risk perception can be due to differences in age or education, personal experiences or nationality. In many contexts, differences between men and women how risks are perceived and acted upon are found. For example, it is a common result that men score lower on risk perception scales than women. Also, women express more concern for the environment and state to be more willing to take steps in order to improve the environment than men do. Some theories have been suggested to explain these differences. Some state that women are by nature more nurturing than men, making them biologically wired to be more risk averse. However, the differences between men and women are not consistent in all studies of risk. This lack of coherence suggests that either differences between men and women are not stable or predictable, or that questions relating to risk are so complex that simple dichotomies between people are not good explanations. Other theories suggest that differences between men and women are cultural, rather than biological, and that gender differences should be examined from a perspective that includes issues of power, stereotypes, and influence. In this chapter, I will focus on differences between men and women found in studies concerning the perception of technical and environmental risks. These differences are most often observed although not always explained, but a few models that have attempted to explain these differences will be discussed. The chapter continues with a discussion of current research and ends with some suggestions on future directions.

Before moving on, I will attempt to position myself on the risk field. In most contexts, there is a division between different types of risks. There are those risks that we are exposed to on an everyday basis. These types of risks include getting hit by a car while crossing the street or falling off a chair while changing a lightbulb. Close to this category are the risks that we face as a result of individual choices in lifestyle for example smoking or making specific dietary choices, or engaging in more risk-filled activities such as driving recklessly, skydiving, and base jumping. Differences between men and women in this category of risks – both with regard to perception and behavior – will not be addressed at any length in this chapter, even though gender differences are observed here (see, e.g., DeJoy 1992; Andersson and Lundborg 2007; Deeks et al. 2009). Instead, this chapter will focus primarily on risks that are imposed on us, where the options for personal control and opting-out are limited. Yet another line that divides different risks is the cause or origin of the risk itself and this can also affect perception. For example, even if the consequences are the same, such as number of injured or exposure to chemicals, the reactions will be vastly different if the risk is caused by an unforeseen accident or because of neglect (see Weisæth et al. 2002; Wester 2009). In this chapter, this will not be of specific focus, even if the effect of cause or origin of risk and how this links to gender still needs further research (Finucane et al. 2000). The concept of risk will be used in a very wide context with the full understanding that risk is a multifaceted and complex concept. However, the main focus here is to account for differences in perception between men and women, and what implications this has for risk management.

## History

---

The distinction between men and women as fundamentally different beings is certainly not a novel concept. Early records reveal that Aristotle suggested that a woman actually is a man that had failed to develop to his full potential (Horowitz 1976; Merchant 1980). This division between men and women was not just a mere observation but also included values: masculine characteristics were more highly valued than feminine attributes and traits. In Aristotelian time, free men were regarded as superior to women and slaves, thereby consolidating the differences and values associated with them (Horowitz 1976). Treating men and women differently is not unique to western societies. Anthropological studies have revealed that men and women have not only been perceived as distinct from each other in other cultures, but have also lived separately. With the first ethnographic field studies in the nineteenth century, ethnographers discovered that in some parts of Papua New Guinea, for example, young boys are moved from their mothers home around the age of seven and moved into the men's house. In this house, boys would grow into full men under the supervision of other, older, and initiated men and into this house women were not allowed (Keesing 1981; Kulick 1987). This division between men and women is not limited to them living in different areas; it has also lead to a division of labor in most cultures. Caring for children and performing domestic chores and small-scale agriculture have traditionally been the domain of women, whereas men have primarily performed their duties outside of the home. In our Western society, differences in distribution of men and women in different areas are clearly visible. For example, science and technology have long been areas where men have outnumbered women, whereas occupations in the service or public sector, female employees are in majority. This separation between men and women in the workforce corresponds with unequal representation in various

fields of education. This division of men and women is found in many levels of society such as differences in academic degrees, differences in wages, and an underrepresentation of women in executive positions. Given this division of gender, it is not surprising that there will be differences between how men and women perceive and relate to the world.

Still today, the view of men and women as different from each other is apparent in many contexts. Even if it is recognized that women and men are not entirely different species, popular books like “Men are from Mars, Women are from Venus” make it clear that there are differences between sexes that need explaining. The word processing program used for composing this contribution defines “female” as: feminine, motherly, and soft, whereas “masculine” is defined as: virile, manly, brave, and proud. Even though there has been a shift in language from “sex differences” to “gender differences,” implying that focus is not so much on biology as it is on social role, men and women are still perceived as separate from each other. No longer reduced to biological creatures, the function of estrogen and testosterone is still widely held to affect not only the physical development of sexes, but also to influence preferences or specific behavior. However, it is becoming more widely acknowledged that specific behavior relates as much to stereotypical roles as they do to biology. Early in childhood, we learn what it means to be a boy and to be a girl. How these stereotypes are internalized and develop are of course complex matters, but research suggests that children as young as 3 years old realize that men and women are different, and some suggest that as early as between 2 and 4 years of age, it is clear to both girls and boys what is expected of them and others as gender-specific behavior (Bem 1983; Weintraub et al. 1984). Even though the concepts of what is male and female differs over time and within cultures, it might be safe to say that most of us do incorporate images of what it entails to be a man or a woman into our way of thinking about the world and how it works. This also means that we learn how to behave in accordance with the gender roles – whether we agree with them or not. Within social psychology, most scholars agree that differences between men and women in many areas are the result of placing men and women in stereotypic roles and ascribing typical attributes to individuals based on their gender (Eisler et al. 2003). Now, in order to navigate a complex world as the one we live in, there are situations where relying on stereotypes makes life a bit easier. For example, when we meet a new person we rely on known rules of engagement for that situation: we shake hands and introduce ourselves in a given order. There are also situations where we encounter groups of people; like students, tourists, or costumers, we expect these encounters to follow a certain pattern. Any breaks with the norm can cause us to reevaluate something taken for granted, which leads to us having to change our preconceived ideas and question our perception of the world. The implication of this is that we often have a tendency to rely on stereotypes and to do what is expected of us. An obvious question is how this internalization of specific roles affects us throughout our lives, what education we choose, what we expect from others, and how these differences are linked to how we perceive the world. The focus in this chapter is how the differences in gender affect risk issues. More specifically, this chapter will focus on what implications differences between men and women have for shaping risk perception and what measures are taken in order to address some of the risks that we face. For this purpose, the role of potential variations due to biological differences is not important. For the purpose of the argument presented here, whether the differences between men and women are caused by biology or social processes is subordinate to the discussion of what the implications of these differences are. In other words, it does not matter if testosterone makes men behave in a certain way or if this behavior that we associate with the male sex is learned behavior. This is because in

the context of risk perception and risk management, using biological differences as a reason for prioritizing the view of one group over another is not a legitimate reason. In this chapter, issues that influence the perception and acceptance of genetically modified organisms (GMOs) or measures taken in order to adapt to climate change and the levels of testosterone or estrogen in individuals are of limited interest.

In an overwhelming majority of empirical studies on matters ranging from environmental risk perception to risk-taking activities, there are systematic and consistent differences between men and women. In this context, one legitimate question one might ask is “so what?” What does it matter if we think that women are more emotional than men; that boys are louder and fight more than girls; or that women are biologically wired to care for children? If we are free to decide on the content and direction of our own lives, the stereotypes will not affect me or my family – so what? This attitude could be true if we lived our lives in isolation or a social vacuum, but most of us do not. When differences between men and women are expressed systematically, it means that men and women have different views of risks in a general sense and this is not a result of a single study or single fluctuation. Systematic differences between any two or more groups are results of a stable and reoccurring factor that affects both groups to an extent that is measurable over time. This includes differences in opinion on which risks are perceived to be acceptable, how benefits are valued, what risks are to be avoided, and how resources should be allocated in order to mitigate specific risks. In these cases, we have to choose one view over another and act in line with that decision. As the review of research literature and discussion in this chapter hopes to illustrate, is that the dominant view of risks is more aligned with the perception that men hold rather than the view that women have, and by choosing this we run into issues that need to be addressed. Of course, choices need to be made and priorities set, but in a democratic society, one groups’ perception cannot systematically be the dominating one. Just like the biological claims of racism are acknowledged to be unfounded, and discrimination against individuals because of race or ethnic belonging is not accepted, so is sexism recognized to be unjust and morally questionable. This is not the same as saying that there are no differences between men and women, or that men and women as groups are internally homogenous. However, there might just as well be differences between tall and short individuals, or between individuals that prefer yellow cars to green cars, but these are questions we rarely ask.

Sociologist Ulrich Beck claims that we live in a risk society (Beck 1986). In the risk society, citizens are faced with risks that are produced as a direct of modern technology and these risks often elude our senses. As most individuals do not have the means to detect, for example, radiation or the presence of hazardous chemicals in our food or water by using our sight, smell, taste, or touch, these “new” and invisible risks that ordinary citizens are exposed to but cannot detect are heavily dependent on science, both for the detection of and management of risks. This means that risks become known after an adverse effect has already been identified, that individuals have already become ill from eating contaminated food, or that we can see the negative effects in nature. If we accept that we live in a risk society, differences between men and women cannot be fully understood unless risks are seen in this broader context. Some would argue that risks are “out there” in the natural environment for the scientific community to discover. Other scholars argue that risks are socially constructed and contain as much social elements as technical ones. Whatever perspective one chooses, and perhaps a middle ground is to be preferred, the first step in discovering (or creating) a risk as the risk identification. Once we have identified a risk, a hazard assessment needs to be done. In this step focus is on

what the danger is, who or what is exposed to the risk, and what consequences this can lead to. After this, policy decisions have to be made and priorities have to be set. Risks are not distributed fairly and as a society we make decisions on what risks we are willing to accept and what risks are to be avoided at all costs. The process of identifying and deciding what risks to avoid has traditionally been a technical task that requires knowledge in technology and the natural sciences. Compared to 150 years ago, the risks we face today are vastly different. There are risks that we cannot see, taste, or smell, and in order to detect these risks, special tools and knowledge are needed. The consequences are also different today: One failed crop for a family in a small community would strike hard at that family; one failed crop for a multinational actor can have effect on the international price of grain on the global market. If we accept that risk society has made us dependent on experts that possess the knowledge and have access to the tools needed to identify and assess the risks we face, then we must take a closer look at who are included in this group and examine their risk perception. The process of risk management can in short be seen like this: there are risks in our society that are known but also some that are unknown. In order to determine what risks we need the most protection from, some priorities have to be made. This setting of priorities is the first instance where we have to choose what to protect. One example of this can be a choice between prioritizing human health or the environment, where different values or preferences act to guide our decision. As can be seen in controversies over certain risk issues, environmentalist groups can have a different set of values than the local environmental protection agency and this might cause conflict between the two views. Once a risk has been identified as something that needs further investigation, the process of risk assessment starts. Here, what is dangerous is determined and at what levels. In this process, there is a need for experts in various fields that will be able to contribute specific knowledge on a variety of issues including hazard identification, dose-response ratios, and calculating exposure scenarios. These steps of the process are fairly technical and the individuals that have access to the information in this stage of the process are often scientists working in labs. Once the risk has been assessed, now comes the time to decide how this risk is best managed. In this stage, the risk has left the lab and is increasingly becoming an issue for regulators and policy makers. In this stage, questions on how best to avoid, reduce, or accept some of the negative possibilities with the risk arise. When the risk management has reached this stage, there can also be great differences in how different groups view what resources should be put toward certain risk mitigation and what constituted an acceptable risk. In this context, it becomes clear that the risk identification process and the decision on the distribution of resources are related to issues of power and political influence (see Slovic 1999). Looking at what individuals that are involved in various stages of the process, there is a need for natural scientists, engineers, and medical experts. At most universities, women are a minority as students of engineering and natural sciences and this creates an unbalance in the distribution of gender in the expert groups. In the risk society, the experts that are called upon to make risk identifications, risk assessment, and handle risk management are predominately male. But the differences do not stop at this end of the risk management spectrum. In most risk research studies, women express a higher risk perception than men and also report being more willing to take pro-environmental action, indicating that men and women not only have separate views on risks, but also choose different ways of dealing with risk issues. Differences in perceptions of risk between men and women are observed in the majority of studies, but the reasons for these differences are rarely discussed and the implications of this discrepancy on a management level have received limited attention.

In this chapter, these issues are among those that will be expanded upon. The source or cause of the risk treated here are those risks that are dependent on or created by science and technology, where environmental risks are included.

## Current Research

---

Risks are central to our lives. It can be argued that without risks, there can be no growth. When we subject ourselves to risks, it is done in order to gain or benefit something. As societies have changed, so have the stakes. The risks we create today can have consequences that are not immediately visible, that might manifest in an unforeseen place and manifest in way so the consequences are irreversible.

In the field of risk perception, social scientists have worked for many years to increase our understanding on how different groups in society view risks. Some would say that as our society has grew more and more complex and the identification and management of risks issues have become primarily a scientific task, the differences in opinion between different groups have become more apparent. It might be important to point out that risk perception does not translate into fear or worry. Instead, a high-risk perception can be interpreted as a strong reaction toward a risk, a stronger desire to have that risk regulated or an increased concern over possible consequences of a risk. Risk perception does not necessarily measure an emotional reaction to a risk, even if there are examples of this. Instead, in this context I would like the reader to interpret the term “risk perception” as an opinion or reaction toward a risk. This reaction can be based on many things; such as moral considerations, personal control, ability to take action, or demands for stronger regulation, or outrage, but fear or worry is not the primary experience. Today it is more the rule than an exception that risks are debated and differences in opinion are voiced. There are many factors that influence the way we perceive risks. Some factors that influence risk perception of technical, or man-made risks, can be said to be perceived benefits, acceptance of a technology, and trust in the institutions that regulate the risk (Davidson and Freudenburg 1996; Siegrist 2000). Age is one example, where differences between generations are found on most risk issues. In some cases the younger generation is more risk averse, whereas the older generation sees a risk as less threatening, and in other situations it is the other way around. Education and experiences also influence how we view risks, and linked to this are values and ideologies. For example, if a student chooses to study nuclear physics, chances are that this student will pursue a professional career in the nuclear energy field. It is unlikely, but not unheard of, that a person will spend years in training to a substantial financial cost, only to end up working in a field that deals with a form of energy production that this person opposes. In this regard, education is linked to values, and in some cases values are reflected in ideology. Continuing with the example of nuclear energy, the implications this will have is that the probability of a person working in the nuclear field that at the same time opposes this technology is quite low.

Differences between genders are found in the majority of studies that investigate risk perception. Women express a higher risk perception for most risks we face, compared to men. From the available research, three models or strands can be identified to explain gender differences (see Davidson and Freudenberg 1996; Blocker and Eckberg 1997). These three models offer different explanations for understanding these differences and they are: differences in knowledge and familiarity with science including issues of trust; differences in risk

perception biological or social differences; and issues relating to cultural differences. It could be argued that differences due to biology or social processes should be treated as separate models. However, it has previously been argued that for the purpose of this chapter, whether these differences are socially constructed or in some manner appear “naturally” because of biological factors is not interesting. What is interesting however is how differences in risk perception are expressed and how this affects risk management in a larger perspective. If we were to acknowledge and accept that there are differences in perception between African, Asian, and Caucasian groups because of race and we would accept one groups’ perspective as superior to the others, we would (correctly) be accused of racism. Today no one would argue that one of those perspectives is better suited to deal with risk issues, but great care is taken to ensure that all perspectives are included in the risk debate. Many efforts have been taken, and some still remain to be realized, to ensure that different ethnic groups are not victims for an unfair balance of risk and benefit. To acknowledge and accept differences between men and women because of biology is equally sexist, still these claims are sometimes heard in the public debate to defend the position that one groups’ perception is better than the others.

In what follows, the three models will be further developed and empirical studies in these fields will be reviewed. Now, it is important to point out that none of these models claim to have the power to account for all differences found between men and women. Instead, they are to be viewed as partial explanations. They are also overlapping in many respects but will still be treated as three separate models. First in line is the model that used knowledge and familiarity with science as one explanation of the differences between men and women relating to risk perception.

## Knowledge of and Familiarity with Science

---

As risk issues are highly dependent on science, one way of explaining differences in perception of risks can be traced back to how much we know about the risks we face. Given this model, one explanation often used to understand women’s higher risk perception is related to women’s unfamiliarity with science and technology (Slovic 1999). Some scholars have suggested that opposition or skepticism toward new technologies is often interpreted as a lack of knowledge (Frewer 2004), suggesting that an increase of knowledge would alter risk perception. The “deficiency of knowledge”-assumption can also be used in order to discredit the opposition as they are portrayed as less knowledgeable and therefore not eligible to participate in risk discussions (Davidson and Freudenburg 1996).

If we examine the role of knowledge and risk perception, this would imply that increased knowledge of the scientific and technical aspects related to a risk will give a lower risk perception, whereas a lack of knowledge will make us more concerned. In most studies that focus on knowledge, men are more likely to state that they have more knowledge about technical environmental issues, or knowledge concerning risk sources in general as compared to women (O’Connor et al. 1999; Wester-Herber and Warg 2000). This reported greater knowledge leads men to have less concern for the environment, even though the link between knowledge and concern is not always clear (Blocker and Eckberg 1997). Indeed, this does not mean that women are less informed or men more knowledgeable – the opposite relationship can also be found. For example, those groups that feel most vulnerable to risk are the same ones that collect all information that is available to them on the issue that concerns them

(O'Connor et al. 1999). The link between an increase in knowledge and a reduced risk perception seems to have some empirical supports. However, a distinction needs to be made between reported knowledge and actual knowledge. It might also be worth asking that question exactly what is known: is it a better understanding of the probabilities, a wider grasp of the consequences, or a more sophisticated awareness balance between the risks and benefits?

In several studies, women are found to have a higher risk perception of the risks associated with GMOs, perceive fewer benefits, and have a lower acceptance of GMOs than men (Siegrist 2000; Kirk and McIntosh 2006; Simon 2011). It would seem then that women are less knowledgeable of the benefits with GMOs or have less knowledge about the probabilities of the possible negative consequences. The next logical step then would be to make women as knowledgeable as men in these issues. However, the differences in acceptance and benefits remain even though men and women have the same education (Kitto et al. 2003). In fact, it has been demonstrated that men and women with the same profession, and thereby the same education, judge risks differently (Slovic 1999). Another field where these differences are found is in the area of nuclear power or deposits of nuclear waste. In these studies, women generally express a higher risk perception than compared to well-educated white males (Greenberg et al. 2007; Greenberg 2009). It is not only in the complex technical risks that emerge from heavy industry that differences in risk perception between genders are found. In the new emerging information technologies, there are differences between men and women. In the context of social media, women are less likely to share personal information about them in social networks than men do, and also have greater concerns for privacy (Fogel and Nehmad 2009). Linked to this is the view of technical solutions to a range of risks. In the field of environmental perception, the view that technology can and will solve all ecological problems is more widely supported by men than women (Wehrmeyer and McNeil 2000). It should be stated, again, that these questions are rarely followed by a measurement of factual knowledge, implying that it is now known that men really *are* more knowledgeable – only that men more often state that they are.

## Issues of Trust

There are a few studies that look at the internal structure of the groups “men” and “women.” Some studies have added ethnic groups to the mix. Finucane et al. (2000) demonstrated that white males had a lower risk perception regarding both risks that individuals face and risks that the public are exposed to. This means that men are more likely to judge risks to them, for example risks of violent crime or natural disasters, as lower than what the same risk is to women or men of another ethnic group. In other words, there are studies that confirm that the groups of white males have a risk perception that is lower not only to that of women, but also other males of different ethnic groups. So when the level of education is the same, and the groups of white males are excluded, risk perceptions become more similar. Perhaps the reliance and confidence white males have toward technology is a reflection on the *faith* men put toward technology and technical solutions, a faith that other groups in society do not share.

Going back to the one study that diversified the group of men to include ethnic groups was found that white males expressed a higher confidence in technology managers and lower trust in government than the other groups (Finucane et al. 2000). This group of white males also reported to be not as sensitive to potential stigma that can be associated with high-risk ventures

as the other groups were. Also in other contexts, a difference in confidence toward governing authorities has been found. Regarding information security, men have been found to express lower confidence and trust in government than women do, even though both men and women express a view that personal information is at high risk of being misused (Wester and Sandin 2010). Men also tend to place higher trust and confidence in technology and technological progress than women do. This link is found in risk perception studies that measure the perception of man-made or technical risks (Siegrist 2000), but have not been fully explored in the environmental risk perception field (Blocker and Eckberg 1997). Along the same lines, as noted above: women often report that they intend to engage in more pro-environmental behavior, whereas men tend to place more trust and confidence into governmental policies that address environmental issues (O'Connor et al. 1999; Sundblad et al. 2007). However, as there is some evidence that even if women express more worry, they also report to have more hope in changing human behavior to make the world a better place; report to be more goal-oriented and more inclined to think about new and innovative ways of addressing environmental issues (Eisler et al. 2003). It is also found that women have stronger moral objections to technological developments where the consequences are seen as immoral or unethical. In fact, some studies suggest that men are more accepting of unethical actions than women (James and Hendrickson 2008). In similar contexts, studies suggest that men express a higher ideological motivation as one factor influencing their decisions to face risks compared to what women express (Billig 2006). This implies that values and ideology have a strong impact on perception and behavior, but in different ways from men and women. As will be developed in greater detail further on, women are more willing to act in a pro-environmental manner, even if the values toward the environment are similar between men and women. It could be wise then to focus on what options are available for action, and if these differ from men and women.

However, the differences due to ethnicity indicate that differences between genders cannot be explained by biological factors, nor can it be sufficient to relate to undiversified gender roles. Instead, differences are due in part to individual factors that are influenced by values, beliefs, and social roles. These roles are affected by both genders but also other aspects of group membership, where ethnic belonging is one. It would seem then that men tend to put more faith in technology and science than women do, and that men are more distrustful toward government. The interesting question then becomes why the group of (white) males have this perception: Are these differences due to nature or nurture? This will be developed below.

## Differences in Risk Perception due to Biological or Social Differences

The function of testosterone in the human body is to develop male sex characteristics, just like estrogen developed female sex characteristics (Seifert and Hoffnung 1997). These characteristics are both physical, such as the development of facial hair and muscle tissue, but are also believed to have an effect on the personal characteristics. Testosterone's influence on the male character and male behavior is seen primarily in relation to aggression, competitiveness, and the male libido. In many situations, it is found that men tend to engage in more risk-taking behavior than women. This is found in studies that report findings on different risk-taking activities such as sporting, such as skiing or mountain climbing (Lupton and Tulloch 2002); in risk-taking behavior in online social networks (Fogel and Nehmad 2009); and in financial

risk-taking (Barber and Odean 2001). Women on the other hand, report to be more afraid of nature, such as being afraid of spiders, lightning, or darkness, to a greater extent than men (van den Berg and ter Heijne 2005). Another possible explanation is that women experience emotions more vividly than do men, presumably due to biological factors. This would suggest that women react more emotionally to risks, rather than cognitively, and this would account for the higher risk perception of women (Sundblad et al. 2007).

Also, a majority of studies indicate that men are more risk-taking than women but that this difference decreases with age (Byrnes et al. 1999). It might be very tempting to interpret these differences as a willingness among men to be bold and daring, whereas women's actions are seen to be protective and cautious. Presumably also these differences would be caused by the male sex hormone: testosterone drives men to be daredevils and take risks as dictated by their biology. As men get older, and the levels of testosterone decrease, so does the frequency of risk-taking. However, looking at the statistical probabilities in some areas of having an accident or being injured, it reveals that women have a more realistic risk perception. For example, young male drivers systematically underestimate the risk of accidents even though this group is overrepresented in the statistics on motor vehicle accidents (Andersson and Lundborg 2007). Some studies report that men feel more fascinated by threatening situations, display less negative emotions in these situations, and would not avoid these situations in the future. However, it is difficult to provide empirical support that these differences are explained by differences in sensation-seeking (van den Berg and ter Heijne 2005). Put in other words, the subjective risk perception of males is lower than the objective risk and not because men are more prone, for one reason or another, to exposing themselves to dangerous situations. These results might encourage a view that looks at what groups are fearless, rather than those who are fearful (Kahan et al. 2007). These traits or characteristics are found elsewhere and there is no evidence that the lower risk perception and threshold for risk found among men is more objective or functional than the perception of women (O'Connor et al. 1999). Of course, there are situations where biological differences between men and women are relevant in risk research. For example, due to biological differences women can be more vulnerable to exposure of toxins, making it necessary to be more sensitive to gender in toxicological and epidemiological studies. In general, these studies fail to include gender differences caused both by biological and psychosocial differences. For example, in some cases there are differences in sensitivity to toxins caused by biological factors, such as women having more body fat than men due to higher levels of estrogen, but the (social) division of labor can also make women more exposed to toxins as they occupy other positions than men (Vahter et al. 2007). From this perspective, both biological and social differences between men and women need to be considered.

For a moment, we might consider that there are biological differences that cause the differences in perception of risk between men and women. Does the risk perception also affect behavior, and if so what does it mean for one of the biggest risks we face today? If men are driven by their biological wiring to take more risks, how will it affect their views on the environment and responses to the risks of environmental degradation? In many, but not all, studies on attitudes toward the environment, women show more concern for the environmental and hold more pro-environmental values than men. Women are found to have greater concerns about health and safety as they in their role are the primary caregivers to children and elderly. This, we could argue, can be caused by biological factors where women are different from men because of their childbearing abilities (Wehrmeyer and McNeil 2000).

One reason that women see higher risks than men can then be explained by, because of their biological functions, women take more responsibility for the family, such as being the primary caretaker for children and domestic chores. This would make women more observant toward risks that relate to their children (Lupton and Tulloch 2002). Included in this general framework is the explanation that differences between men and women in the perception of environmental concern relate to parenthood. The reasoning goes like this: It is hypothesized that when people become parents, women will have a nurturing role and be more concerned for the environment. This implies that nature is important for children and therefore also for women, but the reasons for this are not developed. Men, on the other hand, will be driven toward economic growth in order to care for his family. This will produce the result that men will be less concerned with environmental degradation and more focused on using the environment for economic growth (Davidson and Freudenberg 1996; Blocker and Eckberg 1997). Besides assuming that men are either ignorant or in denial of the risk we face today and that the environment will not sustain mankind at all if pushed to its limit due to their biology, closer scrutiny of empirical data reveals that this assumption does not hold. If the above stated reasoning is correct, studies would find that women that have children and that are removed from the workforce and stay at home should have the highest risk perception and would also be most inclined to engage in pro-environmental behavior. However, studies reveal that this group is less likely to engage in recycling and is less willing to pay for nature conservation. The empirical evidence also suggests that it is only women with children under the age of 6 that are more “green” in their perception of the environment: women and men with older or no children tend to not believe that humans are harming nature or engage in pro-environmental organizations (Blocker and Eckberg 1997). Women who stay at home on a full-time basis are also more prone to agree with statements that endorse salience of the economy over the environment, compared to women that work outside of the home. Perhaps this is because homemakers have to rely on the continuity or even growth of the economic capacity of their husbands in order to be able to stay at home and remain homemakers. This can make women dependent on men, but this is hardly due to biological characteristics.

These results suggest that parenthood seems to influence women to be more caring for the environment, but only for a limited time. Does this suggest that men are influenced by their hormones all the time, whereas the hormonal influence on women’s attitudes varies more during her life-course? Looking at biological differences between men and women might not be useful or constructive, as at best the male biology makes men underestimate risks whereas the female biology causes women to be more realistic, and these differences will fade over time. This is not the general view on how sex-specific hormones affect us as men and women. Perhaps it is more fruitful to examine the social roles that men and women inhabit and how this leads to specific differences in behavior. If men and women perceive risks differently, they will also respond to these risks in different ways – even if these behavioral differences have no biological origin or function.

The same explanation model – differences in attitudes toward economic growth and environmental risks – can be used, but instead of arguing that the differences between genders are due to biology, they can be seen as differences due to (social) gender roles. According to our gender-specific stereotypes, men are more often seen as the providers for their families and in that sense they might be more directed toward economic growth and more oriented to see benefits and be more accepting of risks. In this way, differences between men and women in economic growth orientation can be one explanation to differences in, for example,

environmental risk and concern for the environment. As men are more likely to believe that economic growth is important, men are also more inclined to have less concern for the environment. This argument builds on two assumptions: First, human beings in Western culture use the environment as a resource to further the growth of science and technology for economic progress. Second, through different social processes and through the division of labor, men are encouraged to engage in science and technology, whereas women are denied entrance to this field (Blocker and Eckberg 1997). Now, the discussion of how nature is perceived is outside the scope of this chapter. It might suffice to say that there are those that differences between men and women in how they perceive nature and what is believed to be natural. Instead it is argued here that the differences in environmental risk perception would be a result of how men and women occupy different roles in their lives and that these roles include behavioral responses that are limited by the options that are provided. An investigation of pro-environmental behavior reveals there is often an expressed behavioral intent among women that indicate that they would be more willing to engage in voluntary pro-environmental actions than men (Davidson and Freudenberg 1996; O'Connor et al. 1999; Slovic 1999; O'Connor et al. 1999). Women are also more likely to justify that it is never too expensive to regulate risks, implying that women are more likely to defend a higher cost in order to reduce risks (Slovic 1999). Interestingly enough, this tendency is higher among women even if men have similar environmental values and risk perception. However, issues of environmental concern and risk perception are complex and it is not possible to divide the population into clear and distinct groups, where some never engage in pro-environmental behavior and others do nothing but behave environmentally conscious in every situation. Also, that women show more concern for the environment does not imply that men are less willing to address environmental issues or that women are "eco-angels" (Wehrmeyer and McNeil 2000). Environmental degradation is an issue that concerns and engages many groups in society, not exclusively women. Individuals are complex and support some measures that aim to protect the environment and oppose others (O'Connor et al. 1999). However, the tolerance for and willingness to accept a certain degree of environmental damage seems to be more pronounced among men (Eisler et al. 2003).

Where does this leave us? If we summarize the two models that we have covered so far, it can be concluded that the effect of biology is limited but social roles and knowledge are factors that seem to matter. If we choose to focus on explanations that include social processes, this means that the differences found between men and women are reflections of the social context around us. Men are seen as the providers for the family, whereas the role of women is to pay closer attention to the needs of the family. This is also reflected in the division of labor in our society. Specifically, it means that men will occupy certain professions that will affect, or be affected, by their risk perception. In most areas that deal with progress of science and technology, where risks are produced, men more frequently occupy the role as experts than women do (Sjöberg 2002). It can then be argued that the risk perception of men is closer to the expert view of risk and that this perception is more often believed to reflect knowledge and science. However, a combination of these two models presented above suggests that the risk perception of women is in some cases more realistic than the perception men have, even if men claim to have more knowledge on the risks themselves. Certainly not all men can be experts, nor do all men have professions that allow them to influence the risk-producing or risk-governing processes that would make them less prone to experience a high-risk perception. So if the common link between different groups of men (and women too for that matter)

is not shared education or shared professional norms, what other factors can be present that link the gendered-role of men together? Perhaps examining the function of cultural groups can be one possible way.

## Cultural Explanations

---

Perhaps one of the most acknowledged theories that argue that men and women have different perceptions toward risks and particularly environmental risks is the ecofeminist theory. Theories found within ecofeminism are as diverse as the larger feminist research field (Longenecker 1997). Ecofeminist theorists, however, are similar in that they treat the differences between men and women in the perception and actions toward nature as closely linked to gender inequalities that are also found in other part of society. Parallels have been identified between the oppression of women and the exploitation of nature, making pro-environmental action more relevant to women rather than men (Agarwal 1992). Another more a critical position, where factors such as the dualism between nature/culture, male/female is explored to explain gender differences is also found in ecofeminist theories. Here it is argued that men are cast in the role as exploiters of the environment and women as the caretakers as a results of social processes, not biological ones (Agarwal 1992; Blocker and Eckberg 1997; Longenecker 1997; Wehrmeyer and McNeil 2000). This approach rhymes well with the explanation models presented above, where in the risk perception literature the same conclusion has been drawn. Now, ecofeminist theories have been criticized for treating women as a homogenous group, but attempts have been made to address this and bring about a more nuanced image of women (Agarwal 1992; Mellor 2007).

Another model that attempts to explain differences between men and women starts from the observed differences between white males and men and women of different ethnic groups found in the risk perception literature (Flynn et al. 1994; Finucane et al. 2000). The model of cultural groups focuses on the role of worldviews as they are expressed through a cultural theory of risk (Kahan et al. 2007). The cultural theory of risk suggests that there are differences in peoples' perception that, along with convictions on how society should be organized, makes them concerned with different risks. This model also suggests that the groups will prefer different risk management strategies. There are four dimensions, or "types," that individuals sort under: egalitarians, hierarchists, individualists, and communitarians (Sjöberg 2000; Kahan et al. 2007). Although this model has been criticized for being difficult to prove empirically (Sjöberg 1996, 2000), it has the advantage of offering an explanation that addresses the sociocultural differences between men and women in relation to risk perception. White males are found to hold more individualistic and hierarchical views than women or men of other ethnic groups (Finucane et al. 2000). This means that men are more likely to feel that they are in control over the risks to their health and that it is alright to impose small risks on people in order to receive a benefit. It has also been found that when an individual belongs to a cultural group, he or she is more likely to dismiss information that threatens the position or views held by the group (Cohen 2003). In other words, if white males believe that the world is a safe place; that risks are regulated properly and to a sufficient cost; believe that science and technology will solve ecological problems – it is highly unlikely that this perception will change. This cultural models presented here is very similar to the model presented previously, that differences in perception are due to social differences between men and women. Adding a cultural

perspective implies that these differences can be seen in a wider perspective. From this larger perspective, it can be seen that sociocultural norms and expectations are likely to cause differences in perception between men and women, rather than biology. Since the 1980s, the notion of gender differences, rather than sex differences, has made studies of men and women more sensitive to issues like power, influence, and control that are present both within families but also in larger social spheres (Ferree 1990). Adopting a gendered perspective implies that more attention is put toward identifying structures and roles, rather than focusing on biological differences. Women are *expected* to take a greater role in matters that relate to social life, which involves children, social relationships, and a consideration for the future of these relationships (Eisler et al. 2003). Men, on the other hand, are *expected* to be more risk-taking and involved with technical progress. In some ways and situations, women face a different reality than men. The division of labor and power inside the family to make formal decisions can lead to men making decisions that place women at risk.

## Cultural Divisions: Practical Implications

Before leaving the domain of cultural explanations for differences in perception, I would like to comment on how risks affect women differently from men, differences that are a result of social and cultural processes with a particular focus on the division of labor.

It can be argued that men and women face different realities or situations and this can be a contributing factor to differences in risk perception. One example of how the gender-based division of labor and how risks affect women can be found in the use of pesticide. In traditional farming in certain parts of the world, it is the men that decide how to conduct farming, what to grow, and what pesticides to use. The actual labor is carried out by women that work in the field. In combination with lower literacy rates and lower levels of education among women, this means that women are exposed to risks with pesticides but lack the formal training on how to handle them properly (Atreya 2007). It also means that the decision is outside of their domain, as women are not included in the decision-making process. In recent years, the frequency and extent of extreme weather phenomena has increased. This means that risks are moving from probabilities to actual events that need to be responded to. However, in preparing for disasters, gender is rarely taken into full consideration and the vulnerability or needs that are particular to women are often neglected (Norris et al. 2005; Enarson and Morrow 1998). In disaster response, women are greatly involved in relief and recovery efforts, but usually as part of the implementation not the decision-making or planning process (Noel 1998). This is done despite the recognition that women, as primary caretakers of their families, are vital in the disaster preparedness or response phase. In disaster response, it is found that women take warnings more seriously than men and also perceive to have the main responsibility for children. This is also evident after a disaster has struck, as women take on more responsibility for providing the immediate necessities. One example of the different situations facing men and women in the aftermath of a disaster is that men are free and encouraged to seek work outside of the community, where women remain in often unsecure environments to care for the children or elderly (Enarson and Morrow 1998). The same research team concluded that women are often in greater need of counseling and protection from abusers in the aftermath of a disaster, but it is doubtful that efforts of this kind is undertaken in a larger disaster response perspective. This lack of response that specifically

target women, and the areas over which women are responsible, is also present in how victims of disasters are portrayed. During the 9/11 disaster, men were more frequently depicted as victims in their roles as fathers, husbands, and sons and women portrayed as the grieving party (Monahan and Gregory 2001). The occupations as firefighters, police, and other first responders, have a long tradition of being predominately male, making women even more invisible from this arena. This connects back to the discussion above, where it is often found that men occupy certain professions, particularly those that involve science and technology. This means that women are mostly absent from fields where risks are created, identified, regulated, and responded to. Women report feeling more socially isolated during normal conditions and this becomes worse during a disaster as the social bonds are dispelled (Jackson and Henderson 1995; Norris et al. 2005). There is a danger however, to perceive women as vulnerable by default and to oversimplify the needs of women as a group (Fordham and Ketteridge 1998) but this does of course not mean that the special needs of women are to be ignored. Instead, this calls for an increase of gender-sensitive education that addresses the risk perception and response to them. However, even if increasing information and educational efforts to women in order to get a more “accurate” risk perception is acknowledged, it will not affect or alter the decision-making processes within the families. It will be interesting to see when observed differences between genders in risk perception also become a priority in risk research.

## Summary

---

It would seem that all models share one thing: differences in gender are due to differences in cultural roles. We learn early on what it means to be a man or a woman, and these roles are communicated through social and cultural expressions. These roles affect our values, where men are more likely to value individualism, favor economic growth, trust and rely on technical developments to make the world a better and safer place. Women on the other hand are more likely to value the environment, express more reservation toward technological development, and engage in sustainable behavior than men.

In sum, the models presented above would suggest the following:

The identification, assessment, and management of risks are highly dependent on science and technology. Some would also argue that risks stemming from the modern society are also created in this realm. What risk we choose to focus on, and perhaps to some extent also produce, is determined in large part due to what values we have. If economic development and growth is prioritized, other areas will not receive the same attention or resources. In our society, developments in the fields of science and technology are valued highly, making this field dominated by experts that have training in science and technology. It would seem then, that especially in areas of risk to health and the environment, the division between men and women becomes very clear. Usually these issues touch upon matters of scientific evidence, cutting-edge research, allocation of research funds (Jasanoff 1987), and the status that comes along with having influences on policy and future development of society (see, e.g., Oreskes and Conway 2010). This means that because of the way society is divided, in terms of education and profession, men are more likely to occupy the roles where risks are created and defined. Most of us can name few female scientists, save for Marie Curie, whereas the names of male

scientists are readily available from memory. This is not a coincidence, or collective laps in memory, but a reflection of what roles women have occupied within science (Watts 2007). Even if today the number of women involved in higher education and scientific work is increasing, the division of different social groups, of men and women, begins at early ages. Vocational choice is influenced not only by personal preference, but also by social processes, pressures, and norms. When it comes time to choose education that will eventually lead to a profession, the gap between girls and boys becomes evident. If we define some risks as a result technical progress, it can be worth noting that a technical university, such as my own, has about 30% female students and women make up about 10% of the senior faculty. Even though there are fields where women are increasing, such a biotechnology, this raise in women's presence often happens as the field has lost its initial high status and is becoming more mainstream (Rosen 1994). It might be worth reflecting over how institutes that are developed to ensure that the environmental risks that we face, such as the Intergovernmental Panel on Climate Change, has predominantly men – albeit not exclusively white men – in the highest positions whereas women are found on lower positions as cochairs and support staff.

It is tempting then, in order to address this issue is to increase the number of women in science and technology but this is not my point. If we strive toward making women more involved in these spheres, we run the risk of heading down a dead-end road (or at least a cul-de-sac). First, involving more women in science and technology in order to make women more educated on these matters, tends to support the idea that if only the level of knowledge was equal, so would the risk perception between men and women be. In this way, we make the same mistake as mentioned above and disregard that risk issues are issues where values, ideologies, and power are equally important as any scientific calculation. Second, if we include women not to increase their knowledge but to increase the female representation in these spheres, what do we expect women to contribute with? Do we expect women to provide a softer perspective on hard technological issues? Do we assume that women will add a gentler touch and be more considerate to vulnerable groups in society? Whatever contribution we assume that women will make if only their number were increased in the risk debate, we need to be careful and rethink what that contribution might be. If not, we apply the same stereotypical models and expectations of what men and women *are expected* to contribute and the time has come to move beyond these stereotypes.

## Further Research

It was stated in the beginning of this chapter that the risks presented here were risks that to a great extent lay outside of an individual's personal control and risks that are impossible to escape from. Despite this, men and women perceive these risks differently even if we can agree that the consequences are the same for all groups if things do wrong. If we live next to a high-risk facility, we will be equally affected from a physiological perspective, even if we *perceive* the risk differently. In light of this, we need to pay more attention to why there are differences between men and women in risk perception and especially how these differences express themselves in risk management. It was concluded above that knowledge and familiarity are important for risk perception. One suggestion for future research can be to critically examine these claims of greater knowledge that men have, but not in a general sense. Measuring the level

of knowledge among the general public on risk issues does not seem to bring this research field forward. Instead, examining men and women with the same education that presumably have the same level of knowledge can help shed light over the role knowledge has in risk matters. Judging from the above discussion, I would like to put forth the hypothesis that knowledge plays an inferior role in risk perception when compared to underlying values and cultural belonging (or ideology). If future research can identify the relationship between estimated knowledge and “real” knowledge, perhaps we can move beyond the simple model of a knowledge-deficit among women.

The second research challenge calls for a critical examination of the function of stereotypes in risk matters. Examining the difference between men and women is not a simple question of discrimination. Forcing more women into technical fields or passing legislation that would require men to become homemakers or become more involved in the care for children and the elderly does not seem to be an appropriate response to the question of gender differences in risk perception. No one benefits from being cast as a victim, and in this chapter it has not been my intention to portray women as victims. Personal preferences and choices need to be respected, and living in a democratic society we are free to plot the course of our lives. Still the question that would need closer examination is how stereotypes limit life for all citizens, not just one group. Perhaps men suffer equally from the gender division in education and labor, or have difficulties finding options that enable them to act in manners that are more in line with their character and not with their gender role. Here, issues of power are important as they are central to risk debates. The second area I would like to suggest for future research is an increased attention paid to the inequalities that not only exclude women from risk discussions, but to focus on issues of power and the distribution of risk and benefit. Being able to identify and demonstrate how privileged groups, regardless of gender, influence decisions on risks is vital to a democratic society. My second hypothesis is that the internal variation within the group of men will be greater than the differences between men and women.

The third and final research direction I would like to suggest it by examining hard facts. Differences between men and women are present in many areas that involve risks: risks are perceived differently; risks are handled differently, but also the risks men and women face are different (Gustafson 1998). Women face different consequences from the same risk, than men do. For example, a woman walking home late at night might consider the probability of being attacked, robbed, beaten, and raped. For a man, that same situation can cause him to think about the probability of being robbed and beaten but perhaps not raped. This often makes women more concerned about risks of violence than compared to men (Lupton and Tulloch 2002). However, there is some evidence that white men that are wealthy are more fearful of being victims of a crime than men of more modest means, as the wealthy men have more to lose in terms of property and assets (Franklin and Franklin 2009). Often, this leads to two different judgments that are caused by the differences in consequences and not by the statistical probability. Another way of expressing this, rather than in terms of perceived risk, is perceived insecurity. Also in this area, studies find that women score higher than men, suggesting that women see the physical environment as more risky and less secure than men (Carro et al. 2010). This is also found in situations where individuals live under stressful conditions, such as in areas of conflict or violence, where men perceive the area as less risky than women (Billig 2006; Rodionova et al. 2009). The third suggestion I would make then is to document and demonstrate how men and women’s lives are affected by risk and crises on a very concrete level, and to let this empirical evidence have a real influence on the risk management process. I would encourage the

reader to closely examine the daily newspapers and television broadcasts during a crisis and search for images of women that are not portrayed as victims. My third hypothesis is as follows: there will be no images of women as first responders or any reporting of the special needs of women. This does not mean that there are none.

**Abstract:** Policy and technology actors seem to focus “naturally” on risk rather than on technology’s social and ethical impacts that typically constitute an important focus of concern for philosophers of technology, as well as for the broader public. There is nothing natural about this bias. It is the result of the way discourses on technology and policy are structured in technological, liberal, pluralistic societies. Risks qualify as “hard” (i.e., objective, rational, neutral, factual), other impacts as “soft” (i.e., subjective, emotional, partisan, value-laden) and are therefore dismissable. To help redress this bias, it is necessary to understand how this distinction between hard and soft impacts is construed – in practice and in theory. How are expected (desired, feared) impacts of technology played out in expert-citizen/consumer interactions? We first discuss online patient deliberations on a future pill for celiac disease (“gluten intolerance”) promising to replace patients’ lifelong diet. By “rejecting” this pill, patients displayed concerns about how the new technology would affect their identity, and the values incorporated in the way they had learned to handle their disease. Secondly, we analyze how experts construct a consumers’ concern with “naturalness” of food: as a private – and invalid – preference that requires no further debate. The point of the analysis is to make available for discussion and reflection currently dominant ways to demarcate public and private issues in relation to emerging technologies, including the accompanying distributions of tasks and responsibilities over experts and laypersons. However, the actors themselves cannot simply alter these demarcations and distributions at will. Their manoeuvring room is co-shaped by discursive structures at work in modern, technological, pluralist, liberal societies. In the third section, we therefore identify these structures, as they provide the hegemonic answers to the three key questions with regard to the possible impacts of emerging technologies: how are impacts *evaluated*; how are they *estimated*; and how are they *caused*? We conclude with some suggestions for further research.

## Introduction

---

“Risks” typically concern harms to values like health, environment, and safety. But the larger public sometimes is interested in another type of consequences of existing or emerging technologies as well, positive or negative consequences that we refer to as “soft impacts.” Until now, these soft impacts receive relatively little attention in Risk Studies, and go largely ignored by policy makers and technologists. In this chapter we show how concerns with soft impacts often get overlooked. And if they are acknowledged, they typically get subtly removed from the agenda. We offer some explanations for this exclusion of soft impacts (Swierstra et al. 2009; Boenink et al. 2010), and conclude with some suggestions for further research.

## History

---

For a long time scientific and technological progress seemed to equal societal progress. From the 1950s onward, however, the conclusion became inescapable for policy makers and technology actors that technological innovations can and often do have unintended, unforeseen, and/or undesirable impacts. Risk assessment was invented to warn society in advance for such impacts, and thus help to avert them by taking social and/or technical precautions.

It is interesting to observe that the growing awareness of technology's unintended and unwanted impacts during the previous decades was hardly informed by the philosophy of technology. Classic philosophers of technology, e.g., Martin Heidegger and Jacques Ellul, had already devoted ample attention to technology's darker side at the time when "technological risk" became prominent on society's agenda. But they tended to focus less on safety, health, or environmental issues, concentrating instead on the consequences of new and emerging technologies for

- Established meanings, world and life views (cultural)
- Existing values, norms, and conceptions of the good life (moral)
- The (global) distribution of power and control (political)

Some complained about technology because it eroded tradition, replacing it by uniformity and conformism. They feared dehumanization, depersonalization, spiritual shallowness, desensitizing, and mind-numbing as a result of automation, and in the end, the substitution of humans by machines. Others stressed technology's moral consequences: technology would lead to the devaluation of life's fundamental values, cause moral corruption, and result in eternal unhappiness or shallowness, through the creation of artificial needs. A specific variety of the moral corruption thesis is couched in religious terms: technology was accused of creating false gods and of giving the false illusion that man is no longer dependent on God, thus leading man to commit the sin of hubris. Again others warned that technology would help create new tyrannies, that would be all the more secure because of psychological manipulation. These tyrannies would undermine our privacy through observation techniques and data banking, or their anonymous systemic logic would marginalize democratic deliberation.

Of course, these doom prophets invited all kinds of reassuring rebuttals by other philosophers, who argued that this ink-black pessimism was ungrounded. In fact technology had exactly the opposite impacts: enriching culture, strengthening morality and religion, and enhancing democracy (For an overview, see Van der Pot 1985).

Thus far, policy makers and technologists by and large ignore these discussions. In the past that could be justified by the fact that according to many philosophers technology was inseparable from its unwanted consequences. Because of this technophobic bias, their work held little promise for policy makers and technologists who were faced with the practical task to make technology safer, but were not prepared to throw out technology altogether. But this situation has changed drastically since. Most modern philosophers of technology are no longer in the business of dismissing Technology (with a capital T). Since the "empirical turn" (Achterhuis 2001) they tend to study the impacts of specific technologies in specific contexts, without a priori leaning toward pessimism of optimism.

## Current Research

Like their predecessors, modern philosophers of technology still tend to focus on a *different* type of impacts than is common in risk studies. In this chapter, we will argue that it is important to broaden the assessment of technology's impacts from risk to the kind of "soft impacts" that are typically in the center of attention of philosophers of technology. We offer two reasons for this broadening of the agenda. The first one is that many laypersons worry about these soft impacts, and therefore democracy requires that at least they are being assessed

and discussed openly. The second reason is that Technology Assessment aims at better technology. To realize this aim, it is important to take a wide array of possible impacts into account, not only risk.

However, getting soft impacts on the agenda of policy makers and technologists is not a simple matter. Broader cultural, moral, and political aspects are regularly voiced in public discussions, but seem to have difficulty gaining access to the agendas of policy and technology actors. These parties “naturally” seem to focus on risk rather than on technology’s social and ethical impacts. Or rather, their focus is on risk assessment and everything else is dubbed an “ethical issue.” This framing then makes the prevalent “non-risk” issues ready to be recognized as legitimate but solely private concerns (Wynne 2001; Swierstra 2002), which are out of place on the public agenda.

We will argue that there is nothing natural about this bias. It is the result of the way discourses on technology and policy are structured in technological, liberal, pluralistic societies. Impacts of (emerging) technologies that qualify as “hard” (i.e., objective, rational, neutral, factual) attract much more attention than impacts that can be dismissed as “soft” (that is, subjective, emotional, partisan, value-laden). And risks qualify as “hard,” social and ethical impacts as “soft.” While the relation between soft impacts and the evolution of public controversy is not linear and direct, experience and research (see for example Marris 2001) have shown that the dismissal of latent concerns about soft impacts (soft concerns) may easily engender unexpected – at least for technologist designers – outbursts of public discontent later in time. By then, repeated experiences and cumulated irritations have replaced the early, largely invisible and not necessarily *negative* concerns. Technologists may feel nothing but annoyance about the public’s irrational moves – no longer being able to recognize that, for instance, religious critiques (“playing God”) might also pose questions about the limits of science (Wynne 2001). The paradigm case here is the Monsanto debacle of the mid-1990s. A lot of public concerns seemed to regard the *hard* impacts of modified crops – environmental risks and health concerns – but these concerns often sprang up from other concerns about *soft* impacts, e.g., that genetic modification exemplified technological hubris, or that it increased the power of big corporations over small farmers (Marris 2001).

To help redress this bias, we need to analyze how this distinction between hard and soft impacts is construed – in practice and in theory. As we are aware of, our concern with the impact of “other than risk issues” on public dialogue is not entirely new. Other studies, mainly in the area of science and technology studies (e.g., Jasianoff 2003; Hobson-West 2007; Wynne 1996, 2001), have pointed to the importance of seeking to evaluate technology’s aims rather than its mere consequences in terms of risk (Jasanoff 2003, p. 224), and “the uncritical framing of contemporary controversies as primarily about risk, or even about different understanding of risk” (Hobson-West 2007, p. 211). Brian Wynne’s work (e.g., 1996, 2001, 2006) perhaps most prominently refers to the significance of addressing wider social and political questions in public debate on emerging technologies.

While these authors do recognize the importance and dismissal of other than risk issues, little is known about how these demarcations between hard and soft impacts of technology are performed in real-life situations, for what purposes (consciously or not), and with what consequences. Furthermore, the question remains what these impacts, and the difference between them, actually consist of. (How) can they be characterized, and what makes them susceptible for more or less devoted attention? In this chapter, we will make a start with both questions.

First, we will analyze in close detail how expected (desired, feared) impacts of technology are played out in expert-citizen/consumer interactions. We first discuss an illustrative example of how soft impacts surface in online patient deliberations on an emerging technology, namely, a future pill for celiac disease (“gluten intolerance”) patients that was promised to replace their lifelong gluten-free diet. We show how these patients, by “rejecting” the proposed technology, displayed concerns about how the new technology would affect their identity, and the values incorporated in the way they had learned to handle their disease. Their rejection was targeted not so much at the pill itself but at the experts’ construction of their current life as highly problematic and the pill as a perfect solution for that problem. The example illustrates the indirect way in which soft concerns often manifest themselves.

In our second example, we study closely how subtly – respectfully – these soft concerns often get dismissed. To illustrate this point, we look at an example of expert interaction in which a consumers’ concern with the “naturalness” of food is both constructed as a private issue and discounted as nonvalid. We are claiming neither that the expert is wrong nor that the consumer or patient is right. The point of the analysis is to make available for discussion and reflection currently dominant ways to demarcate public and private issues in relation to emerging technologies, including the accompanying distributions of tasks and responsibilities over experts and laypersons.

However, it would be naïve to assume that the actors themselves could simply alter these demarcations and distributions at will. Their manoeuvring room is co-shaped by discursive structures at work in modern, technological, pluralist, and liberal societies. In the third section we therefore will identify these structures, as they provide the hegemonic answers to the three key questions with regard to the possible impacts of emerging technologies: how are impacts *evaluated*; how are they *estimated*; and how are they *caused*? Together these answers help construct some positions as being rational, public, neutral, and serious, and others as being irrational, private, partisan, and not to be respected. We conclude by pointing out why, if one aims for an open and comprehensive public dialogue about science and technology, it is crucial to modify these discursive structures.

## **It Is Not All About Health: How Soft Concerns Tend to Get Overlooked**

---

The point of medical technology is to help increase (or defend) our health. Therefore, it seems a pretty straightforward matter that discussions about emerging medical technologies would concentrate on these would impact our health. In reality, however, matters are not so simple. We will illustrate this by drawing on examples from a broader study of celiac patients’ accounts regarding a future pill (te Molder et al. [submitted](#); Veen et al. [2010](#)).

In our analysis, we applied a discursive psychological approach that starts from the assumption that talk is oriented to *action* rather than merely *reflecting* reality. So instead of determining the truth-value of what people report – by looking at what a person really wants, thinks, or feels, or what the world really looks like – the focus is on what people’s utterances *do* in the interaction, such as accusing, complaining, and complimenting (Edwards [1997](#); Potter [1996](#); te Molder and Potter [2005](#)). People use the turn-by-turn development of a conversation as a resource to make sense of each other’s talk. They may treat displays of anger as a request to

leave the room, claimed losses of memory as reluctance to answer a question, or deal with a description of their behavior as implicating blame. These continuously updated understandings of what is being said and done constitute an important “proof procedure” for the analyst, that is, he or she can use these displays to provide support for the analysis. Whether something is blame or compliment is not decided upon by the analyst in the first place but analyzed as a participants’ concern.

People also talk rhetorically, in that they routinely resist or deny actual or potential alternative versions of what is being said. Inspecting stretches of discourse for these alternative versions helps the analyst to make sense of the actions performed. Presenting yourself as a woman resists “being a man,” and that may provide cues for the action at stake, for example, in the context of alleged or claimed transsexualism. It is the combination of a sequential and a rhetorical analysis which forms the basis of a discursive psychological approach (te Molder 2008).

The discussion on the gluten pill is part of an online forum for celiac disease patients ([www.celiac.com](http://www.celiac.com)). Celiac disease is a genetic disorder that causes an autoimmune reaction to the wheat protein gluten, which results in serious damage to the small intestine. At the moment, a lifelong diet is the only remedy. This requires not only discipline but is also difficult to implement as gluten is found in many daily foods.

Now let us have a look at extract 1, in which a (self-reported) scientific expert introduces the pill. The focus is on what the expert’s question is *doing* – in terms of discursive action – by looking at how the participants at the online discussion forum *treat* his or her contribution:

### Extract 1

- 1 Researcher (Sept 6 2004, 09:38 AM)  
2 Newbie  
3  
4 I am doing some research on developing potential new therapies for celiac  
5 disease and am wondering, how much would you be willing to pay each day if  
6 you could take a pill that would let you eat a normal diet? How much would  
7 you pay per year?  
8 ((9 lines omitted))  
9  
10 Sammy (Sept 9 2004, 08:04 PM)  
11 Member  
12  
13 I wouldn’t give one red cent for a pill. I have taken pills all of my life  
14 because of this disease. I would just keep on with the diet as is. I feel  
15 better than ever and have more energy than most 60 year olds should have.  
16 Pills? Thanks any way. Sammy

The topic is initiated by a researcher, obviously not a celiac patient and in this respect an outsider on the forum. Notice how by requiring into the amount of money that patients would be willing to pay each day (lines 5–7), the issue of need or desire to have this pill is already answered for. Second, the pill is presented as an *easy solution* to the disease in comparison to the current treatment (“a pill that would let you eat a normal diet,” line 6).

Sammy's contribution challenges the validity of both presuppositions. By saying that she "wouldn't give one red cent for a pill" (line 13), she explicitly brings down the assumption that celiac patients would take the pill anyway. She grounds her rejection in her elaborate experience with pills (lines 13–14). If you have used pills all your life, and the disease has ultimately been treated effectively by a diet, it makes no sense to go back on a pill and give up the diet and its payoff ("better than ever" and "more energy than..." line 15). Sammy's reply thereby questions the assumption in the researcher's post that the pill will radically change her life for the better.

Interestingly, the question including the presupposition that celiac patients will take and need a pill no matter what, evoked much stronger reactions than the careful suggestion that a pill might be developed:

**Extract 2** If they came out with an anti-gluten pill thingy (IV, 1–2; 4; 6–7)

- 132 If they found a pill that would neutralize the effects of  
gluten on your body (sort of like the pill people  
133 take who are lactose intolerant), would you use it?  
134  
135 Yes, definitely – all the time [18] [43.90%]  
136 Sometimes, but only when I am eating out [12] [29.27%]  
137 Sometimes, maybe once or twice a week [4] [9.76%]  
138 No, I'd be afraid that it wouldn't work [4] [9.76%]  
139 No, I don't think I could ever look at wheat the same way [3] [7.32%]

146 It could happen, eventually.....

This then shows that it is not the pill *itself* which is disputable, but the assumption that patients will use it *as a matter of course*. It is at this point that we become aware of the presence of concerns that do not regard health or safety ("risk") issues. Sammy, for example, rejects being characterized as a passive patient. She presents herself as a healthy individual who is able to maintain her vitality in the face of adverse circumstances. By resisting the notion that they would straightforwardly accept the pill patients construct themselves as proactive, thoughtful people with a healthy way of life. Presenting new possibilities as cure-alls makes the gluten-free diet appear as a hardship, and undermines the complexity of the patients' relation to their disease, including the positive values embedded in that relation. This example shows that an apparent straightforward rejection of a new medical technology is drawn upon by patients not so much to show concern about the pill's impact on their health, but about how the presentation of this innovation impacts their identity and sense of achievement (see also Veen et al. 2010; te Molder et al. submitted).

So, "less tangible" concerns often *emerge from* rather than stand out in discussions about new technologies. We find these, in this case, identity- and lifestyle-related concerns (who am

I – a patient, a victim, a naïve believer in cure, a healthy person?) only by looking at the ways in which patients *treat* the expert's contribution, and not so much by focusing on the content of what they say (e.g., I do not want the pill). This shows that these concerns are often only available indirectly for the analyst or debate facilitator. Moreover, participants themselves often do not have direct access to such interactional concerns. More precisely, we should say that this type of concerns regarding emerging technologies typically seem to arise as interactional goals – consciously or not – of what people say, rather than that they can be found directly in the content of the arguments that are put forward.

Now we turn our attention to an example that illustrates how experts operate to allow some concerns about technology's possible impacts access to the public agenda, while denying a similar access to other concerns. Again, this is typically done in a way that is far from straightforward.

## How Soft Impacts Tend to Disappear from the Public Agenda: The Case of "Naturalness"

The next fragment is part of a larger study of expert talk on future foods. It illustrates how a relatively classic citizen theme – naturalness, in this case of food – may be removed from the public agenda. In contrast to the previous example, in which an identity concern emerged from the discussion in such a way that it was neither available for experts nor patient participants, here "naturalness" appears as an explicit theme on the agenda. This can partly be explained by the fact that this discussion about the future of food was organized (not spontaneous, as in the first example) and the theme was put forward by the discussion leader. But naturalness is also a classic theme when it comes to citizen concerns about all sorts of new technologies. The argument is both attributed to citizens by experts and drawn upon by citizens themselves (e.g., Marris 2001 for naturalness in relation to food). It is treated as a typical citizen concern that is readily available and needs no further explanation, as we will also clarify with the following example.

The extract is taken from a discussion among twenty Dutch stakeholders about future food technologies, nine of whom were scientific and industrial food experts (Middendorp et al. *in prep.*). It illustrates how "naturalness" is removed from the public agenda by attributing the theme to the private domain of consumers such that no special account need be given, and no further exploration of its meaning is required:

### Extract 3<sup>1</sup>

- Facilitator 1 bu- but the picture that emerges now  
2 is of uh as it were  
3 an uhh (0.4) somewhat  
4 powerless industry  
5 that have to dance to the contradictory whims  
6 of the consumer (0.6)  
7 uhh is that the current feeling  
8 or are there also ideas about naturalness  
9 with the industry itself  
10 ((expert gets his turn from facilitator))

Expert      11 yes I think the industry  
12 views it a little bit-  
13 a little bit differently (0.4)  
14 uhh there are indeed (0.8) consumers  
15 who indeed want natural  
16 →without probably many consumers  
17 →uhh understanding what that then means  
18 →and what it entails (1.3)  
19 ehh subsequently (0.6) one wants e-number free  
20 well the industry can make it (0.7)  
21 the only problem of course is  
22 if you want to produce it e-number free  
23 that is more difficult that is more expensive  
24 the quality is generally less  
25 and it ultimately costs a little bit more (0.7)  
26 well if the consu- if the consumer wants that  
27 then I think that the industry simply has to  
28 ↑make it (1.1)  
29 as simple as that

We are interested in the kind of *action* that the expert performs by responding in the way he does. First note how the expert's remark about industry and consumers having different views (lines 11–13) avoids answering the facilitator's question whether the industry also has its own ideas about naturalness (8–9). The naturalness issue is reformulated from also, possibly, being an industry problem into a consumer concern only: it is consumers who want natural foods (14–15). In addition, the preparedness of the industry to listen to consumers is underlined. While it may not be the most logical choice to produce natural or e-number free food (more difficult, more expensive, etc. 23–25), we produce what they want. In so doing – turning naturalness into a private consumer concern which is attended to by experts (though somewhat reluctantly) – the need to further explore that concern is taken away. There is no reason for consumers to complain, so why investigate their concerns in a more than superficial manner?

Potential reasons to explore what "naturalness" refers to are further undermined by adding that consumers want natural food "without probably many consumers uhh understanding what that then means and what it entails" (16–18). This formulation defines the food expert as having superior access to what "naturalness" is, by suggesting a yardstick along which (other) definitions can be measured. By merely *implying* epistemic superiority, the actual definition of naturalness is claimed to be in the hands of experts such that there is no need to have it disclosed. Black-boxing the expert definition of naturalness prevents having it available for discussion, and opening it up – and other definitions for that matter – for debate.

Both discursive actions, i.e., framing naturalness as a private consumer-citizen concern that is already met by food experts as best it may, and claiming a superior definition of naturalness without having it explicated, work to establish naturalness as a concern that need not be dealt with in the public sphere. It is presented as already dealt with, without undermining scientific superiority or creating any pressure to ask explorative questions (as in: "What do you mean by natural food?").

While there is only space to discuss two cases here, the fragments shown here seem to represent a broader pattern in which potential soft impacts of future technologies either emerge as difficult-to-pin-down and mediated concerns (as with the celiac pill), or come up in the form of black-boxed, classic arguments (as with naturalness). While in the first case, the soft impact or identity concern is only implicitly available (as an interactional goal of participants' utterances rather than in the literal content of what they say), in the second case it is explicitly there but constructed as private and not in need of further exploration (this is again achieved indirectly, as an interactional consequence of the expert's arguments). Both ways of dealing with soft impacts make them susceptible to denial in the public domain, either because they are not visible, or because they are treated as private, known, and already dealt with (though nonvalid). The question is: how come?

## **Three Dimensions of the Hard/Soft Distinction: An Explanatory Model**

---

In our analysis we focused on two concrete cases, in which impacts regarding health, identity, lifestyle, taste, and naturalness were at stake. In the first case we showed how a patient raised her concerns about the pill's impacts on identity and lifestyle only in an indirect, roundabout way. In the previous section we saw how technology actors manoeuvered to allocate accountability for impacts. Some of these got accepted as public concerns that deserve the attention of technology actors and policy makers, while others got framed as private concerns and delegated to the citizen-consumer. These two cases seem to exemplify a wider pattern: some topics get taken up by technology actors, such as health, safety, and environment, while others, such as identity, lifestyle, and naturalness, are hardly taken serious. In this section we offer an explanatory model: in liberal, secular societies in which science and legal conceptions of accountability play pivotal roles, some of technology's impacts get qualified as "hard," others get dismissed as "soft." This crucial distinction is made along three dimensions.

### **Valuation**

---

The first dimension regards the valuation implicit in hopes and fears regarding the impacts of emerging technologies. If we look back at the examples given in the previous sections, the values underlying the concerns would be something like "having a sense of achievement," as exemplified in the diet-centered lifestyle of the celiac patient, or the "naturalness" of food. But the defenders of these values have, as the analysis shows, a hard time making themselves heard. It shows in the way Sammy talks: She *blurts* out that she doesn't need the pill, rather than "rationally" assessing the pros and cons of that particular medical technology, and without explaining how the prospect of the pill somehow affronts her. In the second example, it is clear that some consumers worry about whether modern food technology somehow results in "unnatural" food. It is equally clear, however, that this concern is not really taken seriously by the technologist. He bows for the demand, but only like an adult sometimes bows to the demand of an obstinate child: It may not be wise, but it is easier as it avoids a hassle.

Lifestyle concerns like "sense of achievement" or "naturalness" somehow seem to be taken less seriously. Nominally, there is no reason why these values would not be included in risk

assessments. Risk is simply defined as the probability that something undesirable will happen, so that could refer to any value. However, in actual practice, the values usually implied in Risk Assessment are only two: Safety and Health. True, in recent years, the Environment (Sustainability) was an important addition to the values implied in risk, and yes, more recently Privacy seems to be gaining prominence. Finally, Technology Assessment is usually broader than Risk Assessment and also takes into account values like Economic Growth and Employment. But that is about it, value-wise.

This is strange, as people have worried about a much broader palette of values in relation to technology: about the erosion of tradition, the tendency toward uniformity and conformism, about alienation, dehumanization, depersonalization, spiritual shallowness, enslavement by the machine, devaluation of life's fundamental values, artificial needs, about Faustian hubris, playing God, Frankenstein, about threats to democracy and justice, privacy, and so forth. Or they have hoped for much more important benefits: true self-development, post-humanism, true religion, world peace, cosmopolitan understanding, and so forth.

How then to explain this narrow focus of Technology and Risk Assessment? The answer lies in the dominance of liberalism in our societies. The key value informing liberalism is individual freedom, nowadays most often operationalized as "freedom of choice." The restriction of that freedom by the state is *a priori* under suspicion and always has to be justified. To this day, the simplest, most powerful, and most wide-spread justification of state intervention circulating in Western societies is J.-S. Mill's no-harm principle: "That the only purpose for which power can be rightfully exercised over any member of a civilized community, against his will, is to prevent harm to others" (John Stuart Mill 1859, pp. 21–22). So, in the case that there is no clear, noncontroversial instance of harm done, liberals lose interest. Those issues are left for everyone to decide upon individually, that is, they get relocated from the public to the private domain, where they are treated as matters of subjective preference. In John Rawls' influential terminology: public reason deals with the "Right," not with comprehensive conceptions of the "Good" (Rawls 1993, pp. 173–211).

When a nuclear reactor explodes, that is harmful. No one hesitates to affirm such a statement. Hard impacts are considered to be hard because they refer to such indubitable instances of harm: a technology is good when it helps avoiding it – e.g., by providing a cure against cancer or by helping to feed the hungry – and bad when it causes such harm. In the latter case, the state should move in. Safety, Health, Sustainability, Privacy, Profit, and Employment: When technology touches upon these values, relevant actors (technologists, policy makers, citizens) agree that these impacts qualify as harm, and should therefore be recognized as matters of public concern.

But unfortunately things are not always so clear-cut. When the television pollutes our minds by producing large quantities of inane chatter, is that harmful or innocent fun? And does Internet turn our friendship into a travesty (Turkle 2010) or do our ideas about friendship simply evolve with the new technological reality? Or, to return to the examples discussed in the previous sections: is it harmful when new medication threatens to rob a particular lifestyle of its value, and the ones living it of some of their sources for self-esteem? Or when technological interventions alienate us from our food, is that bad? Some would answer yes, but many would not.

If a technology is detrimental to one's safety or (preferably physical) health, few are going to argue. But it is much more difficult to establish a broad consensus on moral, cultural, or political "harms." In a liberal, pluralist society that prides itself on its tolerance of diverging conceptions of the good life, technologies cannot be forbidden on such a shaky basis. And

because it cannot be forbidden, why talk about it at all? In liberal societies about the only harm that is considered a legitimate topic for public discussion, is physical (or maybe medically certified psychological) harm, because only on this topic citizens can reach consensus. In other words, there is an – admittedly gliding – scale between impacts that are conceived to be “hard” because they involve clear instances of harm, and impacts that are conceived to be “soft” because they do not. Technology and policy actors take the first type seriously, but rarely the latter type (Swierstra 2002).

## Quantifiability

---

Now let us turn to the second dimension of the distinction between hard and soft impacts: quantifiability. Quite apart from the kind of harm we are dealing with when assessing the impacts of a technology, we also want to know how big the chance is that a technology will cause such harm in the future, and how big the harm then will turn out to be. So, how big would be the risk that the gluten pill would indeed affect the diet-centered lifestyle of Sammy, and how harmful would that be exactly? Or: how big is the probability that modern food technologies diminish the “naturalness” of our food, and if so, how bad would this be exactly?

Both technology actors and policy makers tend to prefer answers to these questions in the form of numbers. For them, numbers equal objectivity. The more readily impacts lend themselves to quantification, as the better they fit into the discourses prevailing among technology developers and policy makers and the more readily they are accepted as “rational” and “serious,” in other words, the “harder” they are perceived to be (cf. Slovic 2000; Jaeger et al. 2001; Roesser 2010). And indeed, some risks do lend themselves to this language of numbers. An example of high quantifiability is the risk of a nuclear disaster, both in terms of probability and in terms of body count. In general, we can say that impacts on Health and Safety, and on Profit and Employment, can be quantified well using numbers. Environmental risks, on the other hand, already lend themselves less readily to quantification. Their probability may still be calculated but it often proves difficult to attach numbers to the harm/impact itself. Of course, one can estimate how many fish will die, but how to translate this quantity into a magnitude of harm – to us? This is why harms to the environment often get translated into economic terms. Risks to our Privacy are also hard to quantify.

But many of technology’s impacts lend themselves even less to quantification. Take for example the risk that a new medication will change my diet-centered life style and undermine my sense of achievement? By what means to assess the probability that that will happen, and how even to begin quantifying such an impact? Or the risk that food technology will alienate us even further from Nature. How to calculate the probability that that will happen? And how to even start measuring different degrees of alienation?

Quantifiable risks count as hard, nonquantifiable risks get dismissed as too soft to merit rational discussion. Why do technology actors and policy makers seem to prefer the language of numbers? The answer to that question is not self-evident. More than a century ago, Wilhelm Dilthey argued that there are two ways of investigating the world: scientific explanation for the natural world and (historical) understanding for the social world of meanings. But still, up to this day scientists and policy makers consider the contributions of history, anthropology, and other qualitative sciences as too soft to take seriously. Similar to the way “harm” is considered

as an objective criterion in liberalism, allowing for a rational discourse capable of generating consensus, in science and policy making “quantifiability” is perceived as a sign of objectivity and rationality.<sup>2</sup> Only on this basis a rational consensus is deemed to be possible.

## Causality

---

However, to be really accepted as “hard” by technology actors and policy makers, an impact has to meet a third and final condition. To be relevant to these actors, they have to somehow feel responsible, or more passively, afraid to be held accountable, for the impact in question. A major precondition for responsibility/accountability is that there exists a clear causal link between technology and impact.<sup>3</sup> When such a link can be established, this considerably adds to the hardness of an impact. And who would try to deny the causal link between a nuclear explosion and the dead bodies around?

But the causal link between technology and impact is not always easy to establish. Philosophy of technology, Actor Network Theory, and (post-)hermeneutics have argued convincingly that the conception of technology as a passive, neutral instrument is naïve. Philosophers of technology point out that technology is far from passive and neutral, because it mediates our (theoretical and practical) relations with the world in specific ways. Technology can change the way we interpret the world (Idhe 1993), and how we act in it (Akrich 1992; Latour 1992; Verbeek 2005; Swierstra and Waelbers 2010; Waelbers 2011). Studies show over and over again how technological artifacts, for instance, can “invite” or “facilitate” certain behavior in the user. These instances of technologically mediated behavior are, however, difficult to assess in terms of accountability. The causal link between technology and impact is not straightforward, but bent, diffused. A philosopher may consider accountability for undesirable impacts distributed over technologists, users, artifacts, and policy makers; in legal practice it is still usually the user who ends being blamed.

As American bumper stickers never tire to explain: Guns don’t kill people; People kill people. Of course, even the gun lobby is willing to admit that in some cases guns do kill people, that is, when they malfunction and explode in the face of the shooter. But in all other cases, according to the weapon-lobby, it is solely the user who is to be held accountable, not the innocent (neutral, passive) *instrument* or its designer/manufacturer/seller. Similarly, if a new anti-gluten pill threatens someone’s identity, this can never be attributed to this pill. Some people will be able to withstand the pressures of this new medical technology, and stick to their old identity, so ultimately it is a matter of free individual choice.

Now, even if we think this reasoning is a little too comfortable, we have to admit that the attribution of responsibility is difficult when it is clear that effects are co-produced by a plurality of actors. We as yet have very limited means to conceptualize and organize collective responsibility. Our dominant moral models ultimately refer back to individuals making conscious choices. In cases where humans and nonhumans share responsibility, it is easier to conclude that no one is responsible. As a result, impacts of technology that cannot be clearly and unequivocally linked to technology actors are treated as “soft” and removed from the public agenda. Do not blame the makers of the gluten pill for undermining your sense of achievement. Do not blame the food technologists for making you eat unnatural food. It is no one’s fault, really, and therefore not a matter of public concern.

## Concluding Remarks

---

We started our chapter by pointing out that the participatory agenda is managed in such a way as to deal with certain topics and not with others. In the previous section, we argued that some concerns were allowed on that agenda because they are perceived to be “hard” enough to allow for rational debate. Hard issues are essentially considered to be hard, because they promise to be the object of a rational, uncoerced, consensus: because the type of harm is noncontroversial, because no one can argue with numbers, and/or because technology or policy actors cannot deny accountability because of the clear causal link between technology and impact. Everything that does not score on (one or more of) these three dimensions, runs the risk of being dismissed as too soft – subjective, unproven, and/or messy with regard to whom is to be held accountable.

The celiac pill example showed how “soft” concerns cannot be recognized so much in what people literally say as in what becomes visible in the interactional concerns that they display, e.g., treating the anti-gluten pill – couched by an expert as a panacea to their problems – as a threat to their identity and a devaluation of their current lifestyle. This appearance clarifies why soft concerns may surface in a roundabout way rather than become apparent straightforwardly, and thus may be difficult to identify.

In other cases, soft concerns seem directly available for discussion, as in the food expert discussion on naturalness. However, this soft concern was subsequently constructed as a private consumer issue that does not require any further scrutiny or exploration, as it is already known and can be met (if somewhat reluctantly). While in this case the soft concern seems easier to recognize, the interactional result is the same: it is constructed as not deserving any further attention in the public arena.

The three dimensions of soft impacts as laid out in the previous section (difficult to value; quantify, and explain causally) make their indirect emergence or lack of exploration plausible, for this type of soft concern can expect an unwelcome reception. The patients’ talk shows an orientation to such challenge and marginalization by phrasing the rejection of the anti-gluten pill in extreme terms and not spell out the nature of the affront. But the dismissal of these concerns also requires a detour. By couching the dismissal of natural food in the obligatory language of mutual respect and of the sovereignty of the citizen-consumer’s wishes, the expert’s talk shows anticipation of the “hardness” of democratic norms and rules that demand that everyone’s concern counts.

We want to argue that this dismissal of soft impacts by technology actors and policy makers is shortsighted. It is a cause for concern when citizens fail to acquire a fair hearing for their concerns, even if the values concerned are contested, even if the chance that the harm occurs cannot be quantified, and even if there is no one who can be held accountable in a clear and unequivocal manner.

It is worth pointing out that hard impacts are not as hard as they are taken to be. There is always room for conflicts about what constitutes harm, how to quantify it, and who is to be held accountable. But more importantly, taking soft impacts seriously is not only paramount for democratic reasons – if large strata of society hold these concerns, that is in itself enough reason to discuss them carefully – it is also crucially important for substantive ones.

First of all, taking a broader range of values seriously opens a door to a more positive heuristics with regard to emerging technologies, away from the present binary discourse about the question whether a technology should be forbidden or not. Currently the main thrust in Risk or Technology Assessment is negative: How to avoid or minimize harm? If no clearly

harmful impacts are to be expected, policy makers and technology actors lose interest and the success of the technology is now left to the unreflective preferences of individual consumers. But in a technological culture like ours, the issue should rather be: how to establish a practice of public deliberation on what *good* technology is. What technology do citizens want to see developed? The aim should be goal-setting rather than harm-avoidance. Taking soft impacts seriously helps to move away from the binary risk discourse (“Should this technology be forbidden: yes/no”), to a discourse of the (common) good (Swierstra 2002).

Secondly, laying too much stress on quantifiability can be highly counterproductive. Because they only had eyes for the hard impacts of GMOs, decision makers for too long dismissed the public’s doubts as irrational, emotional, private, and religious, etc. The resulting break of mutual trust between producers and consumers has frustrated the development of biotechnology (Wynne 2001).

Thirdly, ignoring indirect impacts may thwart the technology’s intended aim, as in the case of so-called revenge-effects (Tenner 1996). Technology actors and policy makers often fail to anticipate that the user’s behavior changes because of the new technology. The “light” cigarettes that in the end only increased the net intake of tar and nicotine because people assumed these were not so unhealthy, provide a good example. Such technologically mediated behavioral change is currently dismissed as a soft impact, because responsibility cannot be unequivocally located with the technologist. But when such indirect impacts are foreseeable for the marketing department of the tobacco company, why should technology developers and policy makers be excused from taking them into account?

Summarizing: In the case of controversial technologies, like the life sciences for instance, stakeholders point out a large array of possible impacts. However, decision makers, like; technology actors and policy makers, tend to concentrate on “hard” – quantifiable, harmful, direct – impacts. But it is essential that in a technological culture soft impacts of emerging technologies are equally taken into account. This is the only way to make the co-evolution (Rip and Kemp 1998) or co-production (Jasanoff 2004) of technology and society reflective and democratically checked. Technology does far more than simply providing the means to our existing goals. Technology redefines these goals; changes or affirms power relations; affects values, standards, and norms; informs aspirations; installs new needs and preferences; teaches what it is right to hope for.

## Further Research

Having said that responsible innovation processes require soft impacts to be taken into account, it is important to point out what we mean by the latter, and whose responsibilities we are and are not referring to. For one thing, “taking into account” soft impacts does not equal accepting these impacts as true or right, and/or following them up immediately. We do not propose that expert-technologists start to grow natural food straight away, or that policy makers acknowledge that genetic modification transgresses ethical boundaries once citizens have pointed those out to them. The validity of soft impacts, and acting according to them, should become part of the negotiation. Furthermore, while technologists and policy makers may be inclined to display little concern for soft impacts, this neither implicates that it is their responsibility alone to solve the matter, nor that it would be the most effective way to go.

As the conversation analysts Heritage and Raymond (2005, p. 2) point out: “the distribution of rights and responsibilities regarding what participants can accountably know, how they know it, whether they have rights to describe it, and in what terms, are directly implicated in organized practices of speaking.” Looking at the actual dynamics of accountability attribution and denial, particularly at the level of what expert participants claim to accountably know, i.e., claim to have access to, and for what interactional purposes, is crucial as a first step for revealing the ways in which the hard/soft distinction are made and sustained. Not only as to understand better the concerns that guide, consciously or not, the referral to soft and/or hard impacts, but also because different attributions of accountability may have different implications for how to achieve a more comprehensive public dialogue.

That naturalness is both constructed as a private consumer concern and black-boxed as requiring no further investigation, makes it a different problem than, for example, the issue of good taste (Middendorp et al. *in prep.*). Food experts tend to attribute complete responsibility to consumers for telling them what good taste is, and only claim epistemic access to the technicalities of how to achieve a certain taste. Since anything can be made – is the suggestion – there is no such thing as a lack of good taste when it comes to future foods. In both cases, soft concerns are pushed off the discussion table but the starting point for a more comprehensive dialogue would be different. Naturalness and good taste are both treated as private preferences that require no debate, but taste is constructed as a legitimate concern, whereas naturalness is dismissed as invalid. For one thing, naturalness would need to be explored, and the conclusion may well be – jointly with consumers – that “natural food” is infeasible, or precisely the reverse, because it stands for something other than expected. Up till then, experts keep the “problem” intact as much as they blame consumers for.

Our analysis shows that these concerns are often not or only indirectly available for the debate facilitator. Likewise, participants themselves tend not to have direct access to interactional concerns although, when confronted with them, they will recognize them immediately. The Discursive Action Method (Lamerichs and te Molder *forthcoming 2011*) is a reflection method that aims to turn participants into analysts of their own discourse by making these concerns visible and open for discussion. This not only counts for the expert-designer or policy makers but just as well for (potential) users of technologies. Natural food may be reshuffled into a private consumer concern with which a food expert should not be preoccupied, but “naturalness” may just as well be drawn upon by consumers to delineate their territory such that no expert is allowed in.

A close and critical reflection on how soft/hard concerns are drawn upon, and for what interactional business, may be the starting point for a new area of research, and a practice in which a more comprehensive dialogue could make a start. This research should then be complemented by a philosophical critique of the three dimensions that together make up the hard–soft distinction. Such critique will have to draw its inspiration from quite diverse traditions. The primacy of the no-harm principle in liberal political philosophies has to be investigated in the light of the new realities of a technological culture. Does the way this principle is applied allow for fruitful public deliberations about the (un)desirability of technologies? A similar investigation has to focus on the widespread belief that only numbers allow for rational consensus. Part of this investigation will be primarily philosophical in character, but important inputs are also to be expected from more empirical research in Science and Technology studies that explore how these numbers are constructed and contested. Last but not

least, the issue of technological mediation has to be explored further by both philosophers of technology, who investigate the various forms of technological mediation, and moral philosophers, who have to develop convincing conceptions of collective, or shared, responsibility. These types of research in the philosophical foundations of the hard–soft distinction will help to create the necessary discursive space for the technologists, policy makers, and citizens. Because they are the ones who have to make sure that in their mutual dealings the (implicit) distinction between hard and soft impacts no longer serves to remove relevant topics from the agenda for the public dialogue on technology.

## Notes

---

1. Transcripts employ the notational convention used in conversation analysis (Jefferson 2004). The transcription symbols used here are:

bu-	a cut-off or self-interruption
↑	sharp rise in pitch
(1.0)	numbers denote silence in tenths of seconds
wants	underlined items were hearably stressed
(( ))	transcriber's description of events

The fragment is translated from Dutch to English, remaining as close as possible to the original Dutch text.

2. A separate issue, of course, is whether all the relevant data are available. The precautionary principle is a procedural rule devised to deal with such a (temporary) lack.
3. Although it has to be admitted that in the case of positive impacts, this demand for a direct causal link is usually interpreted less strictly. As Ravetz famously put it: "Science takes credit for penicillin, while Society takes the blame for the Bomb" (Ravetz 1975, p. 46).

**Abstract:** This chapter provides an overview of the changing relationship between risk, technology assessment (TA), and risk assessment (RA). It does so by comparing the development of the practice of parliamentary TA and RA, the way risk is interpreted in these practices, and the political role these practices play in dealing with risks. The basic argument is that originally RA and TA presented politically separate practices. Over the last decade, the conceptual gap between these two practices has been bridged to a large extent. We start with describing the classical approaches to TA and RA, which developed in 1960s in the United States and were guided by the belief that scientific methods would improve decision making around the risks involved in science and technology. Classical parliamentary TA and RA present very distinct scientific and political practices, with different conceptions of risk and political roles. The classical approach to risk operated with a narrow mathematical definition of risk. Classical TA defined risk in a much broader fashion; risk referred to a broad set of (potential) negative social effects of science and technology. RA was thought to help the government in managing risk, by depoliticizing risk management. In contrast, parliamentary TA aimed to enable a political debate within Congress, and thereby strengthening the position of Congress vis-à-vis the executive branch. Throughout the years, both practice and scientific literature have revealed basic shortcomings of the classical approach to TA and risk. Driven by the concept of uncertainty, the role of RA and TA and their interpretation of risk have changed. Modern risk approaches are expected to deal with both calculable and uncertain risk. TA is encouraged to look beyond effects, to also analyze current visions and values that drive science and technology. Based on the concept of uncertainty, attempts have been made to characterize risk or problem situations in order to clarify the limitations of the classical RA and TA approaches. The claim is that in case of scientific and regulatory uncertainties, and value dissent more participatory approaches to RA and TA are required, which seek to represent public controversy. The IRGC risk governance framework can be seen as exemplary for the new risk approach. From a risk governance perspective, RA and parliamentary TA have become complementary practices. The case of risk governance on nanotechnology in the Netherlands proves this point. However, parliamentary TA's role within risk governance presents a remarkable blind spot on the current research agenda.

## Introduction

---

This chapter aims to discuss the relationship between risk and technology assessment, in particular parliamentary technology assessment. Technology assessment (TA) is driven by an awareness about potential positive and negative effects of technological change, and the hope that one can anticipate these effects. Since it deals with the interplay between technological change and (potential) social problems, TA has a clear political side to it (Van Est and Brom 2012). This counts in particular for parliamentary TA, which this chapter will focus on. Although risk and TA clearly touch each other in all kinds of ways, such an exercise – to our knowledge – has never been undertaken before. This is quite surprising since on first sight, the relationship between risk and TA seems to be a close and obvious one. Take, for example, this quote by Grunwald (2009, p. 1131): “One of the main reasons for the emergence of TA was because of the risks directly or indirectly caused by technology and its use... TA should and does contribute to the early signaling of risks and how they should be dealt with.” Discussing the above relationship, however, is a rather complex, but still worthwhile task, because it is of particular interest for current debates on risk politics and governance.

## No Straightforward Connection

---

Discussing the relationship between TA and risk is not a straightforward task. Take for example, the fact TA is not built around a precisely defined concept of risk. At least the classical risk approach provides a clear technical definition of risk, even a formula to calculate risk. Namely risk is generally defined as the product of the magnitude of the possible adverse consequence(s) and the probability of occurrence of each consequence. In contrast, “risk” within the current TA practice tends to refer to a “colloquial meaning of the term risk” (Maasen and Merz 2006, p. 25), in the sense that risk in TA equates with (negative) social impacts of science and technology in general. There are at least three other reasons why the connection between risk and TA is not obvious.

First, no unambiguous and selective definition of TA exists (Grunwald 2009). This is because TA is neither a separate field of scientific research nor a well-defined, clear-cut practice. Disciplines ranging from policy and political sciences to ethics, science, and technology studies; communication sciences; and social and cultural studies have all influenced the way TA is understood, performed, and institutionalized. TA is being employed in a wide variety of institutional settings, covering many functions, goals, methods, and target groups. TA can be found in industry to help product development, close to politics to provide information, and stimulate the parliamentary and public debate. TA is also employed as an instrument to guide scientific research from a societal perspective. For example, studies on ethical, legal, and social aspects (ELSA) of science and technology have been increasingly integrated in large research programs in order to integrate societal considerations in research choices.

Second, risk assessment (RA) is about assessing (technical) risks. RA provides scientific input into the risk management process, that is, the political decision-making process about how to deal with risk. Parliamentary TA is not primarily about assessing (technical) risks. Its main political role is to help the democratic system to deal with (potential) public controversies on science and technology. These public controversies might be driven by concerns on safety, but also wider public concerns. Public controversies come into play because various groups may have different interests or different views on what the problem is, and what kind of solutions should be strived for. Democratic politics is a way to deal with public controversies that includes free and open deliberation and also exercising power. Political practice is about connecting these two poles (cf. Jaspers 1965), and TA is supposed to play a positive and constructive role in achieving that.

Finally, the practice of parliamentary TA and the practice of assessing and politically managing risk are not static ones, but constantly developing. Both the classical approach to TA and risk were first developed and institutionalized in the United States during the 1960s and the 1970s. Since then, both practices have spread around the world. Throughout the years, both practice and academic literature as well as encountering new political cultures have changed the practice of parliamentary TA. Also the classical risk approach has received a lot of criticism. In particular, the political value of the technical definition of risk has been hotly debated over the years.

## Complementary Political Roles

---

The fact that analyzing the relationship between risk and TA is dynamic and complex does not imply that it is impossible or not useful to do so. We believe that it can be fruitful to clarify in

a systematic way how parliamentary TA interprets risk and how this practice touches the practice of risk assessment. Both TA and RA provide scientific input into the political decision-making process on how society handles risks. One might say that TA relates to the parliamentary debate in the same way as RA relates to the political process of governing risks. Lynn's (1981) game metaphor of the political decision-making process gives us a second impression of how the practice of TA and RA relate to each other. Lawrence E. Lynn distinguishes three games within the political decision making, corresponding to three levels within the political system. The high game involves deciding on whether there is a role for the government. It focuses on deciding the right thing to do and identifying the social values that are explicitly at stake. The middle game is more concretely about what the role of the government is going to be, about the effectiveness and efficiency of policy interventions. The low game is about the formulation of the precise design of the related policy instruments. Roughly speaking, parliamentary debate and TA are situated in the high and middle political game, while risk assessment and management are situated more in the middle and low game. The roles and practices of TA and RA thus seem to be complementary, and partially overlapping. From this line of argument follows the central aim of this paper: to analyze to what extent the political practice of (parliamentary) TA and risk assessment may inspire and complement each other in a constructive manner. For this, we will describe and compare the political role TA and RA play within the political decision-making process on risks, in connection to the way they interpret the notion of risk.

## Contents

---

The first section compares the classical approach to TA and RA. Both practices arrived in the 1960s and were politically legitimized in similar ways. Both approaches were based on the assumption that science-based expertise would rationalize the political decision-making process on technology-related risks and controversies. Nevertheless, their political roles and their conception of risk differed strongly. While RA was meant to rationalize the political debate on technological risks, parliamentary TA's role was to strengthen the position of the parliament vis-à-vis the government. Besides, while RA had a narrow probabilistic definition of risk, TA used a common sense notion of risk, referring to a broad set of (potential) social effects of science and technology. The classical forms of RA and TA became severely challenged by two fundamental and interrelated forms of critique: the issue of problem framing and representation. The next three sections deal with these two aspects of problem framing.

The second section analyzes various shifts in the interpretation of risk within TA and RA. TA has broadened its scope from focusing on (potential) effects of technology toward the current visions and values that shape science and technology. RA has broadened its perspective from risks that are calculable based on past experience toward (future) uncertain risks. The third section looks at the relationship between characterizing the risk situation and its implications for the appropriate roles and approaches to RA and TA. With respect to characterizing the risk situation the notion of uncertainty has slowly entered the minds of political decision makers during the 1990s. This awareness revealed the boundaries of the classical risk approach, by limiting it to so-called simple risk problems. Moreover, it underpinned the legitimacy of participatory approaches in TA and RA.

The fourth section deals with the issue of representation, that is, the question of who is allowed to define the risk problem at stake. The basic complaint is that expert-based classical

approaches do not sufficiently represent public concerns on risks. To address this shortcoming, new (participatory) approaches to TA and RA have been proposed which aim to involve a broader set of social actors within the political decision-making process on technology-related risks. In particular, this section investigates the relationship between the risk governance model (see also ➤ [Chap. 44, Risk Governance](#) by Hermans, Fox, and van Asselt in the present book) and TA. Our analysis shows that the risk governance model includes various typical TA elements and visions. Exactly this makes a comparison of the practice of politically dealing with risk and parliamentary TA of current interest.

The fifth section describes the case of risk governance on nanotechnology in the Netherlands. This case shows how parliamentary TA has a fruitful role to play in the governance of risk. The final section will make some concluding remarks and describes some themes that require further research.

## Classical Risk Approach and TA

---

Risk assessment and technology assessment were first developed in the United States (Bimber and Guston [1997](#)). During the 1960s, the rise of decision theory, operations research, and system theory had raised the hope that scientific methods could improve decision making around science and technology (Bereano [1997](#)). This belief rendered political legitimacy and support to the idea of risk assessment and technology assessment in the United States.

For example, to calculate the probability of accidents in the field of nuclear power and aerospace quantitative risk assessment tools were developed. This led to the so-called classical risk approach. In the same period, the scientific community in close interplay with the Congress developed a classical TA approach, which defined TA as “a policy study designed to better understand the consequences across society of the extension of the existing technology or the introduction of a new technology with emphasis on the effects that would normally be unplanned and unanticipated” (Coates [2001](#), p. 303). Eventually, this led to setting up a TA institute in the U.S. Congress in the early 1970s. This section gives a short description of both the classical risk approach and classical TA, and compares the way they interpret risk, and their presumed political roles within the decision-making process.

### Classical Risk Approach

---

#### Risk as a Calculable Property

In the scientific literature many definitions of risk can be found (for an overview cf. Renn [2005](#), pp. 141–142). Most definitions, however, normally consist of two elements. The first element refers to damage, undesired impacts, or adverse effects. The second element speaks of chance, likelihood, or probability of such harmful consequences. The most prevailing definition combines the chance that a given hazardous effect will occur and the impact this will have. Risk became interpreted as the product of the magnitude of the potential loss or damage and the probability that that loss will occur. This is reflected in the often used (risk) formula: “risk = probability × effect.” The corner stone of the classical approach, thus, is to quantify certain risks.

## Separating Science and Politics

This formula forms the basis for the classical risk approach which became dominant during the 1960s in the way Western societies politically deal with risks. In this approach, basically, two stages can be distinguished. In the risk assessment phase, risk experts try to quantify relevant risks (Renn 2005, p. 27). Risk experts first have to identify and, if possible, make an estimation of the hazard. Next, they have to assess the exposure and/or vulnerability to the danger. Finally, they have to make an estimation of the risk based on the former two steps by using the risk formula. In the risk management stage, risk managers take measures to deal with or control various unacceptable risks. The classical risk approach is founded on a clear (institutional) distinction between the risk assessment and management stages, or in other words, between the “science” of estimating risks and the “politics” of taking risk measures (National Research Council 1983). It was feared that otherwise political pressure could harm scientific independence, which could lead to over- or underestimating certain dangers.

## Classical TA as Expert-Driven Policy Analysis

---

### Empowering Congress vis-à-vis Government

Over the 1960s, public awareness grew of potential health and environmental risks related to new technologies. It was felt that representative institutions were failing to deal with the negative side effects of technological change. The need to estimate the environmental impact of a proposed (technological) project became regulated by the National Environmental Policy Act (1970). TA was “in some ways an enlarged version of the awareness that lead to the extensive development of environmental impact statements (EIS)” (Coates 2001, p. 303). In 1972, the Technology Assessment Act acknowledged the need to anticipate on a broader spectrum of social effects of technological change, besides health and environmental impacts (U.S. Congress 1972). Its passage in the House led to the creation of the Office of Technology Assessment (OTA) in the U.S. Congress. The foundation of OTA was driven by the U.S. Congress’ desire to assess the political, economic, and social aspects of technological change independently from the executive. Already, in the early 1960, the Congress of the United States was confronted with an increasing science and technology budget, related to ambitious projects, like putting a man on the moon. Congress became concerned about its lack of ability to evaluate matters of scientific and technical complexity. Lacking critical, independent information, Members of Congress feared they were becoming “the rubber stamps of the administrative branch of government” (Democrat George Miller 1961 quoted in Kunkle 1995).

### Policy Analysis Versus Democratization

Several competing political agendas concerning the function of TA were in play. While some saw OTA primarily as an instrument to strengthen the Congress’s scientific oversight of federal science and technology initiatives, others wanted TA to be an instrument for democratization (Bereano 1997). The 1960s had seen the revival of Jeffersonianism, with its trust in community self-reliance and grassroots democracy. With respect to the practice of TA, Jeffersonian ethics implied a call for more public participation in the political decision-making process

concerning new technologies. In 1973 and 1974, a coalition of public interest groups and individuals tried to assure that OTA would develop participatory processes. This, however, did not become common practice within OTA. In the early 1960s, members of Congress realized that the executive branch had close relationship with the National Academy of Sciences, while Congress was lacking such contacts (Kunkle 1995). During the 1960s, closer bonds between the National Academy of Sciences and Congress were created. In that process, the scientific community was successful in turning OTA primarily into a scientific instrument. Accordingly, OTA defined its practice of TA primarily as a form of critical-rational policy analysis. The aim of this expert-driven policy analysis was seen as “speaking truth to power.” Nevertheless, Congress continued to call for inclusion of wider social values and perspectives in TA. This led to the development of a system of controlled consultation with some experts and interest groups.

## Comparative Conclusions

Both the classical risk approach and classical (parliamentary) TA are guided by the belief that scientific methods can improve political decision making around science and technology. Still, they clearly present very distinct scientific and democratic practices, with different conceptions of risk and different political roles (see ➤ *Table 43.1*).

Within the classical risk approach, risk became mathematically defined through the risk formula. Within TA risk was interpreted in a much broader and more social science oriented fashion. Although RA was part of the TA methods toolbox, “risk” within the TA community referred to everything that forms a danger. This definition reflected the demand from Congress, which was interested in a broad set of (potential) social effects of science and technology.

Related to this, the political roles of RA and TA were quite distinct. Risk assessment was thought to help the government in managing risk. The hope was that the scientific information delivered by RA could depoliticize risk management and make it into a bureaucratic process. The objective of classical TA was to provide neutral expert advice, which would strengthen the Congress’s position vis-à-vis the executive branch. In other words, its role was to enable and

■ **Table 43.1**  
Comparing the classical risk approach and classical parliamentary TA

	Classical risk approach	Classical parliamentary TA
Science	Risk assessment	Technology assessment
Interpretation of risk	$\text{Risk} = \text{Probability} \times \text{Effect}$	Broad set of (potential) social effects of science and technology
Political role		
Interface science – policy making	Informing (governmental) risk managers about technical risks	Informing MPs on social effects of S&T
Interface government – parliament	Rationalizing the political decision-making process on risk management	Empowering the Congress vis-à-vis the government
Interface society – policy making	–	Rationalizing (preventing) public controversy (by anticipating on social effects)

strengthen the political debate about risk. Also, the fact that TA was intended to assess a broad set of social effects gave Congress the means to discuss risks related to science and technology from a broad public perspective.

## Two Basic Shortcomings of the Classical Risk Approach

---

Over the last decades, both practice and scientific literature have revealed many shortcomings of the classical approach to TA and risk. Basically, two closely related categories of critique can be discerned. The first type of concerns relates to problem framing. Section [● Interpretation of Risk with RA and TA](#) deals with the issue of how to interpret risk, and what this implies for the object of study and role for RA and TA. Section [● Risk Characteristics and RA and TA](#) looks at the discussion on characterizing risk or TA problem situations. In particular, this debate plays a role in clarifying the limits of the classical approaches and legitimizing new (participatory) approaches to RA and TA.

The second category of critique is about the question of “who defines,” causes or is affected by or is responsible for dealing with the problem. It was described above that from the onset parliamentary TA was confronted with a competing participatory perspective on parliamentary TA. The classical risk approach received similar points of critique. The complexity of assessing risks was thought to give room to experts to bring in their own values in the decision-making process in a way that could not easily be detected by the public. Such an opaque highly expert-driven assessment was found not to be in tune with modern democratic principles. Since risks are often problematic complex constructs, it is a major democratic challenge to translate these constructs into “debatable risks” (WRR 2008, p. 113). Section [● New \(Participatory\) Approaches to TA and RA](#) describes and compares the rationales for new (participatory) approaches to TA and RA.

## Interpretation of Risk with RA and TA

---

Throughout the years, both RA and TA practices have been criticized for having a too narrow focus, and therefore for being scientifically misdirected or politically biased. For example, both TA and RA were accused of focusing too much on bad chances and too little on good chances. Moreover, classical risk assessment was criticized for employing a too narrow definition of risk, i.e., risk as a calculable entity. It was feared that such a narrow conceptualization would preclude a debate about broader public concerns. Classical TA was less vulnerable to such a critique because it employed a common sense definition of risk, encompassing all kinds of social effects of science and technology. Still, classical TA was criticized because of its sole focus on “social effects,” and not on “social drivers” of technological change.

## RA: From Calculable to Uncertain Risks

---

The classical risk approach assumes that it is possible to define and assess risks. The assumption that risks can be objectified and calculated has met with a lot of criticism. Notions like complexity and uncertainty to characterize the risk situation have played a central role in clarifying the limits of the classical risk approach.

## Bad and Good Chances

In *Searching for safety*, Wildavsky (1988) argued that “playing it safe” may also present a danger. He argued that besides bad chances, there are also good chances. Risk assessment then should also be able to characterize the good chances.

## Public Perception

Already in the 1970s, the assumption that risks can be “objectified” and calculated met with a lot of criticism. The classical risk approach was attacked for not being able to take account of human perceptions (cf. Slovic 1978/2000). For example, the risk formula might attribute equal weight to a major disaster having a low probability and a small accident having a high probability. Most people, however, are more fearful of a major disaster with a low probability. This critique challenges risk assessors and risk managers to come up with an approach that takes into account the way people talk about and perceive risks.

## Complexity

Moreover, it was argued that in many circumstances, it is not self-evident to define what the hazards, their probabilities, and the consequences precisely are (cf. Fischoff et al. 1981). In particular, the interactions of humans and/or technological subsystems are much more complex than an a priori risk assignment can capture. Perrow (1984) even talked about “normal accidents,” arguing that when a technology has become sufficiently complex and tightly coupled, accidents are inevitable and therefore in a sense “normal.” As a consequence, the role played by organizational failures are very hard to take into account. This also counts for the human element in the decision-making process around risk.

## Broader Public Concerns

It was also feared that a narrow focus on the assessment of risks, but also “risk perception,” would prevent a debate about broader public concerns (Felt 2007). For example, with respect to GM food, the classical risk approach focuses on assessing the related safety risks. In the public debate, however, freedom of consumer choice plays a central role. Another major source of public concern is the inadequacy of the classical approach to deal with risk. The classical risk approach does not provide space for a proper discussion about the institutional incapacity to deal with (often unpredictable) ethical and social impacts of science and technology. As a consequence, the shortcoming of the classical risk approach exactly provokes such a debate.

## Risk Versus Uncertainty

The concept of uncertainty has played an important role in clarifying the limits of the classical risk approach and promoting new approaches and considering wider public concerns. It has been argued for long that not all decision-making situations can be characterized as situations of risk. The economist Knight (1921) made a distinction between situations characterized by

risks and uncertainty. In some circumstances, entrepreneurs may be able to calculate certain risks based on experience. In other cases, decision making is more speculative. In those cases, Knight talked about making decisions under uncertainty. Harremoës et al. (2001, p. 192) have emphasized a third type of problem situation: ignorance. According to the authors, risk is about “known” impacts and probabilities, and a situation of uncertainty is characterized by “known” impacts, but “unknown” probabilities. One may speak of a situation of ignorance when also the impacts are “unknown.”

## **Uncertain Risks**

Various authors have argued that the above dichotomies – risk versus uncertainty, calculable versus non-calculable, and knowing versus non-knowing – are flawed (cf. WRR 2008; Van Asselt et al. 2009). For several reasons, they prefer to talk of “uncertain risks” (Everson and Vos 2009). First of all, such a term better connects to the way society speaks about and deals with risks. In the public debate various types of uncertainty – e.g., scientific uncertainty and regulatory uncertainty (Hood et al. 2001) – are attributed to the notion of risk. Here, risk broadly refers to “bad chances,” like damage, loss, calamities, and disasters. Moreover, despite all the uncertainties involved in waste disposal, genetically modified food, or climate change, these developments are subjected to RA and management. Second, risk situations characterized by uncertainty have become increasingly common. This relates to the fact that current risk assessment is mostly future-oriented. The basis for risk assessment, therefore, has shifted from *probability*, based on experience in the past, to *possibility*, based on expectations about the future. Finally, these authors prefer to speak of “uncertain risks” to imply that risk situations of uncertainty do not make science and expertise irrelevant. Although most risk situations are characterized by uncertainties, they are certainly not characterized by the absence of knowledge. Within the classical risk approach the role of science was “to speak truth to power.” Uncertain risks imply a different role. As Van Asselt et al. (2009, p. 363) hold: “In the context of uncertain risks, risk assessment has, or should have, a different meaning: delineating uncertainty information seems an important challenge.”

## **TA: From Social Effects to Drivers**

Classical TA was criticized for focusing too much on the potential negative effects of science and technology. Moreover, ethical and policy analysis have stimulated TA to focus on novel types of side effects and the social visions and values that are shaping the technology.

## **Bad and Good Chances**

From the start, some American politicians were hostile to TA, based on the perception that it would automatically imply regulation of technology. In the early 1970s in America, critics of government intervention in the innovation process, therefore, derided the concept as “technology arrestment” or “technology harassment” (Kunkle 1995). Developing a “constructive” view of TA substantially contributed to the growing acceptance of TA in the German Bundestag

(Paschen 2000, pp. 102–103). The institutionalization of TA in Germany was driven by a need to rationalize the debate on science and technology. One way to rationalize the debate was to also focus on the positive aspects of technological change and explicitly explore its social, economic, and ecological possibilities. This also politically legitimated German parliamentary TA.

## New Types of Side Effects

Over the last two decades, ethical analysis has become more and more integrated in the practice of TA. The ethics view opened up the debate on what risks or aspects should be taken into consideration. Taking deontological perspectives and discussions regarding the good life and the good society into account, broadens the TA agenda. Ferrari and Nordmann (2009, p. 56), for instance, propose to expand the notion of “risk.” In addition to economic, scientific, or technological benefit/risk analysis, they promote a “philosophical hope/risk analysis.” Besides, ethical analysis challenges TA to assist society in reflecting upon the possibility that technologies, like augmented reality and brain implants, may have an effect on our morals and ethical vocabulary (Swierstra et al. 2009).

## Social Drivers

Moreover, the ethical perspective forces TA to take into consideration the (variety of) deep core values of people that are currently at stake in the debate on technology. A similar plea comes from policy analysis. The argumentative turn in policy analysis presents a shift away from a rational decision making model of politics (politics of interest model) toward a more constructivist approach to policy making (Fischer and Forester 1993). Within this so-called politics of meaning model policy makers are guided by their policy belief systems and political decision making is examined in terms of interacting belief systems. The argumentative turn in policy analysis has stimulated the development of new TA methods, notably interactive TA (Grin et al. 1997) and vision assessment (Grin and Grunwald 2000). Starting from an analysis of the background theories of the various involved actors, the main challenge is to develop joint constructions and, ultimately, lines of action.

## The Boundaries of TA

Finally, classical TA is founded on the belief that one can anticipate on the various effects technology has on society. Ethical analysis questions this central assumption behind TA that one can influence science and technology. It, thus, forces the practice of TA to be very reflective on its own role, methods, and impacts.

## Comparative Conclusions

---

Throughout the years, various scholars have pleaded for RA and TA to embrace a broader perspective on risk and/or their object of study (see ➤ *Table 43.2*). Both RA and TA are advised

**Table 43.2****Comparing interpretation of risk within RA and TA**

Science	Risk assessment	Technology assessment
Classical interpretation of risk	Risk = probability × effect Calculable risk based on past experience	(Potential) social effects
Modern interpretation of risk	Calculable risks based on past experience and uncertain (potential) risks based on assessment of the future	(Potential) effects and current social drivers
	• Bad and good chances	• Bad and good chances
	• Role for public perceptions	• New types of effects (e.g., change in our moral vocabulary)
	• Role for broader set of social values to come into play	• Social visions and values that shape technology
	• Reflection on risk governance	• Reflection on role and impact of TA

to look at both bad and good chances. It is suggested that risk assessment should include a broader set of social issues, just like classical TA. Moreover, classical risk approach assumed that risks were calculable based on past experience. Modern risk approaches are increasingly oriented toward the future and should be able to deal with both calculable risks and uncertain (potential) risks. Interestingly, TA is encouraged to broaden its view in the other direction; by mapping not only (potential) effects, but also analyzing current visions and values that drive science and technology. The various shortcomings of RA and TA also constantly provoke discussions about the (in)capacity of government and political institutions to steer technological change from a societal point of view.

## Risk Characteristics and RA and TA

This section describes how, driven by the concept of uncertainty, attempts have been made to characterize risk or problem situations in order to clarify the limitations of the classical approach and to promote and legitimize participatory approaches in the field of risk management and TA.

## Risk Situations and Risk Management Strategies

Inspired by the academic considerations on risk and uncertainty that were described in the former section, also the awareness among risk assessors and managers has grown that different situations of risk require different risk management strategies. In particular, the *White Paper on Risk Governance* (Renn 2005) by the International Risk Governance Council has played a major role in bringing academic ideas into the risk assessment and management field (see also [Chap. 44, Risk Governance](#) by Hermans, Fox, and van Asselt in the present book). Based

**Table 43.3**

Risk characteristics and their implications for risk management (Source: Renn 2005, p. 16)

Knowledge characterization	Risk management strategy	Stakeholder participation
“Simple” risk problem	Routine-based	Instrumental discourse
Complexity-induced risk problems	Risk-informed and Robustness-focused	Epistemological discourse
Uncertainty-induced risk problems	Precaution-based and resilience-focused	Reflective discourse
Ambiguity-induced risk problems	Discourse-based	Participative discourse

on the different states of knowledge about each particular risk, the risk governance framework distinguishes between “simple,” “complex,” “uncertain,” and “ambiguous” risk problems. The argument is that the classical risk approach only suffices for simple risk problems. The other three types of risk situations require other risk strategies.

Resolving complex risk issues requires discussion among experts. Klinke and Renn (2002) plea for an “epistemic discourse,” within which experts argue over the factual assessment and the best estimation for characterizing the risks under consideration. The management of risks characterized by high uncertainties should be guided by a “reflective discourse.” Such a discourse includes policy makers, stakeholder groups, and scientists. Besides dealing with the clarification of knowledge, reflective discourse is about finding a balance between over- and under-protection. Finally, ambiguity-induced risk problems are typified by the fact that risk information is interpreted differently by various stakeholders in society and (potential) intense conflict over values and priorities of what should be protected. According to the International Risk Governance Council (IRGC), this type of risk problems which are characterized by interpretative and normative ambiguity demand a participative discourse. Participative discourses are meant to search for solutions that are compatible with interests and values of the people affected and to resolve conflicts among them (● [Table 43.3](#)).

## Characterizing Problem Situations and Type of TA

Interestingly, also with regards to TA, attempts have been made to clarify the role of TA depending on the problem situation. Even more so, the approach taken by the IRGC has its roots within the practice and theory of participatory TA (cf. Renn 1999). Here, we present a taxonomy developed by Grin et al. (1997) to decide about the role of TA with regards to a certain problem situation (see ● [Table 43.4](#)). According to these authors, there will be little need for TA when there is little uncertainty regarding facts and little value dissent (so-called structured problems). When there is little value dissent, but high uncertainty about the facts (so-called moderately structured scientific problems), the role of TA may be to clarify the facts and their relationships. In such a situation, classical TA suffices. When the problem situation is characterized by a great deal of value dissent, expert-driven analysis is no longer sufficient. In case of (moderately structured or unstructured) political problems, participatory forms of TA need to come into play.

**Table 43.4**

Role and type of TA depending on problem situation (Adapted from Grin et al. 1997, p. 21)

	Uncertainty regarding facts: little	Uncertainty regarding facts: much
Value dissent: little	Structured problem	Moderately structured scientific problem
	<i>Little need for TA</i>	<i>Classical TA to clarify facts and their relationships</i>
Value dissent: much	Moderately structured political problem	Unstructured political problem
	<i>Participatory forms of TA might be beneficial</i>	<i>Participatory forms of TA are required</i>

**Table 43.5**

Comparing the relationship between problem characteristics and their implications for risk management and role and type of TA (Adapted from Grin et al. 1997, p. 21 and Renn 2005, p. 16)

Knowledge characterization	Stakeholder participation within risk management strategy	Role and type of TA
“Simple” risk problem	Classical risk approach: instrumental discourse	Little need for TA
Complexity-induced risk problems	Epistemological discourse	Classical TA to clarify facts and their relationships
Uncertainty-induced risk problems	Reflective discourse	Participatory TA might be beneficial
Ambiguity-induced risk problems	Participative discourse	Participatory TA is required

## Comparative Conclusions

The arrival of the notion of uncertainty regarding to science and values has led to a systematic reflection on the limits of the classical approach to TA and risk (see [Table 43.5](#)). This has led to the insight that in the case of “simple” risk problems, the classical risk approach works well. It is interesting to note that in such structured problem situations, there is little need for TA. In other words, the practices and roles of classical RA and TA do not overlap each other. In case of complex, uncertain, and ambiguity-induced risk problems, both practices start to overlap, or better, complement each other. In particular, the latter two problem characteristics challenge TA and risk assessment and management to introduce participatory approaches in the political decision-making process (see section [New \(Participatory\) Approaches to TA and RA](#)). Systematic reflection has – politically and intellectually – legitimized the need to use and experiment with participatory approaches. In fact, we saw that experience and reflection in the field of participatory TA at the end of the 1990s (Renn 1999) has had a marked influence into the field of risk management in the middle of the first decade of this century, leading to the so-called IRGC risk governance model (Renn 2005).

## New (Participatory) Approaches to TA and RA

A second basic complaint about the expert-based classical approaches concerns the fact that they do not sufficiently represent (broader) public concerns about science and technology. To address this shortcoming, new participatory approaches to TA and RA have been proposed and to a certain extent implemented. These approaches aim to involve a broader set of social actors within the political decision-making process on technology-related risks. This section describes and compares these new participatory approaches.

### New (Participatory) Approaches to TA

We saw that classical TA aims to both rationalize public controversy and aims to strengthen representative democracy by empowering the role of parliaments vis-à-vis the government (see ➤ [Table 43.1](#)). In contrast to classical TA, new (participatory) approaches to TA seek to *represent* public controversies over technological change (Joss 2000). As such, they attempt to organize the interface between the (political) decision-making arena and society in a more interactive manner. This participatory approach is also promoted to improve the interface between TA and the parliament in order to strengthen the impact of TA.

### Improving the Interaction Between TA and Politics

The establishment of OTA inspired MPs in various European countries to start discussing the need for parliamentary TA in their own country. During the 1980s, countries like Germany and Great Britain adapted the classical TA model. The institutionalization of parliamentary TA in Europe, however, also introduced new rationales and roles for TA. For example, the French MPs decided to start doing TA themselves, supported by the staff of OPECTS (Office Parlementaire d’Evaluation des Choix Scientifiques et Technologiques). In this way, the French MPs organized the interface between science and politics in a novel way.

Namely, in the classical TA model, MPs are basically informed by technology assessors through written scientific reports. Communication through writing, which is dominant within academic circles, does not match well the dominant oral culture within parliaments. Moreover, the agendas of MPs are often overloaded. This has challenged parliamentary TA institutes to rethink and redesign the way they communicate and interact with MPs (Decker and Ladikas 2004). It was realized that playing a role in the interface between science and politics does not simply mean bringing scientific insights to the parliament. Instead communication implies a two-way process. This realization has led to more participatory forms of communication, in which issue framing and identification of information needs result from interactions between TA practitioners and MPs. In fact, OPECTS exemplifies such an approach. For other parliamentary TA institutes organizing hearings, expert workshops, and Future Panels present ways to stimulate the (direct) involvement of MPs. For a comprehensive overview of European parliamentary TA development, see Vig and Paschen (2000), see also [www.eptanetwork.org](http://www.eptanetwork.org).

## TA as an Interface Between Politics and Society

Parliamentary TA was also given a new and extra political role in countries like Denmark and the Netherlands. Besides playing a role within the interfaces between parliament and science and government, TA was set up to strengthen the interface between the political arena and society. This was an institutional response to social activism in the 1970s. Public demonstrations, notably around nuclear power, put public authorities under pressure, and created a legitimacy crisis of the State. As a result, controversies over technologies were seen as a problem between the government, the parliament *and* the wider public (Van Eijndhoven 1997). Besides scientifically informing the Parliament, TA was also positioned as a more general and “open” process for involving the public in policy dialogues and building societal consensus on issues of technological change. As an attempt to represent public controversies over science and technology, participatory methods were seen as ways to deal with the interface between the (political) decision-making arena and society. Danish and Dutch MPs saw public engagement and deliberation as a legitimate add-on to representative democracy. As a result, besides monitoring and assessing technological development, the Danish Board of Technology’s (DBT) and the Dutch Rathenau Institute got the task to also stimulate public debate.

In order to fulfill this task, the DBT and the Dutch Rathenau Institute started to experiment with participatory methods to involve experts, stakeholders, and citizens in TA. This involvement has taken various forms, including citizens’ panels and juries, scenario workshops, round tables and consensus conferences. An overview of different participatory methods is presented in Joss (1999) and Slocum (2003). These methods have become more widely established over the last two decades (Joss and Bellucci 2002). In particular, at the beginning of this century, concerns about the science-society relationship and calls for public dialogue became part of the mainstream policy discourse in Europe. In the context of nanoscience, the adjective “upstream” entered the existing discourse on public participation (Wilsdon and Willis 2004). Policymakers and the business and science communities wanted to avoid nanotechnology becoming “the next GM.”

Also, participatory TA has been the target of criticism. First of all, participatory TA is as sensitive to framing as classical TA. In particular, the issue of representation – who should participate and what degree of representativeness should they have – presents an enduring challenge. Secondly, the lack of impact of participatory exercises on the political decision-making process is a central source of concern for parliamentary TA.

## New (Participatory) Risk Approaches

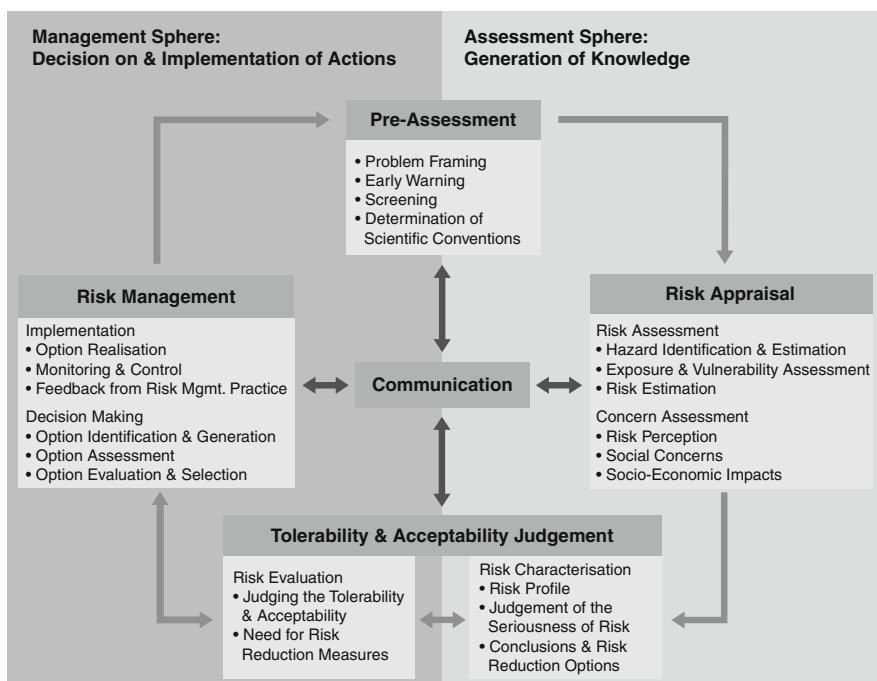

Participation has also been promoted in the field of risk assessment and management (Klinke and Renn 2002; Felt 2007; Klinke 2009). Participation is thought to enable the assessment sphere to take into account broader public concerns on risks. Allowing interested parties to participate in risk appraisal, however, is not yet a common phenomenon. Besides, participation is employed to improve the interface between risk assessment and risk management. One of the main promoters to include deliberation in the risk field is the International Risk Governance Council (IRGC).

## The IRGC Risk Governance Framework

In the wake of BSE and the GMO controversy, a new risk approach developed in the first decade of this century (WRR 2008). The risk governance framework of the International Risk Governance Council (IRGC) forms the most prominent and most elaborated example of this new approach (Renn 2005). As we saw above, the IRGC risk governance framework distinguishes between four types of problem situations and related risk management strategies (see [Fig. 43.3](#)). In particular, in the case of uncertainty-induced and ambiguity-induced risk problems, the IRGC advises to make use of participatory exercises.

### Risk Assessment Plus Concern Assessment

In the classical risk approach risk assessors are assumed to be able to calculate risks, and in that way would present the public interest. This assumption about the science – society interface has been severely criticized. In the risk governance framework, risk assessment is complemented by concern assessment (see [Fig. 43.1](#)) (Renn 2005, pp. 12–15). Together they form the risk appraisal phase. Concern assessment is about getting “knowledge of stakeholders’ concerns and questions – emotions, hopes, fears, apprehensions – about the risk as well as likely social consequences, economic implications, and political responses” (Renn 2005, p. 14).

**Fig. 43.1**

IRGC risk governance framework. (Source: Renn 2005, p. 13, with kind permission from the International Risk Governance Council)

## Improving the Interface Between the Risk Assessment and Management Sphere

The classical risk approach is based on a clear distinction of risk assessment and risk management. In this model, the usability of the results of the expert-based risk assessment for policy decision making are taken for granted. The IRGC risk governance framework includes various extra activities in the risk-handling chain to improve the interaction between the risk assessment sphere and the risk management sphere (see Fig. 43.1) (Renn 2005, pp. 12–15). The framework proposes to include a pre-assessment phase. Risk framing is the first step of this stage. This exercise presents an attempt to come to a common understanding among relevant social actors on what kind of risk issues should be addressed.

After the risk appraisal phase, the risk governance framework proposes to have the stage of risk characterization and evaluation. Risk characterization is a decision-driven activity, directed toward informing decision makers, and is, therefore, the final and most controversial part of the risk assessment sphere. For long, risk characterization was commonly seen as a summarization of scientific information (National Research Council 1983, p. 20). In the early 1990s, the National Research Council in the United States started to promote risk characterization as a process which combines analysis and deliberation (Stern and Fineberg 1994).

## Comparative Conclusions

Participatory approaches have been promoted and developed both in parliamentary TA and RA practices. These participatory exercises try to deal with the interfaces between TA and RA and society and the (political) decision-making arena (see Table 43.6). While classical TA aims to rationalize public controversy, participatory TA seeks to represent public controversy. For RA, something similar is the case. Within the risk governance model, the risk assessment

**Table 43.6**  
Comparing the new approach to risk and parliamentary TA

	New risk approach	New parliamentary TA
Science	Risk appraisal = risk + concern assessment	Technology assessment
Modern interpretation of risk	Calculable risks based on past experience and uncertain (potential) risks based on assessment of the future	(Potential) effects and current social drivers
Political role		
Interface science – policy making	Informing risk managers within the government about technical risks	Informing MPs on social effects of S&T
	Risk characterization based on analysis and deliberation	Involving MPs in TA projects
Interface society – policy making	Pre-assessment: problem framing and early warning	Participatory parliamentary TA: representing public controversies over technological change
	Concern assessment	

sphere is complemented with new types of analysis and deliberation – notably, concern assessment, risk framing, and risk characterization (see [Fig. 43.1](#)) – that aim to include the concerns of various social actors. Besides improving the interface between society and RA or TA, participatory approaches can also be used to improve the interface between TA and MPs and RA and risk managers.

If we take the risk governance framework as the exemplar of the new risk approach, it becomes clear that from a conceptual point of view TA and RA have grown closer to each other over the last decade. Actually, concern assessment, risk framing, and risk characterization, which combine analysis and deliberation, can be seen as typical TA-like activities. In fact, from the perspective of risk governance parliamentary TA and risk assessment and management all have an important role to play. Unfortunately, the complementary roles of these practices have not yet been given enough academic consideration. The next section explores the potential synergy between parliamentary TA and RA in the risk governance of nanotechnology in the Netherlands.

## An Example: Risk Governance of Nanotechnology in the Netherlands

---

In 2003, the public debate on nanotechnology was in its infancy. At the same time, a strong growth in worldwide funding and patenting combined with high scientific and social hopes and concerns fueled the debate. The Dutch government invested large sums in nanoscience, mainly within the framework of the national research program NanoNed. The debate in Europe received a strong impulse, when the ETC Group, an international civil society organization, called for attention to the issue of nanotoxicity at the European Parliament. Triggered by these events, the Rathenau Institute, the Dutch parliamentary TA organization, started activities which aimed to stimulate the public and political debate on the social and ethical issues related to nanoscience and -technology. This section presents some examples of various political roles played by parliamentary TA within the risk governance of nanotechnology.

### Setting the Agenda

---

The Rathenau Institute started by conducting a TA study, to provide an initial concept agenda for public and political discussion (Van Est et al. [2004](#)). That first agenda included a broad range of topics, ranging from health effects of nanomaterials to privacy issues related to nanoelectronics (and the vision of smart environments), and ethical issues related to human enhancement. The Rathenau Institute also wrote a position paper (Van Keulen and Van Est [2004](#)) and organized an expert-stakeholder workshop in February 2004 on the chances and risks of nanomaterials. At the workshop, the nanoscientific community was confronted with societal and policy actors for the first time. As a result, the government commissioned exploratory studies by the National Institute for Public Health and Environment (RIVM) (Roszek et al. [2005](#)) and the Health Council (Gezondheidsraad [2006](#)). Researchers at RIVM had wanted to study the safety aspects of nanomaterials before, but had lacked funding because the issue had not been on the policy agenda before. These activities of the Rathenau Institute helped in overcoming that deadlock and got a wider risk governance process going.

In 2004, the Rathenau Institute continued by writing position papers and organizing workshops on various application fields of nanotechnology. All these public activities fed into a parliamentary hearing at the end of that year. Besides creating a first agenda for discussing nanotechnology, the Institute stimulated the development of an initial heterogeneous network of actors – consisting of nanoscientists, policy makers, politicians, social scientists, and people from industry and civil society organizations – to become involved in the public debate. In response to various discussions with the parliament, the government announced at the end of 2005 to come up with an integral policy on nanotechnology. An interdepartmental working group for nanotechnology (ION) was set up to prepare such a vision.

## Setting Up the Risk Governance Machinery

---

In the political discussion on dealing with the risks of nanotechnology, the advice of the Dutch Health Council (Gezondheidsraad 2006) played an important role. The Health Council produced an extensive report, which used the IRGC risk governance framework (Renn 2005) as a model for dealing in an integral manner with complex, uncertain and even ambiguous risks related to nanotechnology. Anticipating the political significance of the Health Council advice, the Rathenau Institute organized a workshop which brought together key experts and stakeholders to discuss the implications of the Health Council advice for priorities in risk policy (Malsch 2006). The workshop was attended by ION members who were preparing the Cabinet View on Nanotechnologies (Kabinet 2006).

In the Netherlands extensive discussions on dealing with systemic risks had led to the development of a particular risk governance framework, called *Dealing sensibly with risks* (VROM 2004). Within this model, key strategies for dealing with risk are transparent decision making, a clear distribution of responsibilities, early involvement of citizens, balancing risks and benefits, and factoring in accumulation of risks. The Cabinet view was based on this model. In addition, however, the government announced to identify ethical and social issues relating to nanotechnology developments and to set up a broad public dialogue on these issues. From this point on, the Rathenau Institute focused on three challenges for risk governance: dealing with possible physical risks, how to organize a public dialogue, and further developing the wider public agenda, in particular, related to technological convergence (Van Est and Walhout 2010). We will focus here on the first two issues.

## Dealing with “Organized Irresponsibility”

---

With regards to dealing with nanotoxicity, the government followed the European Commission’s statement that the existing regulatory frameworks are sufficient to deal with nanomaterials, apart from specific amendments to be made. These regulations assign responsibility for safety primarily to producers. The government also recognized its responsibility for setting up the participatory aspect of risk governance. The government asked the Social Economic Council – an established negotiating platform for employer organizations and labor unions – to come up with an advice on occupational safety. Besides, a broad sounding

board on nanosafety became part of the interactive policymaking the government already deployed for consumer and environmental affairs.

Assigning responsibilities and facilitating dialogue does not automatically leads to a proactive handling of nanotoxicity. By closely following the risk discussion, the Rathenau Institute recognized that the actual risk governance of nanotoxicity was hampered by a number of mutual dependencies, which caused acting voids and deadlocks. For example, the combination of a lack of knowledge, definitions, and oversight caused a lack of funding and inability for priority setting. This results into a lack of sense of urgency, which maintains the current deadlock. The Rathenau Institute stimulated a political discussion about these examples of “organized irresponsibility” (Beck 1992). Together with a parliamentary committee, it organized in 2009 a parliamentary hearing, which allowed MPs to hear the voice of a broad range of experts and stakeholders. The Institute also advised the parliament about priorities for the political discussion.

## Monitoring and Debating Risk Governance

---

In line with the suggestions of the Health Council, and thus the IRGC risk governance framework, the government had decided to organize a public dialogue on social and ethical issues. According to that model, uncertainty about physical risks was to be discussed in expert-stakeholder settings, and more ambiguity-induced risk problems required communication and social discourse (see section [❸ Risk Characteristics and RA and TA](#)). In practice, however, these issue categories and the related deliberative processes cannot be separated. In other words, these governance processes overlap and relate to each other. This has to do with the fact that both discussions often involve similar types of social actors, and with the priorities these actors have. When the issue of physical risks is surrounded with many uncertainties, most people are inclined to focus on such a concrete issue and tend to ignore or postpone a debate on often more intangible social and ethical questions. The Rathenau Institute highlighted this condition in the publication *Ten lessons for a nanodialogue* (Hanssen et al. 2008). Moreover, it advised the government about do’s and don’ts with regard to setting up a public dialogue on nanotechnology.

## Parliamentary TA’s Role in Risk Governance

---

The Dutch nanotechnology case shows that parliamentary TA can play various political roles within the risk governance process. Parliamentary TA may play a role in developing the public and political agenda. Parliamentary TA developed an initial public agenda and was instrumental in putting nanotechnology on the agenda of the government and the parliament. By using all kinds of participatory methods, parliamentary TA has also stimulated public and political debate by involving all kinds of stakeholders. Finally, parliamentary TA stimulated critical reflection and debate on the risk governance approach and processes itself. With regards to the safety issue, the Rathenau Institute has exposed various regulatory uncertainties that prevent effective governance. Moreover, it clarified that whereas the IRGC risk governance proposes different risk strategies for different risk issues, the practice of risk governance often does not allow for such a clear separation of issues.

## Further Research

---

The structure of this chapter provides an interesting agenda for future research.

We started this chapter by stating that the relationship between risk and technology assessment has been scarcely discussed. This chapter shows that such an exercise is fruitful since parliamentary TA may form a source of inspiration for RA. Whereas RA originally used a very narrow definition of risk, TA employed a common sense view on risk. The latter is due to the fact that parliamentary TA, because of its mission and institutional position, is continuously confronted with the political arena and society. As such, it has to deal with analysis and deliberation on the one hand and power on the other. Defining itself as “science,” the risk field has (had) a hard time in dealing with the two poles of political practice. A crucial step is accepting a broader interpretation of risk, nowadays captured by the term “uncertain risk.” TA’s history, however, shows yet another challenge. Its focus on social effects was broadened with a view on social drivers. This links to the argument that RA and TA should pay equal attention to both “bad” and “good chances” (Wildavsky 1988), and the recent plea for a “philosophical hope/risk analysis” (Ferrari and Nordmann 2009). How to deal with such a broad interpretation of risk and the positive side of risk taking presents an interesting theme for further research.

A second research theme concerns the relationship between risk characteristics and the role and type of TA or the appropriate risk management strategy. Scholars like Renn (1999, 2005) and Grin et al. (1997) present their taxonomies as conceptual guidelines, instead of rigid normative prescriptions. Still these categorizations play an important normative and political role in the discourse on RA and TA. It would be relevant to study this, but also to analyze how the relationship between risk characteristics and the choice for a certain risk management strategy or TA approach is shaped in practice. In this respect, Van Asselt et al. (2009) talk of the so-called “uncertainty paradox.” While there is great awareness among risk managers that a lot of uncertainties are in play, still there is a strong (institutional) tendency to use science to diminish uncertainty. These types of mechanisms are in need of more reflection and analysis.

Related to this, it would be relevant to map in what kind of situations and to what extent new (participatory) approaches to TA and RA are actually used. Do these type of deliberative exercises still play a marginal role or have they become fully integrated? As we saw also participatory approaches face problems with regards to problem framing, representation, timing and impact. There is a need for more insight into how risk and technology assessors view and deal with these issues in practice. Moreover, modern approaches to TA and RA (in particular, the IRGC risk governance framework) are about finding a balance between analysis and deliberation. There is still little knowledge on how science and involvement of various social actors is organized in practice. In particular, there seems to be a large gap between academic research done in this field and the way practitioners view and reflect on their practices.

This brings us to the big theme of risk governance. The history of TA and RA shows numerous attempts to deal with the social risks involved in science and technology. They present institutional attempts to address the democratic deficits of the modernist practice of managing technology. In *Risk Society*, Beck (1992) hinted at the above central research theme by dropping the term “organized irresponsibility.” The IRGC risk governance framework is a great attempt to develop an integral vision on risk governance. Namely, besides “risk assessment” and “risk management,” this framework also aspires to look at “how risk-related

decision-making unfolds when a range of actors is involved, requiring coordination and possibly reconciliation between a profusion of roles, perspectives, goals and activities" (Renn 2005, p. 11). In this chapter, we have indicated that within the classical approach to risk and TA, the gap between RA and TA is impossible to narrow. In contrast, the new risk governance approach, in principle, has the potential to bridge these two practices. To put it stronger: parliamentary TA has a clear role to play within risk governance. Up to now, however, the democratic role parliamentary TA currently plays and may play within risk governance has received very little attention. To conclude: parliamentary TA's role within risk governance presents a remarkable blind spot on the current research agenda.

**Abstract:** Recently, the notion of risk governance has been introduced in risk theory. This chapter aims to unravel this new concept by exploring its genesis and analytical scope. We understand the term “risk governance” as the various ways in which many actors, individuals, and institutions – public and private – deal with risks surrounded by uncertainty, complexity and/or ambiguity. It includes, but also extends beyond, the three conventionally recognized elements of risk analysis (risk assessment, risk management, and risk communication). Risk governance emphasizes that not all risks can be calculated as a function of probability and effect. We argue that risk governance is more than only the critical study of complex, interacting networks in which choices and decisions are made around risks; it should also be understood as a set of normative principles which can inform all relevant actors of society on how to deal responsibly with risks. In this chapter, we take stock of the current body of scholarly ideas and proposals on the governance of contemporary risks along the lines of three principles: the communication and inclusion principle, the integration principle, and the reflection principle.

## Introduction

---

Over the past few decades, modern society has been increasingly challenged to manage potentially negative outcomes of technological developments. The nature of these hazards, as well as their lack of temporal and spatial limits, has given rise to a call for a new integrative approach that aims to understand, assess, and handle risks to human health and the environment by building upon and extending current risk analysis practices. Many discussions about technological innovation occur nowadays in the public arena, which concern not only health and safety but also ethical and social issues. Arguably a decline of public trust in the ability of experts and policy makers to deal with risks has been accompanied by a growing demand for public participation in scientific and technical decision making (Adams 2005; Beck 1992; Giddens 1991; Wynne 1982).

How can we deal with these increasingly complex and demanding risks and with the need for more public involvement? One set of proposals is clustered under the heading “risk governance,” a combination of the terms “governance” and “risk.” “Risk governance” aims to provide an approach for how to deal responsibly with public risks. Risk governance pertains to the various ways in which many actors, individuals, and institutions – public and private – deal with risks surrounded by uncertainty, complexity and/or ambiguity. It includes, but also extends beyond, the three conventionally recognized elements of risk analysis: risk assessment, risk management, and risk communication. It moreover requires consideration of the legal, institutional, social, and economic contexts in which risk is evaluated, as well as consideration of the interests and perspectives of different actors and stakeholders. In sum, risk governance aims to take into account the complex web of actors, rules, conventions, processes, and mechanisms concerned with how relevant risk information is collected, analyzed, and communicated, and how management decisions are taken (IRGC (International Risk Governance Council) 2005, 2007; Renn 2008; Renn et al. 2011; van Asselt and Renn 2011; van Asselt and Vos 2008).

Risk governance has its origins in the scholarly ideas on how to deal with demanding public risks informed by several decades of interdisciplinary research drawing from engineering studies, psychological and sociological research on risk, science and technology studies (STS), social movement theory, and research by policy scientists and legal scholars, including Ravetz (e.g., Funtowicz and Ravetz 1992; Ravetz 1996 [1971]), Nowotny (e.g., Nowotny 1976, 2008; Nowotny et al. 2001), Fischhoff (e.g., Fischhoff et al. 1984), Slovic (e.g., Slovic 1987, 2000),

Wynne (e.g., Irwin and Wynne 1996; Wynne 1982, 2002a), O’Riordan (e.g., O’Riordan 1982; O’Riordan et al. 2001; O’Riordan and McMichael 2002), Beck (e.g., Beck 1992, 2009; Beck et al. 1994), Jasenoff (e.g., Jasenoff 1990, 2005), Tesh (Tesh 2000), the Kaspersons (e.g., Kasperson and Kasperson 1991, 2005a, 2005b, see also Pidgeon et al. 2003), Löfstedt (e.g., Löfstedt 2005; Löfstedt and Renn 1997), Stirling (e.g., Stirling 1998, 2004), van Asselt and Vos (e.g., van Asselt 2000; van Asselt and Vos 2006, 2008; Vos 2000, see also Fisher 2008), Fischer (e.g., Fischer 2002; Fischer et al. 2006), Huitema (Huitema 2002), Mourik (Mourik 2004), and so-called cultural theorists (e.g., Adams 2005; Douglas and Wildavsky 1982; Rayner 1992; Thompson et al. 1990). This body of knowledge provides a convincing and empirically sound basis to argue that many risks cannot be calculated on the basis of quantitative methods alone, and that regulatory models which build on this assumption are not just inadequate, but form a complication to responsibly dealing with many contemporary risks.

In this chapter, we will explain the origins of risk governance and the issues and proposals that fall under this heading. Is risk governance indeed a major change in the ways in which risks are conceptualized, appraised, regulated, and communicated as proponents claim? The contours of this framework are derived from the work of a number of prominent scholars, whom we will discuss in this chapter, but the process of turning these empirically informed theoretical proposals into practical reality is still in its infancy. Hence, this chapter aims to provide an original perspective on risk theory since it examines what is referred to as a “paradigm shift” compared to the classic, quantitative, probability-based approach to risk assessment, management, and communication.

We will first describe the origins of the concept (section [The Origins of Risk Governance](#)), reflecting on the most important scientific approaches and disciplines in risk research that have contributed to the emergence of risk governance (section [Risk](#)). Next, we discuss risk governance as part of the broader governance turn in policy sciences (section [Governance](#)), and its context of origin (section [The Origins of Risk Governance](#)). Following the state-of-the-art review by van Asselt and Renn (Renn et al. 2011; van Asselt and Renn 2011), we will discuss what is agreed to be needed to address uncertain, complex, and ambiguous risks adequately (section [The Typology of Risk](#)). The various ideas and proposals pertaining to risk governance are discussed in terms of a set of principles: the communication and inclusion principle, the integration principle, and the reflection principle (section [Risk Governance](#)). These principles aim to synthesize the most important aspects in organizing structures and processes to govern risks.

## The Origins of Risk Governance

---

### Risk

---

The urge to suppress and control risks has been a human endeavor since the ancient Greeks, followed in modern times by the prominent idea that risks are manageable and measurable (Bernstein 1996). This positivistic, quantitative approach to risk, in which estimation of probability and effect is central, has been and still is the dominant way of conceptualizing, assessing, and managing risks. Only recently an academic change of focus has emerged realizing that many contemporary risks reach beyond this traditional definition of risk as calculable and predictable. The social experience of risk is not confined to or not even expressible as

a technical definition of risk, namely, the product of probability and effect. The way people conceptualize and deal with risks in their everyday lives is influenced by values, attitudes, social influences, and cultural identity. We will describe these critical developments in different strands of literature that have contributed to the current understanding and thus explicitly or implicitly to the idea of risk governance. These contributions are very multidisciplinary, ranging from psychology and law to science and technology studies (STS).

Summarizing the work of many authors for several decades cannot be done without compromising historical or scholarly accuracy. However, this overview aims to sketch a general picture of the broad sweep of major ideas and empirically informed insights that have given rise to risk governance. We therefore do not claim to be exhaustive.

## Positivistic Risk Paradigm

In the beginning of the twentieth century, two influential economists delved into the problems of risk. Frank Knight published *Risk, Uncertainty and Profit* (Knight 1921) in the same year as John Maynard Keynes published *A Treatise on Probability* (Maynard Keynes 1921 [2004]). Both scholars addressed the problems of making choices in uncertain circumstances and both defined the concept of “risk” and “uncertainty,” albeit in opposite ways.

Knight argued that it is possible and necessary to sharply distinguish risk from uncertainty: *risk* can be explained as “you don’t know for sure what will happen, but you know the odds,” while *uncertainty* means that “you don’t even know the odds” (Adams 2005). Thus, Knightian uncertainty is immeasurable and not calculable. By contrast, risk is measurable by using the formula:  $\text{risk} = \text{chance} \times \text{effect}$ . Keynes, on the other hand, did not distinguish risk from uncertainty. He claimed that life was dominated by uncertainty, not probability. If life would obey to the laws of probability, humans would have no choices and no influence on the course of events. He therefore stressed the positive associations of uncertainty. In a way, as will become clearer throughout his chapter, risk governance could be viewed as inheriting from the Keynesian view on uncertainty and risk.

However, the Knightian definition dominated and is still dominant in practices of risk assessment and management and in many scientific disciplines such as engineering and economics, which use technical risk analyses to calculate expected benefits and monetary costs, or as part of engineering planning and design. Knight’s concept of risk narrows the focus to the probability of events and the magnitude of specific consequences. It has had a major influence on risk regulation, becoming the “golden formula” and the basis of what is referred to as the classical or *positivistic risk approach*, which developed in the course of the twentieth century. Following the classical risk approach, two phases are distinguished and are ideally institutionally separated: identification and evaluation of risk (risk assessment) and taking measures to control risks that are deemed unacceptable (risk management).

Below we will discuss research traditions and contributions that implicitly or explicitly relate to a more Keynesian view on uncertainty and risk.

## Enlightened Engineering and Psychology

From the 1960s onward, we notice an important turn in risk research from a narrow positivistic risk focus to an approach incorporating qualitative, social, cultural, and normative aspects that

are believed to be an intrinsic aspect of complex risks. In the 1960s, some engineers expanded their risk research from a pure technical exercise into a focus on risk perception, namely on how individuals perceive risks in everyday life. Starr (1969) developed a quantitative method to look at how people weigh risks and advantages. He was one of the first to show that people accept activities that are voluntary (e.g., smoking) more than those that are involuntary (e.g., living next to nuclear power plant). He furthermore introduced the distinction between “objective” and “perceived” risk, to discriminate between the “scientific definition” and the “lay perception” (Starr and Whipple 1980). Risk perception research, taken up by cognitive psychologists after Starr’s pioneering work, built upon Starr’s observation that experts and the public often have different notions of what constitutes a risk. This observation became particularly poignant in the fierce public resistance against nuclear energy in the 1960s and 1970s. Even though scientific experts declared nuclear energy as a safe and clean form of energy, the public perceived it as a threat and protested against it.

The field of psychology has had a major influence on risk studies since questions arose about the publics’ acceptance of risks. Psychologists claim that the public acceptance and reluctance to take risks needs to be explored in relation to the complexities of the human mind (Bouder 2008). Psychologists have dramatically increased our understanding of individual risk decisions and their wider impact on society. Challenging Starr’s strict voluntary/involuntary model, so-called *psychometric studies*, rooted in psychology and decision theory, focused on the roles of affect and emotions in influencing risk perception. Key characteristics such as familiarity, control, catastrophic potential, equity, and level of knowledge have been proven to influence risk decisions (Slovic 2000; Slovic et al. 1982; see also van Asselt 2000 for an overview). The psychometric paradigm, using standardized questionnaires and large-scale surveys, has become one of the dominant approaches in the field of risk research.

## Anthropology/Sociology

In the 1980s, anthropologist Mary Douglas and political scientist Aaron Wildavsky moved beyond the focus on the individual and his/her subjective estimates and challenged the dominance of the psychometric paradigm by publishing *Risk and Culture* (Douglas and Wildavsky 1982) in which they introduced the “Cultural Theory of Risk.” Cultural Theory stresses the importance of culture and society in shaping perceptions of risk. Cultural theorists analyze social responses to risk as being determined by cultural belief patterns that encourage individuals and social groups to adopt certain values and reject others. Cultural Theory outlines four “ways of life” in a group/grid typology: fatalism, hierarchy, individualism, and egalitarianism. By defining risk as a socially constructed phenomenon, Douglas and Wildavsky aimed to show the limitations of quantitative risk assessment that pin down risk in objective measurements and the limitations of psychometric studies that neglect social and cultural influences on risk perception. They challenged the objective-perceived dichotomy:

- ▶ The main questions posed by the current controversies over risk show the inappropriateness of dividing the problem between objectively calculated physical risks and subjectively biased individual perceptions. (...) Between private, subjective perception and public, physical science there lies culture, a middle area of shared beliefs and values. The present division of the subject that ignores culture is arbitrary and self-defeating (Douglas and Wildavsky 1982, p. 194).

In the last decades, this approach has been further developed by other authors (Rayner 1992; Schwarz and Thompson 1990; Thompson, et al. 1990; Wildavsky and Dake 1990) and applied in various contexts (see e.g., Rotmans and de Vries 1997). Even though the validity of these prototypical descriptions has been debated, cultural analysis has indicated that there is not one single, universal approach and conceptualization of risk (Renn 1998).

## Social Amplification of Risk Framework (SARF)

In the 1980s, the development of sociological risk research was heavily influenced by fierce public resistance and controversies regarding new technologies such as nuclear power and disasters such as in Bhopal and Chernobyl. Several prominent scholars tried to integrate the research on the public experience of risk from psychology, anthropology, sociology, and communication studies into an interdisciplinary framework called “Social Amplification of Risk Framework” (SARF) (Kasperson et al. 1988; Pidgeon et al. 2003).

- ▶ The framework aims to examine broadly, and in social and historical context, how risk and risk events interact with psychological, social, institutional, and cultural processes in ways that amplify or attenuate risk perceptions and concerns, and thereby shape risk behavior, influence institutional processes, and affect risk consequences (Pidgeon et al. 2003, p. 2).

The main thesis of SARF is that information processes, institutional structures, social behavior, and individual responses shape the social experience of risk in ways that either increase or decrease public perceptions of risk. SARF tries to explain why risks or risk events assessed as minor by experts might produce massive public reactions, and even have substantial social and economic impacts (risk amplification), while other risks that have been assessed by experts as dangerous do not produce anxious reactions, but are almost ignored (risk attenuation). Examples of “risk attenuation” are smoking or traffic accidents. “Risk amplification” can fuel risk controversies, such as around nuclear energy or genetically modified organisms. The framework tries to integrate the technical assessment of risk with the social and cultural experience of risk, while at the same time it is questioned whether it offered additional knowledge for understanding risks (Zinn and Taylor-Gooby 2006).

## Science and Technology Studies (STS)

Scholars in science and technology studies (STS), or more specifically sociology of scientific knowledge (SSK), critically examine the role and place of technology and science in contemporary society in an interdisciplinary way (Hess 1997b). STS is not only the study of how modern societies are constituted by science and technology and how science and technology affect society, politics, and culture, but also how reciprocally, cultural, social, and political factors determine technological and scientific developments. STS cannot be defined as a homogeneous field, but is composed of different research traditions with their own particular interest such as philosophy of science, laboratory studies, feminist studies, and contributions to risk research (for broad overviews of the field see, e.g., Hackett et al. 2007 and Hess 1997a).

Risk has been, implicitly or explicitly, a recurring theme in STS research. STS is especially known for its critique on the assumption of superiority of science-based knowledge. The underlying assumption of the objective-perceived dichotomy is that “lay persons”

misunderstand the “real” risks as known to science, and thus nonscientific definitions of risks or problems are labeled as “perception” (Wynne 2002b). This implies that risk controversies are envisioned as disagreements between “objective” risk assessments and public misperceptions constructed by ill-informed and emotive publics (Irwin and Wynne 1996). STS scholars criticize this assumed hierarchized dichotomy between experts and laypersons.

STS start from a new understanding of knowledge: they argue that science is a human product, something that has to be “made” or “constructed.” The constructed nature of scientific knowledge is defined in contrast with a naive view of scientific work as a purely rational process of representing nature by using transparent observations (Hess 2001). What becomes “science” or “risk” is the outcome of complex and strategic interactions between divergent actors (Collins 1985). Especially studies of scientific controversies have revealed the complex processes, involving many more actors than just expert scientists, by which reliable knowledge is created and contested (Jasanoff 1999; Shapin and Schaffer 1985).

By emphasizing the constructed nature of science, STS research claims to be impartial with respect to truth or falsity, rationality or irrationality, success or failure of knowledge. STS explain all belief systems symmetrically: they give equal weight to the views of laypeople and experts (Bloor 1976). STS research does not take the views of experts for granted and challenges the assumption that scientific knowledge is the only valid way to discuss risk issues (Wynne 1982).

## Political Sciences

Political science contributes to risk research through its focus on macro-level decision making processes and public policies in the regulation of risks, often comparing different legislations. In policy sciences, the notion “governance” has become a popular concept, referring to a blurring of the state and civil society; to increasing levels of participation; and a shared responsibility between state, business, and civil society (Walls et al. 2005). Policy sciences have an important influence on the development of the idea of risk governance, as governance is a notion directly borrowed from policy science (see section  [Governance](#) for an elaborate discussion of “governance”). Political scientists reflect on changing patterns of governance and differences in regulatory traditions in managing health-related, environmental, and other risks. The focus of their research can vary from questioning how risks are managed in countries with different political environments (e.g., Huitema 2002; Versluis 2003) to comparing the use of the precautionary principle in different regulatory regimes (e.g., Wiener et al. 2010) and analyzing organizational cultures, structures, functions, and processes in controlling and managing risks (e.g., Sparrow 2008).

## Law

The role of law in dealing with the complex dynamics of understanding risks and uncertainty has been one of laying down rules and procedures, for example, on products, substances, or the environment, among which are also the use of scientific advice, participation, and the precautionary principle. Legal research has particularly contributed to a better understanding of how the various institutions ranging from political actors to court deal (and struggle) with risk and uncertainty in specific policy areas with specific reference to the role of the precautionary principle (Alemanno 2007; Arcuri 2007; de Sadeleer 1999; Everson and Vos 2009; Fisher 2008;

Prevost 2008; van Asselt and Vos 2006; Weimer 2010). Within law, the understanding of uncertain risks relates to looking into the regulatory reality (i.e., issues of legality, legitimacy, credibility, and procedural requirements) when decisions must be taken in the face of scientific uncertainty. Most research on uncertain risks in the context of risk governance has focused on genetic engineering, climate change, food technology and safety standards (Rothstein 2009; van Asselt and Vos 2008; Vos 2009; Surdei and Zurek 2009), and environmental risks with much attention for the precautionary principle (Fisher 2008; Vos 1999; Zander 2010).

## Reflection

From this overview, it becomes clear that there are different disciplinary and interdisciplinary approaches and conceptual frameworks to the concept of risk. But together, the social sciences (including contributions from authors originally trained in natural sciences and engineering) have deeply changed our understanding of what “risk” means, “from something real and physical if hard to measure, and accessible only to experts, to something constructed out of history and experiences by experts and laypeople alike” (Jasanoff 1999, p. 150). The different approaches have mostly been positioned with regard to their epistemological premises: a positivistic/realist or a social constructivist view of risk (reviews of the implications of a constructivist versus a realist concept of risk can be found in Bradbury 1989; Jasanoff 1999; Krimsky and Golding 1992; Renn 1992). A realist perspective implies that there is a standard of “real” risk against which lay perception can be measured and shown to be attributed to a lack of public understanding of science and technology. A social constructivist view of risk argues that risk and technology are social processes rather than physical entities, risks do not “simply” reflect the natural reality but are shaped by history, politics, and culture. Public perceptions are therefore not irrational but are as legitimate as other more technocratic views. Even though this categorization makes perfect sense, some approaches are difficult to position and fields can also change their perspective (e.g., SARF is difficult to classify since many scholars started out from a psychometric “realist” perspective but also acknowledge the diversity of risk judgments, see Renn 2008).

Another way to understand the differences in assumption of the diverse fields is to look at whether, and if so, how and which boundaries are assumed, imposed, or contested. The set of boundaries that play a role in risk research are boundaries between subjective and objective risk; between science and nonscience; between experts and laypeople as well as between experts and policymakers; between individual and groups; and between risk assessment and risk management. Drawing or contesting particular boundaries in risk research has a pivotal role in determining the policy problem of risk and a possible framework for solutions (Bradbury 1989). If it is assumed that scientific knowledge is superior to lay persons’ views, then the ensuing solution is a better education of that public. If such boundaries are contested, solutions will be less straightforward and might, for example, call attention to the critical role of experts in political processes.

Where does the “risk governance” framework set out in this chapter stand in this major debate? The framework both “tries to avoid the naïve realism of risk as a purely objective category, as well as the relativistic perspective of making all risk judgments subjective reflections of power and interests.” (Renn 2008, p. 5). Risk governance is about dealing with both the “physical” and “social” dimensions of risk. It expands beyond the dominating technical criteria

for risk analysis and acknowledges public values and concerns as legitimate in their own right but at the same time it searches for ways to benefit from knowledge qualified as scientific. Public views should therefore not be downplayed by labeling them as mere irrational fears. Risk governance is about diffusing boundaries. In this context, we propose to use the notion of “risk perspective” instead of “risk perception” when talking about different viewpoints on risk issues. Risk perception has the long-standing connotation that it implies a distinction between “perceived” (by the “emotive and irrational” public) and “real” (by “objective” scientists) risks (Marris et al. 2001). Thus, a boundary is drawn between one superior knowledge base above another inferior one. “Risk perspective,” in contrast, acknowledges the multiplicity of views on risk in various arenas and in various cultures in a more symmetrical manner (Hermans et al. [in preparation](#)).

## Governance

---

In the previous part, we have discussed ideas that have paved the way for risk governance. Even though many of them do not use the term risk governance explicitly, their contributions have been indispensable in terms of bringing forward ideas, principles, and frameworks for how to deal responsibly with modern risks. The notion of “risk governance” itself has been coined only recently (our discussion of its history follows van Asselt 2007, van Asselt and Renn 2011, and Renn et al. 2011). Risk governance as an emerging concept should be understood in the context of the broader “governance” turn in the policy sciences (Versluis 2003). The notion “governance” came into fashion in the 1980s in circles engaged with development (Stern 2000) and was soon adopted in other domains. The conceptual use of governance has increasingly been adopted in the political science context to emphasize that the state is not the only, single most important actor (there is also a perspective on governance, provocatively termed “governance without government,” see Rosenaau 1995; Rosenaau and Czempiel 1992), which emphasizes the decreased and decreasing role of the nation state) in managing and organizing society. Many classical policy theories share a hierarchic orientation with government as the central actor. In contrast, policy theories inspired by economics award that central role to the market. Both clusters of theories are single-actor in their perspective on power and control. The governance perspective, however, holds that collective binding decisions are generated and implemented in complex multi-actor networks and processes; it also considers various social actors next to state and market such as NGOs and ad hoc coalitions of civilians, of which it is unclear who their supporters are and whom they represent – civil servants, experts, think tanks, agencies, and all kinds of committees active. Power, knowledge, and the capacity to act are distributed among these various actors.

The governance perspective steers away from two other prominent strands of theories, e.g., supranationalism and intergovernmentalism, by raising new questions considering the role and power of states and by drawing attention to the diversity of actors, the diversity of their roles, the manifold relationships between them, and all kinds of dynamic networks emerging from these relationships. When referring to a *multilevel* governance perspective also “government” is no longer a single entity (Rauschmayer et al. 2009). Scholars subscribing to the governance perspective examine actor-networks, the dynamics and the roles of the various actors in these dynamics as a way to understand policy development and political decisions. The shift to governance is best understood as a response to new challenges, such as

globalization, increased international cooperation (such as the European Union), societal changes, including increased citizens engagement, and the rise of nongovernmental organizations (NGOs), the changing role of the private sector, and the augmenting complexity of policy issues. The culmination of all these challenges leads to the need for a new legitimate form of governance (Pierre and Peters 2000; Walls et al. 2005).

The notion governance is used both in a descriptive and in a normative sense (van Asselt 2007; van Asselt and Renn 2011). In a descriptive use of the term, the idea of a complex web of manifold interactions between heterogeneous actors is used to describe the current state of affairs. Governance is then an observation and an approach. The description of governance as “structures and processes for collective decision-making involving governmental and nongovernmental actors” is an example of a descriptive definition (Nye and Donahue 2000). In a normative use, the notion of governance refers to a model or framework for organizing and managing society. In the famous 2001 White Paper of the European Commission on governance (European Commission 2001), such a normative perspective is propagated. In the White Paper, which can be read as a response to the BSE-crisis, governance is presented as an alternative model, in which transparency, stakeholder participation, accountability, and policy coherence are key principles. Often this distinction between description (of the state of affairs) and (policy) model is not made. As a consequence, it is unclear whether governance serves as reference to the framework guiding the analysis or whether it has the status of a (proposed) policy theory.

This is also true for risk governance. Here, the term “governance” is also used in a descriptive and a normative sense. Van Asselt and Renn (2011) argue that on the one hand the state of affairs pertaining to the regulation of many risks is adequately described in terms of governance. Risk decisions can only be understood as the upshot of complex interplays between multiple actors. The governance perspective is needed to sensibly examine and explain the societal dynamics around issues framed as risk issues.

Van Asselt and Renn (2011), furthermore, argue that risk governance also involves the idea that in regulatory practice this state of affairs is not adequately accommodated. The nature of many risks requires cooperation, coordination, and trust between a range of stakeholders, who have diverging interests and different perceptions of the (potential) risks involved. Many risk scholars assert that in case risks are inadequately addressed and managed, this may lead to what the sociologist Ulrich Beck has called “organised irresponsibility” (Beck 1992). Against this background, ideas and principles for how to deal with risks in a more adequate and more responsible manner are proposed. In doing so, governance is no longer used only in a descriptive but also in a normative sense: a new form, or at least new principles, of dealing with risks. Thus, risk governance is a hybrid of an analytical frame and a normative model. Such hybrids are also found in decision theory where the various stages of decision making that the theory suggests can be used as a checklist of how decisions are made (descriptive use) and at the same time functions as a guideline of how to organize the decision process when complex decisions have to be made (normative model) (Keeney 1992, 2004; North 1968).

## **The Origins of Risk Governance**

---

For a detailed discussion see van Asselt (2007) and van Asselt and Renn (2011). The notion “risk governance” has been coined only recently. The origins of the composition of “risk governance” and its introduction to the scholarly literature can be traced back to different

sources. Notable is the link to “TRUSTNET” (European Commission 2000; Heriard Dubreuil et al. 2002) concerted action on “risk governance” (Amendola 2001; Elliot 2001; Heriard Dubreuil et al. 2002), as well as endeavors preceding TRUSTNET. The OECD work on systemic risk (OECD 2003) and the Hood et al. (Hood et al. 2001) book on the government of risk are examples of key trailblazers. In 2001, the first articles with risk governance in their title appeared in two peer-reviewed scientific journals: *Journal of Hazardous Materials* (Heriard Dubreuil 2001) and *Science and Culture* (Elliot 2001). The notion was furthermore used in EU calls for proposals (van Asselt 2007; van Asselt and Renn 2011).

To complicate the matter, interpretations of risk governance differ. In the scholarly literature, risk governance is used as an opposition to the classical notions of risk assessment and risk management by putting uncertainty in center stage and by advancing multi-actor, multifaceted risk processes including contextual factors which together determine the roles, relationships, and responsibilities of particular actors and mechanisms (Renn and Walker 2008; van Asselt and Renn 2011). The European Commission, however, used risk governance more traditionally as an umbrella notion “embracing risk identification, assessment, management and communication” rather than as an alternative paradigm (as cited in van Asselt and Renn 2011). For some years, there was no serious attention given to how risk governance was used and what it actually meant. This situation changed with the foundation of the International Risk Governance Council (IRGC) in 2003 (See ▶ [Box 44.1](#)).

#### Box 44.1. The International Risk Governance Council (IRGC)

The International Risk Governance Council (IRGC), a private, independent, not-for-profit Foundation based in Geneva, Switzerland, was founded in 2003. In the late 1990s, challenges of global technological change such as genetic engineering resulted in increased public concern about risk assessment and management strategies in the EU. During the annual gathering “10th Forum Engelberg” in Switzerland, scientists, government leaders, and heads of industry decided to create an independent, international body to bridge the increasing gaps between science, technological development, decision-makers, and the public.

Since its formal foundation in 2003, it has organized many expert workshops on risk-related issues ranging from critical infrastructures, natural hazards, to nanotechnology and other emerging risks. The IRGC’s work took off with the White Paper No.1 “Risk Governance – Towards an integrative approach” (Renn 2005). This white paper, written under chairmanship of Ortwin Renn, is the first scholarly effort to develop risk governance conceptually. This paper aims to create “an integrated analytic framework for risk governance which provides guidance for the development of comprehensive assessment and management strategies to cope with risks, in particular at the global level. The framework integrates “scientific, economic, social and cultural aspects and includes the effective engagement of stakeholders” (IRGC (International Risk Governance Council) 2005, p. 11). The framework offered two innovations to risk research by including the societal context in the assessment and management of risk, and by categorizing risks based on the knowledge about it, distinguishing between “simple,” “complex,” “uncertain,” and “ambiguous” risks (▶ [Fig. 44.1](#)).

This framework displays the five key elements which reflect the way in which risk can be dealt with that fully accounts for the societal context of both the risk and the decision that is reached (IRGC 2005).

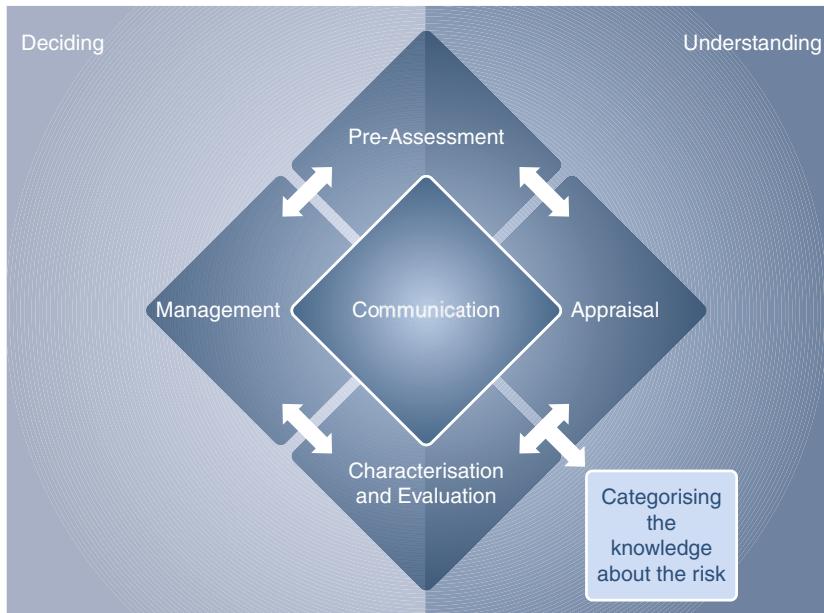

Fig. 44.1

The IRGC risk governance framework. (Source: <http://www.irgc.org/-The-IRGC-risk-governance-framework,82-.html>, with kind permission from the International Risk Governance Council)

Through a network between academia, NGOs, regulators, and industry, it is the IRGC's aim to jointly achieve coordinated and coherent policy making, regulation, research agendas, and communication with regard to the governance of risks.

The White Paper was also published as a lead chapter in the books *The Tolerability of Risk management* (Bouder et al. 2007) and *Global Risk Governance: Concept and Practice Using the IRGC Framework* (Renn and Walker 2008); see also a similar chapter in Bischof (2008), in which next to the framework itself critical reviews and case studies have been included. Subsequently, some agencies and national regulatory bodies have partially adopted the framework and designed manuals on how to use it for their specific purpose (see, e.g., Dreyer and Renn 2009 for EFSA and the Handbook for Risk Assessment and Policy Advice of the Dutch Food and Consumer Product Safety Authority (Voedsel en Waren Autoriteit (VWA) 2010).

## The Typology of Risk

For the typology of risk, we adopt the approach of van Asselt and Renn (2011) and Renn et al. (2011). This typology is a further development of Renn's original typology as set out in Klinke and Renn (2002) and the IRGC White Paper on Risk Governance (2005). Central to risk governance is the recognition that there are various types of risks. Since the Knightian definition (see section **Risk** of this chapter), risks have been treated in terms of probability and effects, dose and response, and agent and consequences. Risk governance involves the

recognition that uncertainty and risk cannot as easily be distinguished as is assumed in the positivistic risk paradigm. Some risks are simple, namely, calculable and relatively easy to manage. In those cases, past experience and the associated availability of statistical data enable to estimate probability and to derive a measure of effect. Existing risk assessment tools and risk management approaches suffice. Examples involve car accidents and regularly recurring natural events, such as seasonal flooding.

However, many risks cannot be classified as “simple.” They are not confined to national borders or a single sector, and do not fit the linear, mono-causal model of risk. Instead, the analysis must focus on interdependencies and ripple and spill-over effects that initiate impact cascades between otherwise unrelated risk clusters (Hellstroem 2001; van Asselt and Renn 2011). A well-known example is BSE which had effects not only on the farming industry but also on the industry of animal feed, the economy as a whole, and politics (Vos 2000; de Bandt and Hartmann 2000; OECD 2003; Renn and Keil 2009; see ➤ **Box 44.2** in this chapter). The transmission effects were globally diffused to all areas of the world, including those that were

#### **Box 44.2. The Impact of the BSE Crisis in Risk Research**

The BSE crisis has provided a turning point in the way actors – industry, regulators, scientists, and many others – have started to deal with risks and uncertainties. Prior to the BSE crisis, the EU managed risks in, e.g., food safety regulation on a rather ad hoc basis (Vos 2000). The BSE case demonstrated the need for a more structural regulation in policy fields in which risks play a role, such as food safety, environment health and safety, and chemical policy. BSE was first identified in Britain in the mid-1980s, and is thought to be caused by the remnants of slaughtered animals that have ended up in the high-protein diets of cattle in the beginning of the 1980s. By eating this, cows could develop a fatal neurodegenerative disease, commonly known as “Mad Cow Disease.” Although it has not been scientifically verified, it is thought that by either eating infected beef or by inhaling the bone meal fertilizer, people risk infection and could develop a variant of the disease, Creutzfeld Jacob, which is a fatal neurological disorder.

The initial response to this uncertain risk by regulators – seeking certainty about the parameters of the crisis – illustrated the need for a new way of approaching risk-related issues. Although research was ongoing, regulators attempted to obtain plausibility proofs, i.e., they increasingly resorted to science for more certainty and conclusive evidence. They hoped that this would sooth an anxious public and would allow for a quick fix to a persistent problem full of uncertainty that was providing a threat to the economy since beef sales plummeted. In 1990, in an ultimate attempt to reassure the public, restore trade in beef, and establish regulatory credibility, the British Minister of Agriculture, well aware of the uncertainty of the risk, fed his 4-year-old daughter a hamburger on British national television, implying its absolute safety. Several years thereafter, scientists discovered a possible link between mad cow disease and the human Creutzfeld Jacob variant.

The aftermath of the BSE crisis led to serious rethinking of risk regulation in academia and beyond and was an incentive for many to develop and advocate a paradigm shift toward a more inclusive way of dealing with risks. It became a “textbook example” to show that the way in which certain risks – such as BSE – were assessed and managed were no longer adequate or acceptable. Moreover, it also led to reforms and/or the birth of major risk regulating institutions in several European countries (e.g., the UK) and the EU (with the formation of a new “European Food Safety Authority,” EFSA) (Oosterveer 2002; Renn 2008; van Zwanenberg and Millstone 2005; Vos 2000).

not immediately affected by the crisis. Such risks are complex (multi-causal) and surrounded by uncertainty and/or ambiguity (Renn et al. 2011; van Asselt and Renn 2011). It is difficult to identify, let alone quantify, multi-causal, usually nonlinear, links between a multitude of potential causal agents and specific effects. Complexity can be caused by interactive effects among agents (synergisms or antagonisms), long delay periods and the associated latency lacunae (this notion has been introduced to the risk literature by Harremoës et al. 2001 – latency lacuna refers to the fact that technologies are improved during the period in which health and/or environmental impacts are studied; when such monitoring and impact studies identify risks, the question is whether those findings still hold for the newer generation of the technology), interindividual variation, etc. Due to complexity, it is impossible to achieve complete deterministic knowledge of cause–effect relationships.

Risk refers to the possibility of damage, whether in health, environmental, economic, or other terms. As long as the risk has not manifested itself in damages, the threat is potential and is evaluated by one or more actors as negative. Due to the fact that these situations often involve structural changes and or new hazards, they are highly uncertain. Uncertainty is not simply the absence of knowledge (compare van Asselt 2000 and Levidow et al. 2005). However, addressing uncertainty is a challenging, far from straightforward, job. Numerous scholars agree that there cannot be a single approach in addressing uncertainty that will satisfy in all circumstances and contexts (Bailey et al. 1996; Funtowicz and Ravetz 1990; Harremoës, et al. 2001; Health Council of the Netherlands 2008; Klinke and Renn 2002; Morgan and Henrion 1990; O’Riordan and McMichael 2002; Pollack 2003; Ravetz (1996 [1971]); van Asselt and Petersen 2003; van Asselt and Renn 2011; van Asselt and Rotmans 2002; van der Sluijs 1997; Walker et al. 2003; WRR (Scientific Council for Government Policy) 2010).

In addition to complexity and uncertainty, risk governance includes a third component: ambiguity (Klinke and Renn 2002; Renn and Roco 2006; van Asselt and Renn 2011). Ambiguity refers to the existence of multiple values. Ambiguity results from divergent and contested perspectives on the justification, severity, or wider meanings associated with a perceived threat (compare Stirling 2003). As a consequence, views differ on the ways to assess and appraise the risks, and more in particular on the relevance, meaning, and implications of available risk information and on which management actions should be considered. This means that there are different legitimate viewpoints from which to evaluate whether there are or could be adverse effects and whether these risks are tolerable or even acceptable. Risks are acceptable in case they are considered low or nonexisting, so additional regulatory efforts are considered unnecessary. Activities are tolerable if they are considered as worth pursuing for the benefit that they carry (Bouder et al. 2007). In cases of tolerable risks, additional regulatory efforts for risk reduction or coping are welcomed. Actors, however, respond to risks according to their own risk constructs and images, yielding several meaningful and legitimate interpretations of risk assessment outcomes (Keeney 2004). As a consequence, whether risks are acceptable, tolerable, or not can be subject of considerable debate and intense controversy. Ambiguity is used to refer to such social situations around risk issues. Examples involve controversies pertaining to passive smoking (although the health risks of active smoking are uncontroversial).

Many of the non-simple risks discussed pertain to future risks, namely, potential hazards that may or may not result in damage in the long run. Take the example of nanotechnology: the risk assessment for this new technological development depends on theoretical, nonempirical insights and ideas about causal relationships between exposure(s) and effect(s) on human health and environment. Furthermore, it depends on the decisions that humans make about

the use, application, exposure barriers, and safety culture with respect to these technologies. Finally, the context, such as the level of trust in the regulators, major accident(s) elsewhere, and coincidences between exposure to nanoparticles and detrimental effects is of influence.

Another illustration is the case of wireless communication technology, a popular and ubiquitous technology with a very high penetration rate that nevertheless ignites public concern, especially at a local level where the technology is implemented with thousands of base stations (see, e.g., Burgess 2004; Soneryd 2007; Stilgoe 2007). Governments attempt to act responsibly, but are confronted with little, inherently uncertain evidence that this technology poses a threat to human health. While the majority of experts emphasize that to date no consistent evidence has demonstrated cancer risks, uncertainties remain about long-term effects and effects on children as well as other health effects (van Asselt et al. 2009). A growing literature has illustrated the difficulty in dealing with such risks, since the nature of the risk is the outcome of a complex interplay of science, technology, and society (e.g., Jasanoff 2005).

Van Asselt and Renn (2011) and Renn et al. (2011) argue that it is possible, in theory, to distinguish between uncertain, complex, and ambiguous risks. However, uncertainty often results from complexity (van Asselt 2000). An illustrative example is the case of the introduction of genetically modified species in the environment. It is generally accepted that the risks to the environment and/or human beings are highly uncertain. Krayer von Kraus (2005) analyzed how experts view such risks. From his analysis detailing the varying ideas on which variables matter and which mechanisms should be included in the causal scheme, it is also clear that GMOs constitute an example of complex risks. Furthermore, taking into account that the risks are evaluated differently by different experts, as has been convincingly demonstrated by Jasanoff (2005), it is clearly also an example of ambiguous risks. So risks associated with genetic modification, and agro-biotechnology in particular, are best characterized as risks that are uncertain, complex, and ambiguous. The same is true for such risks such as nuclear energy or climate change.

Uncertainty, complexity, and ambiguity point to different reasons why many risks defy simple concepts of causation (van Asselt and Renn 2011). Each of the three characteristics of risks contributes to a better understanding of the situation in which risks emerge and manifest themselves. Risk governance thus highlights the importance of uncertain, complex, and/or ambiguous risks. In its 2008 scientific report “Uncertain Safety,” the WRR (the Dutch Scientific Council for Government) calls for a paradigm shift with regard to the governance approach to risks. The WRR (WRR (Scientific Council for Government Policy) 2010) as well as the Health Council in the Netherlands (Health Council of the Netherlands 2006, 2008), for instance, have made an effort to translate the ideas that pertain to risk governance, among which is the acceptance of uncertainty, to practice. These scientific advisory bodies play a key role in advising the Dutch government about societal relevant issues. They furthermore aim to form an intersection in international policy (<http://www.wrr.nl/english/>, accessed April 5, 2011). They argue that the classical risk paradigm and its policy based on “simple” risks are outdated, but should not disappear. Rather, a paradigm shift to risk governance should take place, focusing policy on uncertain, complex, and ambiguous risks. Simple risks, which inhibit little to no uncertainty (WRR (Scientific Council for Government Policy) 2010), the so-called certain uncertainties (van Asselt 2000), should have the status of the special cases, rather than the dominant position that they have in current policy on risk management and assessment practices.

Furthermore, it is a consistent finding in the body of literature discussed in section  **The Origins of Risk Governance** that very often, uncertain, complex, and/or ambiguous risks are

treated, assessed, and managed as if they were simple (Renn et al. 2011; van Asselt and Renn 2011). The assessment and management routines in place do not do justice to the nature of such risks. The consequences of this maltreatment range from social amplification or irresponsible attenuation of the risk to sustained controversy, deadlocks, legitimacy problems, unintelligible decision-making, trade conflicts, border conflicts, expensive rebound measures, and lock-ins. The main message from risk governance is that it is urgently needed to develop better conceptual and operational approaches to understand and characterize non-simple risks.

## Risk Governance

---

Risk governance or the *new risk approach*, as it is called by the WRR, has gradually been created, developed, and discussed in scientific literature and has slowly entered the organizational level as well (WRR (Scientific Council for Government Policy) 2010). However, regulatory and managerial understanding, let alone practical application and implementation of this approach, still need development. Complex, uncertain, and ambiguous risks require an organizational setting which fosters an interdisciplinary perspective, flexibility, and diversity, which is at odds with current managerial practices (WRR (Scientific Council for Government Policy) 2010; Health Council of the Netherlands 2008; van Asselt and Renn 2011).

What is needed to treat uncertain, complex, and/or ambiguous risks adequately? Van Asselt and Renn (2011) argue that first of all, it is important to accept scientific uncertainty and controversy and public debate as the state of affairs. In many cases the governing of risks will involve precaution in the sense of a cautious and flexible strategy that enables learning from restricted errors, new knowledge and visible effects, so that adaption, reversal, or adjustment of regulatory measures is possible (See also De Vries et al. 2011; van Dijk et al. 2011). Precaution also entails the responsibility for early warning and monitoring in order to facilitate systematic searching for new hazards by institutions of government, business, or civil society (Charnley and Elliott 2002). Risk governance is not just concerned with minimizing risks, but also with stimulating resilience (or decreasing vulnerability) in order to be able to withstand or even tolerate surprises (Collingridge 1996).

## Risk Governance Principles

---

Risk governance endorses highly contextualized practices of dealing with risks; it is not a model in the strict sense of the word. The idea of risk governance aims to serve a paradigm shift that helps risk professionals to familiarize themselves with a broader concept of risk. Van Asselt and Renn (2011) and Renn et al. (2011) proposed to synthesize the various ideas and proposals in a set of principles, which can inform about how to deal with uncertain, complex, and/or ambiguous risks in various contexts:

- Communication and inclusion
- Integration
- Reflection

The set of principles are discussed in more detail below.

## The Communication and Inclusion Principle

In the context of risk governance, van Asselt and Renn (2011) argue that communication is crucial. Effective mutual communication takes center stage in the challenges risk governance aims to address and should be approached accordingly. In case of sidestepping communication, successful risk governance is irretrievably harmed. As we discussed in section [The Origins of Risk Governance](#), initially, risk communication has been approached in terms of educating and persuading the public (Fischhoff 1995). However, this “deficit model” has been questioned by research on risk controversies (see, e.g., Horlick-Jones 1998; Irwin and Wynne 1996) that shows that the public is often falsely dismissed as a collection of laypersons incapable of understanding and interpreting science. Risk governance builds on the acknowledgment that there are various, conflicting risk perspectives.

Van Asselt and Renn (2011) refer to communication as meaningful interactions in which knowledge, experiences, interpretations, concerns, and perspectives are exchanged (compare Löfstedt 2005). The role of communication within risk governance is threefold. To begin with, communication entails the process of sharing knowledge and information on the various risk perspectives. Secondly, it may lead to the inclusion of various actors in the decision-making process which will lead to a sense of ownership. Communication might under certain conditions simultaneously increase the level of trust among all actors involved (Löfstedt 2005) which is an important, if not necessary, component in the acceptance of particular risk management arrangements.

However, communication in the context of risk governance is not simple. It is not just a matter of bringing people together. Social learning is required in order to find ways to discuss risk perspectives. Preparing the structure of the process is key. It is also required to figure out which type of communication with whom is important in which phase. Constructive communication does not imply that all actors remain in a constant dialogue with each other. It also does not imply that this question of “who is important in which phase” can be easily answered. Rather, communication requirements may differ depending on the context, such as political culture, the dominant social values and the trust relationships between actors. Hence, enabling communication is insufficient. The interaction level of the actors involved needs to tie into the challenges that accompany uncertainty, complexity, and ambiguity. By keeping a constant eye on “who is important in which phase,” it will become visible throughout the process which type of communication with whom is constructive and contributes to the responsible governance of uncertain risks. This remains a trial and error process in which various actors learn.

Inclusion has deep implications. Contrary to the current state of affairs in which risk topics are usually identified by experts, risk perspectives of other actors may act as the driving agents for identifying risk topics. Inclusion does not just mean that various actors are included, but that they play a key role in framing (or pre-assessing) the risk (IRGC (International Risk Governance Council) 2005; Renn 2008; see also Roca et al. 2008). Inclusion should be open and adaptive at the same time (Stirling 2004). Inclusion is defended for several reasons (compare Renn et al. 2011; Roca et al. 2008; van Asselt and Renn 2011). First, inclusion is needed to explore various sources of information and knowledge and to identify various risk perspectives. Second, it is argued from a democratic perspective that actors affected by the risks and/or the ways in which the risks are governed have a right to participate in deciding about those risks. Thus, inclusion is not just a means, but an end in itself. Third, it is argued that the more actors are involved in weighing the essentially heterogeneous pros and cons, the more socially robust

the outcome. People engaged in the participatory process tend to be more satisfied about the process itself than about its outcomes. Inclusion is thus supposed to support the coproduction of risk knowledge, the coordination of risk evaluation, and the design of risk management.

However, including various actors can be a challenge. The challenge is to organize productive and meaningful communication with, and inclusion of, a range of actors, who have complementary roles and diverging interests. The available empirical analyses suggest that the attempt to include different stakeholders can help to de-escalate conflicts and to legitimize the final decision that will always disappoint some actors in society (Beierle and Cayford 2002; US-National Research Council of the National Academies 2008). Inclusion does not, however, necessarily reduce conflict or lead to more widely accepted decisions (Kinney and Leschine 2002). Participation procedures themselves can become a source of conflict (Wiedemann and Femers 1993). Not every relevant actor might be interested in participating. Some actors might try to impose their framing on the process from the very beginning (van Asselt and Vos 2006). It is important to accept and address conflict, even though in many cases conflicts cannot be settled nor should that be the aim.

## The Integration Principle

Integration refers to the need to collect and synthesize all relevant knowledge and experience from various disciplines and various sources, including uncertainty information and articulations of risk perspectives. Scientific expertise should therefore not be regarded as a panacea to provide clear-cut solutions to non-simple risk problems. Risk governance still seeks scientific knowledge, but in order to look beyond the terms of likelihood and effects when it concerns uncertain, complex, and/or ambiguous risks. The integration principle emphasizes that also values and issues such as reversibility, persistence, ubiquity, tolerability, equity, catastrophic potential, controllability, and voluntariness should be integrated in risk assessment and evaluation. Furthermore, risk governance is not just about risks and usually not about a single risk. Risk governance requires risk(s)–benefit(s) evaluations and risk–risk trade-offs. The integration principle reflects the importance of such multidimensional evaluations.

Although it is quite impossible to ever fully understand uncertain, complex, and/or ambiguous risks, improvements can be made to understand them better. One way of doing this is, on the one hand, by transcending disciplinary (academic) boundaries, and on the other hand, by including more practical and tacit knowledge, in order to reflect a large variety in social and cultural values, preferences, and worldviews. Such an extended perspective will enable a set of consistent and coherent scenarios of future decision opportunities on which the relevant actors can make informed choices (see for an example of such regulation scenarios Fox et al. 2011).

Integration also refers to the process itself. Risk governance advances a holistic approach to framing, appraising, characterizing, evaluating, and managing risks (Zinn and Taylor-Gooby 2006). This implies that a strict separation between risk assessment and risk management is counterproductive and in need of critical reexamination (Jasanoff 1993). Risk governance is not a linear, sequential three-stage process of risk assessment, management, and communication, but it is dynamic and it requires interlinked and iterative processes. Although it may still be useful to distinguish assessment (examining the risks and benefits) from management (identifying regulatory options), it is important to realize that they can and should not be viewed as unconnected activities to be carried out in different realms. In other words, the separation of

risk assessment and risk management does not imply a complete “divorce” (Williams and Thompson 2004, p. 1622). Jasianoff (2005) as well as van Asselt and Vos (2008) have argued that boundary work is an effective way to make problems appear to be simple. Defining risk assessment and management as separate realms enables analysts to ignore uncertainty, complexity, and ambiguity. The integration principle calls attention to the need to consider the interconnections, both content-wise and in terms of process, between the various risk-related activities. Shedding light on these interconnections may also enable the actors involved to gain a better overview of the risks and uncertainties involved, which may lead to better practices.

## The Reflection Principle

Unfortunately, risk governance cannot be routinized. Differentiation is not an exception, but rather the rule. Reflection is a necessary component since it enables actors and institutions to maintain a critical outlook on what they are doing (compare Beck et al. 1994; Schon 1983) in order to continue to treat the risks as uncertain, complex, and/or ambiguous instead of simple, which each require different practices (van Asselt and Vos 2006, 2008; Wynne 2002a). What is needed is a collective reflection about balancing the possibilities for overprotection and underprotection. Van Dijk et al. (2011) refer to this balancing act as “prudent precaution.” If too much protection is sought, innovations may be prevented or stalled; if too little protection is provided, society may experience unmanageable unpleasant surprises. The classic question “How safe is safe enough?” is replaced by the question “How much uncertainty is the collective willing to accept in exchange for some benefit(s)?” So the focus shifts from risk to uncertainty (compare De Vries et al. 2011). The communication and inclusion principle hold that various actors take part in this reflective discourse and discuss how decisions could and should be made in the face of irresolvable uncertainty, complexity, and ambiguity. The reflection principle emphasizes that there are important difficult issues (uncertainty, complexity, ambiguity) which are in need of repeated consideration of all actors throughout the process. Every situation requires differentiation and flexibility and becomes a balancing act. Otherwise, the process risks to (re)introduce the familiar frames and routines developed for simple risks. Hence we have to be alert.

A crucial component of such reflexivity is to remain critical about inclusion and integration. One should not aim for a situation in which there is full trust – even though this might occasionally be achieved – since it often implies an approach aimed at risk acceptance rather than an approach aimed at critical reflection from public skepticism. Moreover it is important to find and maintain a pragmatic balance, whereby each risk is assessed on its own characteristics within a certain context, thereby taking into account its associated social dynamics (Walls et al. 2005). Risk governance thus may contribute to a “repolitization” of risk questions that have been “depolitized,” i.e., risk issues that have only been treated technocratically. In other words, depolitization is not the strategy behind risk governance (compare van Asselt and Vos 2006 who explicitly call attention to the political deficit in current ways of dealing with uncertain, complex, and/or ambiguous risks). Risk governance thus fundamentally differs from the traditional, positivistic approach that aims at depolitization by means of technocratization and strict boundaries between realms and activities. Reflexivity requires more scholarly consideration as well, since the contemporary scholarly debate seems to focus mainly on the communication and inclusion principles.

In sum, risk governance should not be considered as a panacea. It rather aims to facilitate a broader understanding of issues pertaining to contemporary risks. Risk governance aims to integrate insights that can be gained from decades of research on risk. The most recent development is to attempt to synthesize the insights gained into a set of principles. This set of principles has to prove to be both robust and applicable to practice.

## Conclusion and Discussion

---

In this chapter, in order to contribute to risk theory, we have explored and analyzed the origins and contours of risk governance. To that end, we reflected on important scientific developments in different strands of literature that have all contributed to the current understanding and thus explicitly or implicitly to the idea of risk governance in risk theory. These contributions are very multidisciplinary, ranging from psychology to law to science and technology studies (STS). We also discussed risk governance as part of the broader governance turn in policy sciences. Following the state-of-the-art review by van Asselt and Renn (2011), we emphasized that it is central to risk governance that it is recognized that uncertainty and risk cannot as easily be distinguished as is assumed in this positivistic risk paradigm. Many risks which require societal choices and decisions can be adequately characterized as complex, uncertain, and/or ambiguous risks. Risk governance pleads that uncertain, complex, and/or ambiguous risks are recognized and it aims to provide a basis for (more) adequate treatment. It is a consistent finding in the risk literature, that too often these risks are treated, assessed, and managed as if they were simple. The persistent societal controversies pertaining to genetic engineering, nuclear energy, and chemical risks suggest an urgent need to develop alternative approaches to deal with uncertain, complex, and/or ambiguous risks. We have discussed risk governance as an attempt to provide a basis for such alternatives. We discussed the proposal to see risk governance as a set of principles that can inform thinking on non-simple risks practices: the communication and inclusion principle, the integration principle, and the reflection principle. These principles aim to synthesize the most important aspects to be organized in order to be able to govern risks responsibly. The multitude of references to “risk governance” has unduly given it the status of a “buzzword.” However, we believe that it should be understood as a plea for a paradigmatic and practical shift in dealing with modern risks. But it will not be an easy passage. We think that taking stock might help to facilitate a shift in risk practices.

**Abstract:** This chapter aims to understand the role of science and knowledge in the regulation of uncertain risks. In such cases, since scientific knowledge is perceived or portrayed to be limited, experts, stakeholders, or the public have or create doubts about the possibility or severity of hazards. At the same time, regulators habitually turn to science and experts in these cases in order to justify their decisions. This “uncertainty paradox” raises important questions about the role of science, knowledge, and experts in uncertain risk regulation. The analysis reveals that the main challenge for EU risk regulation seems to be as to how to break (out of) the uncertainty paradox. The chapter calls for a systematic comparative research of risk regulation regimes in various domains based on an interdisciplinary approach involving legal and policy sciences as well as STS and risk research. It views that this kind of research has the potential to significantly contribute to risk theory, while at the same time raising new issues and new research questions that would require further interdisciplinary research.

## Introduction

---

The importance of dealing with uncertain risks needs hardly to be emphasized in the post-BSE era. The major institutional shortcomings of national and EU decision-making that were revealed by the BSE (or mad cow disease) crisis triggered a crisis of public confidence in both scientific advice and in the management of risks by EU and Member States authorities. It provided a classic illustration of the complex and vital relationship between science and society and of the difficulties stemming from dealing with uncertainty in science. It led both regulators and the general public to become aware of the risks that are intrinsic to the food industry. Moreover, the continuous stretching of the frontiers of science in areas such as biotechnology has raised public anxiety levels even further. Various such crises combined with public anxiety have, in turn, shaped the way in which risks are perceived and subsequently managed, with strong implications for understandings of political accountability, the role of science, and stakeholder participation.

Post-BSE, therefore, the question of how public authorities should deal with risks and uncertainties has become a predominant concern for the EU in its attempt to achieve one of its main objectives, the free movement of goods and the completion and management of the internal market on which products can freely circulate. How to deal responsibly with situations in which there are suspicions that hazards may exist, although (sufficient) scientific or historical evidence for them is lacking, is in fact a key question that can be derived from Ulrich Beck's (Beck 1986, 1997) agenda-setting critique and provoking notion of “organized irresponsibility.” His sociological conclusions have been mirrored by risk scholars (Wynne 1982; Jasanoff 1993; Hager 1995; Ravetz 1996; Klinke and Renn 2002; Jasanoff 2005; Löfstedt 2005). Not surprisingly therefore, prominent risk scholars have indicated that dealing with “uncertain risks” is a major challenge in current societies (e.g., Beck 1986; Jasanoff 1990; Wynne 1995; Nowotny et al. 2001; Ravetz 2001; Harremoës et al. 2002; Löfstedt 2005; Renn 2006). Such uncertain risks concern situations of suspected, potential hazards, which are usually associated with complex causalities, large-scale, long-term and transboundary processes, and which are generally difficult to control and also transcend human sensory capacities.

This chapter aims to address this key challenge and to understand the role of science and knowledge in the regulation of uncertain risks by examining how various actors deal with

science, knowledge, and uncertainty in the field of EU risk regulation. In such cases, since scientific knowledge is perceived or portrayed to be limited, experts, stakeholders or the public have or create doubts about the possibility or severity of hazards (van Asselt 2005). At the same time, regulators habitually turn to science and experts in these cases in order to justify their decisions (Ravetz 1990; Jasanoff and Wynne 1998; Hilgartner 2000; van Asselt 2005; van Asselt et al. 2009). This situation, which we term the “uncertainty paradox” (van Asselt and Vos 2005, 2006), raises important questions about the role of science, knowledge, and experts in uncertain risk regulation. Our analysis seeks to identify the difficulties of dealing with such risks, to detect ways to address these problems, and to set a long-term research agenda.

## History: Science-Based Risk Regulation in the EU

---

Since the outbreak of the 1996 BSE crisis, there has been much debate on the role of science in European regulatory decision-making and in particular on the need to separate risk assessment from risk management. The Medina Ortega Report of the European Parliament found that in 1990–1994, when the disease had reached crisis levels, the European Commission had suffered from poor internal management; decision-making procedures were not transparent; some national interests held too much weight in the decision-making process; and the resulting legislative controls were not effectively implemented. It moreover concluded, *inter alia*, that the relationship between scientific and political decisions of the EU institutions was blurred. Moreover, it held that the EU institutions, the European Commission in particular, had failed to take public health seriously, and that they had attached more importance to the national interests of agriculture and the interests of industry than the protection of public health. The Report was particularly critical of the committee model (especially the committees composed of national representatives), which it found complex, non-transparent, and undemocratic (European Parliament 1997). The Report thus urged for greater transparency, particularly in relation to the conditions of the functioning and contribution of the scientists on the scientific committees and reform of the rules governing the work of these committees to ensure independence and appropriate funding of the scientists, and the publication of debates within committee and of any dissenting opinions.

Without doubt, the BSE crisis underlined that governance of uncertain risks is difficult, and inherently political. The BSE crisis has been considered an example of “organized irresponsibility” (Hajer and Schwarz 2001). We understand “organized irresponsibility” (Beck 1986) as a situation in which society is unprepared for, and unable to adequately deal with, inevitable surprises, negative consequences, and/or long-term impacts associated with uncertain risks, notwithstanding all institutions and procedures in place and the pretense of certainty and control. The sense of being organized and in control further contributes to society’s unpreparedness and inability, as it appeases people’s awareness and alertness. As a consequence, a situation of organized irresponsibility has negative spiral characteristics. Not surprisingly, in the aftermath of the BSE crisis, fargoing reforms were carried out both at European and national level so as to set and/or restructure the various responsibilities.

**Box 45.1 The EU's Regulatory Structure and Decision-Making Procedures**

The European Union, currently composed of 27 Member States, has a unique institutional structure that is laid down in two basic treaties: the Treaty on European Union and the Treaty of the Functioning of the European Union. It has seven different institutions that are allotted different tasks. For the purpose of this chapter, four institutions are of vital importance: the Council of Ministers, the European Parliament, the European Commission, and the European Court of Justice. Most importantly, in the majority of cases, the Council of Ministers and the European Parliament jointly form the European legislator. The Council of Ministers, or often also referred to only as Council, is composed of the national ministers of each Member State; its composition changes according to the topics dealt with (e.g., when dealing with the environment, the Council is composed of national ministers of the environment). The European Parliament is composed of 737 members who are directly elected. The European Commission is generally charged with the task of promoting and defending the European interests. It is composed of 27 commissioners (one per country) and has the right of initiative in terms of legislation. In addition, it is the EU's executive as it implements at the EU level the legislation set by the European Parliament and the Council. The European Court of Justice consists of two main bodies (General Court and the Court of Justice of the EU), is composed of judges, and is to ensure that the EU law is observed in the interpretation and application of the EU treaties.

Issues about uncertain risks are being mainly dealt with by the European Parliament and Council in their role of European legislator through European legislative acts (regulations and directives) and by the Commission as the risk manager that implements and applies these legislative acts. Of importance are also two other bodies that the EU has created in its institutional structure: agencies and committees (comitology). Today more than 30 regulatory agencies have been created at arm's length of the European Commission. They carry out tasks that vary from adopting decisions as regards the European trade mark to advising the European Commission on the safety of a specific product. The European Food Safety Authority (EFSA) is such an agency and has formally only the power to advise the European Commission on all issues of food safety. EFSA is mandated to act as the risk assessor in the European context. Whenever a company wants to apply for a marketing authorization of a food product as required by specific EU legislation or whenever a Member State wants to deviate from EU law, as in some cases is allowed for, EFSA will give a scientific opinion that is transmitted to the European Commission. Before the European Commission is entitled to adopt a decision, it needs to consult a committee composed of national representatives. This committee-based decision-making procedure is called, in Brussels' jargon, comitology and requires the Commission to submit a draft decision to a committee which will give an opinion on whether it agrees or not with the Commission's draft decision. Depending on the type of procedure, such a committee may ultimately be able to block the Commission and prevent the Commission adopting a decision. Before 2011, this in some cases meant that the Council of Ministers could adopt a decision instead of the Commission.

## Current Research

### The Uncertainty Paradox and the Precautionary Principle

The relationship between uncertainty and knowledge is complex (van Asselt 2005). More knowledge may also imply more uncertainty, as more scientific unknowns are highlighted

(compare van Asselt 2000; Levidow et al. 2005). Surely, uncertainty is in this context not equivalent to no knowledge at all. Scientific experts, whether tacitly or explicitly, do possess what we may call “uncertainty information” (van Asselt and Petersen 2003; van Asselt 2005; van Asselt and Vos 2005, 2006; van Asselt et al. 2009; compare Funtowicz and Ravetz 1990; Morgan 2003; Krayer von Kraus 2005), i.e., insights on which uncertainties are (deemed) important, (attributed) sources of uncertainty, whether and how uncertainty is reducible and which interpretations seem valid in view of the current state of knowledge (i.e., the limits to interpretative flexibility). Acknowledgement of the limits of science in providing conclusive evidence, i.e., the impossibility of full certainty, has led to the development of the precautionary principle. At the same time, all legal formulations (see Fischer 2002; very recently Wiener et al. 2010; Zander 2010) of the precautionary principle include what is called a “knowledge condition” (Manson 2002), i.e., the level of proof needed to trigger application (Petersen and van der Zwaan 2003). Although this knowledge condition is often kept vague or ambiguously formulated, the point is that such a knowledge condition implies that lawyers and policy makers appeal to scientists and experts for some kind of plausibility “proof,” which request has the tendency to run down to demanding conclusive evidence on whether something is a risk. Such requested certainty about uncertain risks seems highly incompatible, if not contradictory, to the notion of uncertainty as the core of the precautionary principle, which implies that neither definite proof nor evidence is available. This leads to a paradoxical situation: on the one hand, it is increasingly recognized that science cannot provide decisive evidence on uncertain risks, while on the other hand policy makers and authorities increasingly resort to science for more certainty and providing conclusive evidence (compare Weingart 1999). This particular pattern in risk regulation we refer to as the “uncertainty paradox”: an umbrella term for situations in which uncertainty is present and acknowledged, but the role of science is framed as one of providing certainty (van Asselt and Vos 2005, 2006). In instances of this uncertainty paradox, policy makers and judicial authorities resort to experts for conclusive evidence and definite answers, despite uncertainty precluding both conclusiveness and definitiveness. In uncertainty paradox situations, a very high level of skepticism as to what science can deliver goes hand in hand with a very optimistic level of confidence regarding what science should be able to deliver (Forrester and Hanekamp 2006).

It seems that this paradox is the consequence of getting stuck in the middle of recognizing the meaning of uncertainty. The inherent limits of scientific observations and studies are recognized, which necessitates to abandon the traditional model of decision-making. The precautionary principle is then seen as “tool to compensate” in situations of unavoidable uncertainty. However, it is often not recognized that uncertainty may also erode the traditional positivistic model of knowledge, in which science speaks truth to power. Although uncertainty is recognized, science is still expected to tell the truth about uncertain risks. Strikingly, advocates of the precautionary principle are willing to rethink regulation, but overlook the need to rethink science and its role in regulation. The uncertainty paradox thus raises important questions about the role of science, knowledge, scientists, and knowledge producers in precaution-based regulation of uncertain risks. It seems that this paradox is the consequence of the difficulty to deal with uncertainty and recognizing its meaning.

Our analysis of Case T-13/99, *Pfizer Animal Health SA v. Council* (hereinafter *Pfizer*) case (European Court 2002a; see also European Court 2002b) illustrates how the uncertainty paradox may become manifest in precaution-based regulatory practice of the EU (van Asselt and Vos 2005). This case concerned a ban of the use of four antibiotics including virginiamycin as

additives in animal feeding stuffs by the EU. This ban was subsequently challenged by the company that produced virginiamycin (Pfizer) before the European Court. The scientific experts on a European scientific committee tried to provide a satisfactory plausibility proof, but uncertainty information crept into their considerations. Instead of following the requested “plausibility proof,” the institutions distracted and reinterpreted pieces of uncertainty information in order to construct uncertainty, which was used as a sufficient condition to apply the precautionary principle. In doing so, the institutions implicitly admitted that reasoning about the “plausibility” of uncertain risk involves normative and subjective judgements, on which basis they implicitly considered it legitimate to “redo” the work originally delegated to the experts.

Although the uncertainty paradox put the scientific committee, the Council of the EU and the European Commission in an uncomfortable straitjacket, it is clear that especially the Court was confronted with a deadlock situation. Such a deadlock, we argued, was the consequence of the way the uncertainty paradox was propagated through the regulatory chain. From the beginning, the role of the experts was framed in terms of providing certainty about uncertain risks. The whole regulatory endeavor further stabilized this illusion, with the consequence that the Court was forced to evaluate the merits and validity of scientific claims. In this case, although the Court managed ultimately to produce a ruling, such jurisprudence can easily be used to abuse the precautionary principle (see, e.g., Marchant and Mossman 2004; Forrester and Hanekamp 2006). A series of such cases, we argue, would be detrimental to the whole precautionary endeavor.

Surely, we recognize that it is a tough challenge to legally accommodate uncertainty. This is even more difficult if we take into account that also EU regulation is at least contextualized, if not dictated, by global regulatory regimes as the World Trade Organization (WTO). Even if we would succeed in developing a coherent precautionary regulatory regime that adequately accommodates uncertainty within the EU context, the WTO’s interpretation of “science-based” may reintroduce vicious paradoxes as the uncertainty paradox. Building upon our reflection and analysis, we concluded that the embedment and integration of uncertainty information in global regulatory processes is an important challenge.

Our analysis of three decision-making processes on uncertain risks, pertaining to the import of genetically modified organisms (GMOs), NK603, GT73, and MON863x MON810, confirmed the uncertainty paradox that was reinforced by the interplay of four mechanisms: (1) uncertainty intolerance on the part of both the risk producer, Monsanto, and the risk assessor, the European Food Safety Authority, EFSA, (2) boundary work which enabled EFSA to claim irrelevance and to construct authority claims which served as building blocks in creating plausibility proofs, (3) the tendency to equate uncertainty with risk, which (further) confined risk producers and risk assessors to the role of uncertainty-intolerant producers of plausibility proofs and technocratic provisions that resulted in (4) an even stronger and de facto political, role for EFSA with the consequence that its uncertainty intolerance became a critical and decisive factor in the interplay (van Asselt and Vos 2008).

## Uncertainty Intolerance

---

First we would like to explain that uncertainty intolerance refers to a situation in which uncertainties are not acknowledged, deemed irrelevant, or are simply evaded, instead of

genuinely and systematically investigated (Wynne 2001; van Asselt et al. 2010). Such intolerance is associated with an unwillingness to demand and produce uncertainty information. In the GMO case studies, we observed first that Monsanto displayed uncertainty intolerance in its framing and assessment behavior. Monsanto's safety assessments seemed deliberate efforts to transform any uncertainty about risk into absolute certainty about safety. To this end, they avoided uncertainty in their communication, they defined it away in their reports, and they seemed to attempt to suppress tests that may question the absolute certainty. Second, we observed that Monsanto violated the obligation to disclose all relevant research as it failed to disclose a rat study. Only upon an order of a German court, Monsanto appeared willing to disclose this study, which indicated that MON 863 caused unexplained kidney damage to rats (Greenpeace 2005).

Apart from the fact that the rat study report was held back by Monsanto, we also noted that this rat study report showed that the tested rats had less mineralized kidney tubules than average. Yet, without giving a proper motivation or justification, Monsanto claimed that this finding was of "no biological significance" (p. 11). Hence, the observed effects are dismissed by Monsanto as irrelevant. Van Asselt (2005) observed that in many practices claims of irrelevance enable experts to suggest certainty. Uncertainty intolerant assessors seem inclined to claim irrelevance, while uncertainty tolerant assessors would have investigated the uncertainty and would have sought to share the uncertainty information. Monsanto furthermore stated that the effect cannot be considered "test related" (p. 11). This we find a quite puzzling statement: There is an adverse effect, yet Monsanto claims that this is not caused by the intake of GM maize. It is not explained how this is possible in a control study setup: The only difference between the two groups of rats was that the rats with altered kidneys were fed GM maize. Here, uncertainty intolerant assessment behavior entailed creating a smoke screen with the aim to keep the uncertainty out of sight. It is intriguing that although Monsanto neutralized the uncertainty in the report itself through claims of irrelevance and a smoke screen, it still decided to conceal the rat study report. The combination of these assessment behaviors – claiming irrelevance, creating a smoke screen and suppression of the report – provide further evidence for our evaluation of Monsanto's stance: uncertainty intolerance is both manifest in the framing and the assessment behavior.

In addition to the uncertainty intolerance of Monsanto, we also observed an uncertainty intolerance on the part of EFSA, which is in line with the earlier observations of Levidow et al. (2005): The opinions of EFSA "generally indicate no uncertainty" that might trigger extra risk management measures (p. 270) and they "have framed scientific uncertainties in such a way that they can be resolved by extra information, or can be readily manageable, or can be deemed irrelevant to any risk" (p. 273). The risk assessor partly inherited Monsanto's uncertainty intolerance, as EFSA's risk assessments were in fact meta-reviews of Monsanto's assessment. This arrangement, which is laid down in the relevant legislation, did not only introduce dependency on the willingness of the applicant to disclose all relevant information, but also in terms of framing and the willingness to disclose uncertainty information. EFSA's room of maneuver is determined by Monsanto's framing and information about uncertainties. The behavior of Monsanto with regard to the tests with adverse effects indicates that this dependency is not a theoretical issue, but a practical difficulty. Another illustration is that during the assessment of MON 863 x MON 810 (EFSA 2004a), the applicant had to repeatedly provide EFSA with additional data for a variety of reasons.

We would however like to stress that the uncertainty intolerance of EFSA cannot only be explained by inheritance of uncertainty tolerance from Monsanto. It is noticeable that EFSA

often sides with Monsanto's evaluations and interpretations of data, and even explicitly "agrees with the applicant," without further explanation or critical discussion of uncertainties that might have been overlooked by Monsanto (as it could/should have done in the rat study affair). EFSA framed its assessment activities as risk assessment, but its actual assessment behavior is very consistent with a safety, i.e., an uncertainty intolerant, orientation. Chalmers (2005) characterizes EFSA's style of reasoning as providing "its own corpus of proof" to find no evidence of risk (p. 658).

It is notable that in all cases, the Commission asked EFSA to "consider whether there is any scientific reason to believe" that the placing on the market of the GMOs "is likely to cause any adverse effects on human health and the environment" (EFSA 2003; EFSA 2004a, b). The particular formulation "whether there is any scientific reason to believe" is relevant if we compare it with the closed question (i.e., whether or not the activity constitutes a risk) the Commission asked in the *Pfizer* case (van Asselt and Vos 2005, 2006). It can be argued that the terms of reference to EFSA were more uncertainty tolerant in the light of the following two elements: (1) instead of asking for a decisive answer and proof on whether the risk is a hazard, the Commission asked for indications that hint at adverse effects, and (2) instead of referring to science as the source of absolute truth and certainty, with the notion "to believe" the Commission seemed to accept that science cannot provide certainty about uncertain risks. As a matter of fact, we observed that also in the regulatory documents related to the directives relevant for the regulation of GMOs and in additional guidelines, the Commission expressed openness to uncertainty or even explicitly called for the description and explicit treatment of uncertainty (Levidow et al. 2005). The terms of reference could therefore have been read as invitation to systematically discuss the uncertainties involved and to provide uncertainty information. Interestingly, however, in all three cases, EFSA provided answers phrased in the following terms: the GMO is "as safe as" the conventional counterpart and it is "unlikely to have an adverse effect on human and animal health and (...) the environment." "Unlikely" can be read as "low risk." Combined with the claim "as safe as," it can be argued that the effective message of EFSA's assessment is a plausibility proof, although such nonrisk contention was arguably not requested by the Commission. This production of plausibility proofs can be read as an uncertainty intolerant interpretation of the goal of the assessment. Observations and analyses of experts involved in risk assessment suggest that EFSA's uncertainty intolerance is indeed not unique, but rather widespread among risk assessors institutionalized in the policy domain (Wynne 2001; Stahl and Cimorelli 2005).

Interestingly, Monsanto's safety assessment and EFSA's risk assessment were similar in that they both were uncertainty intolerant. This resemblance led to accusations of bias and relationships with biotech industry, conspiracy theories, etc. Friends of the Earth (2004), for example, argued that EFSA is used by the Commission to force GMOs onto the market. We do not agree with such views. Building upon our analysis, we argue that EFSA was as uncertainty intolerant and safety-oriented as Monsanto, with the consequence that it is understandable that EFSA felt at ease with Monsanto's arguments and that the assessments were very similar. We want to emphasize that we do neither suggest nor argue that EFSA is deliberately defending or advancing Monsanto's stakes. But, because of the shared uncertainty intolerance, their lines of reasoning were very similar. This similarity is not the point of departure, but in part the *effect* of EFSA's attitude toward uncertainty.

## Boundary Work and Plausibility Proofs

Our analysis of the GMO cases also showed that EFSA managed to evade uncertainty, which enabled it to declare GM products to be safe, through boundary work. Boundary work, a notion coined by Gieryn (1983, 1999), is a strategic and purposeful act in which boundaries are drawn between realms, for example, between science and nonscience and between science and politics. Boundary work involves drawing and maintaining contrasts through selective attributions, which effectively demarcate in order to construct “self-evident justification” and “superiority in designated terrains” (Gieryn 1999). Such boundary work appears to be, as literature shows, not just a matter of formal responsibilities, but an ongoing negotiation process on roles and tasks and how these are portrayed to the others (Bal et al. 2002; Hoppe and Huijs 2002; Halffman 2003, 2005; Jasanoff 1990, 2005). In our case studies we observed how EFSA engaged in boundary work. Dynamic boundary work between risk assessment and risk management as well as between science and nonscience facilitated the construction of claims of irrelevance and authority claims, which were used as building blocks in constructing certainty. EFSA explicitly stated to have been requested to consider scientific objections and not to assess nonscientific ones (EFSA 2003, p. 4). It used the constructed boundary between science and nonscience to argue that possible uncertainties about interference with the European environment and regular maize crops are nonscientific concerns. In this way, the scope of the risk assessment could be minimized. In a similar vein, EFSA constructed a boundary between risk assessment and risk management. Such boundary work enabled EFSA to disqualify and dismiss Member States concerns, which could have been read as uncertainty issues (compare Levidow et al. 2005), as “nonscientific” and “issues of risk management.” EFSA’s boundary work is an example of what Jasanoff (2005) refers to as “less transparent, politically significant boundary work” (compare also Cranor 1990). It can furthermore be argued that earlier boundary work in the processes of setting up the regulatory structures, enabled EU policy to define “agribiotechnology as an expert scientific issues (...) kept separate from socio-ethical issues” (Levidow et al. 2005, p. 266) which facilitated EFSA’s boundary work. It is beyond the scope of our expertise to assess the content of EFSA’s claims: We only describe the assessment behavior. Our analysis demonstrates that in instances that could have been read as uncertainty (Member States’ concerns, adverse effects, open questions), EFSA actively evaded uncertainty through boundary work, instead of discussing these uncertainties and exploring whether and how they may matter. Let alone that the possibility of other and “unknown” uncertainties was systematically considered with an open mind (compare Wynne 2001; Levidow et al. 2005).

EFSA’s responses to concerns regarding the risk of cross-contamination illustrate the dynamic nature of boundary work. With NK 603, EFSA refused to consider the possibility that the GMO could contaminate regular maize crops. It argued that the question of contamination was one of risk management, not of risk assessment and thus felt beyond the limits of EFSA’s remit (EFSA 2003). Landfried (1999) (quoted in Levidow et al. 2005, p. 263) argued: “the difficulty of distinguishing between political and technical questions also provides an opportunity to those who might wish to reduce political questions to technical ones.” In our case, issues of uncertainty were recast as political topics. In this way, boundary work helped EFSA to minimize the scope of the assessment. The cross-contamination issue was also raised with regard to GT 73. This time, however, EFSA did engage in what it had previously

argued to be questions of risk management. Concerns regarding contamination were still quickly dismissed with the reasoning that spillage of the GT 73 plant would likely only occur in ports located in industrial areas. Since these industrial areas offer little room for agricultural cultivation, contact with, and contamination of, other plants was portrayed as highly unlikely. Similar reasoning was employed when contamination concerns were raised with regard to MON 810 x MON 863. Also in that case, EFSA appeared more willing to address issues it dismissed in the NK 603 case. Chalmers (2005) argues that in the case of NK 603, EFSA interpreted its role in the narrowest and most formal sense and thus carried out a very minimal risk assessment. We would argue that minimizing the scope of the risk assessment was an effective way to evade uncertainty.

Boundary work enabled EFSA to construct superiority, which facilitated the production of authority claims. EFSA often mobilized “the scientific literature,” but without specific references or they just agreed with some particular findings or conclusions, without providing further justification. Through this *ex cathedra* style, EFSA presented itself as an authoritative voice. “Believe us, we are scientists,” is the implicit message. The constructed authority is then used as an anchor to evade uncertainty. The boundary work brought about self-evident justification for EFSA’s role in deciding what counts as “new science.” The “new”-requirement (compare Chalmers 2005) in combination with the self-acclaimed authority in this domain enabled EFSA to be satisfied with a reference to earlier assessments. In this manner, boundary work facilitated EFSA to produce certainty about non-allergenicity and hence produce a plausibility proof.

## Tendency to Consider Uncertainty as Equal to Risk

Our case-study research has moreover revealed another mechanism contributing to the uncertainty paradox. We noted that various actors tend to equate uncertainty with risks. Although the notion “uncertain risks” points to situations where risks are highly uncertain, this does not mean that *all* risks are highly uncertain and, importantly, not all uncertainties inhibit dangers. Not all uncertainties are by definition relevant or critical for every aspect in a risk assessment. Equating uncertainty with risks implies that any uncertainty is interpreted as a signal of risk.

In our case studies, both the risk producer (Monsanto) and the risk protestors (Greenpeace and Friends of the Earth) tended to equate uncertainty with risk, notwithstanding the fact that they have opposite positions in the GMO debate. Monsanto’s uncertainty intolerance and the associated desire to prove no effect seemed to be grounded in the belief that zero uncertainty would be equal to zero risk so that it would be considered as 100% safe. As a consequence they seem to fear uncertainty, as it threatens the idea of absolute safety.

The risk protestors also tend to equate uncertainty with risk, but in a different way. Their reasoning seems to be based on the belief that uncertainty is equal to risk which would amount to 100% hazard. For example, both Greenpeace and Friends of the Earth tried to discredit EFSA’s opinions by emphasizing that these opinions had not taken into account irregularities in the molecular characterization of a GMO and that these opinions had not been framed “within the context of continuing scientific debate and uncertainty about fundamental issues relating to its conclusions” (Greenpeace 2004, p. 2; Friends of the Earth 2004, pp. 15–16). They used specific uncertainties to discredit EFSA’s risk assessment.

Such equating of uncertainty with risk may be interpreted as a way to politicize uncertainty. Politicization of uncertainty refers to the role of politicians, stakeholders, special interests

groups and/or the public highlighting, amplifying or attenuating uncertainties in order to serve other interests (e.g., Funtowicz and Ravetz 1990; Smithson 1993; Stocking and Holstein 1993; Pollack 2003). Levidow et al. (2005) suggest that in the debates on GMOs such politicization of uncertainty is taking place: “Policy actors play down or emphasize various uncertainties – to challenge evidence of risk or safety, to justify their stances (...), to pursue greater rigour in demonstrating safety, to mediate among conflicting views and/or to delay (...) decisions” (p. 273). That is not the point we want to raise here. We would like to point to the fact that the risk producer tried to avoid uncertainty in order to demonstrate safety, while the risk protestors highlighted uncertainty to demonstrate risk. This tendency to equate uncertainty with risk sustains the uncertainty paradox as it hampers the production and sharing of uncertainty information. Those who adhere to the absolute safety logic (i.e., zero uncertainty = zero risk) do not welcome uncertainty information. On the other hand, actors who consider uncertainty as a sign of risk tend to politicize uncertainty information, which is, according to Frewer et al. (2003), one of the reasons why experts hesitate to communicate uncertainty.

## Political Deficit: EFSA as the De Facto Risk Manager

---

We furthermore observed in our GMO case studies how regulatory provisions allow EFSA, as the risk assessor, to occupy a central position in the decision-making process, which actually leads EFSA's uncertainty intolerance to increase further. In all three cases, regulatory deadlocks occurred because no agreement for or against import was reached in the relevant comitology committees (created to supervise the European Commission) and/or the Council. To avoid procedural standstill, in such situations the relevant legislative provisions ultimately empower the Commission to adopt a decision. Despite resistance of several Member States, the Commission could issue consents for the placing on the market of NK 603 (European Commission 2004) and GT 73 oilseed (European Commission 2005) under Directive 2001/18, closely following EFSA's opinion. Whereas this procedure is designed for extraordinary circumstances, it became the de facto standard operating procedure in these cases of authorization on GMOs and it gave leeway to adopt authorization in line with EFSA's opinion. The Commission's decisions were a matter of rubber-stamping EFSA's plausibility proofs. As a consequence, it seems safe to conclude that EFSA was the de facto risk manager in the NK 603 and the GT 73 cases.

In the MON 810 x MON 863 case, the decision-making process was more complex, because of disagreement within EFSA. In the framework of comitology, Member States could not reach a majority in favor or against authorization, but this time the Commission could not rely on a plausibility proof. Partly due to pending changes in the regulatory regime, the decision-making process was temporarily blocked. In 2005, EFSA issued a new opinion, wherein it succeeded in producing a plausibility proof (EFSA 2005). This opinion was again the basis for a Commission proposal to be discussed in comitology, but again the Member States could not reach a majority, so that the Commission's proposal to authorize was referred back to the Council to decide. As the Council did not manage to adopt a decision in the prescribed period, the Commission was empowered to authorize MON 863 x MON 810 in line with EFSA's plausibility proof (European Commission 2006).

In view of the societal and political controversies in the EU pertaining to genetic modification (e.g., Durant et al. 1998; Gaskell et al. 2000, 2004; Levidow 2001; Wynne 2001;

Jasanoff 2005; Levidow et al. 2000, 2005, 2007; Horlick-Jones et al. 2007; Lee 2008), it is striking that notwithstanding the political controversy about possible authorization of the three GMOs that we investigated, the decisions about the import were ultimately taken in a technocratic manner: the Commission, following EFSA, simply authorized these products. Our analysis confirms Borrás' conclusion (Borrás 2006) that scientific experts continue to have a central, undisputed position in actual EU regulation of GMOs, notwithstanding rhetoric and institutional changes after the BSE crisis. This would mean that there is a clear political deficit and a trend of scientification of politics (Everson and Vos 2009). It is exactly such technocratic division of responsibility, and associated credibility and legitimacy questions, which were the main political concern after the BSE crisis and the *raison d'être* of EFSA (Vos 1999, 2000; Vos and Wendler 2006). Our analysis adds another dimension to the old concerns: Technocratic provisions sustain or even reinforce the uncertainty paradox in situations of an uncertainty intolerant risk assessor (van Asselt et al. 2010).

## Further Research

---

Over the past years, our interdisciplinary law–social sciences research has sought to deepen and further understanding of the complexities of the governance of uncertain risks and as such to provide input for theory development in the field of risk governance. To this end we have examined various cases to understand how various actors deal with science, knowledge, and uncertainty in the field of EU risk regulation. We aim to provide some insights into the ways in which these actors wrestle with uncertainty. Our analysis suggests that uncertainty intolerance is a core problem. Recognizing and addressing uncertainty can inform knowledge-generation (Levidow et al. 2005). To counteract uncertainty intolerance, uncertainty training is needed. In current education programs, science is presented as a body of certainty (Pollack 2003; see also Collins 1987), which nourishes uncertainty intolerance. In all scientific education, more explicit attention should be paid to uncertainty aspects of science (van Asselt and Petersen 2003). Our own experience with uncertainty training suggests that it is possible to change the attitude toward uncertainty and creates openness for communicating uncertainty, without hampering the willingness to bear responsibility and take decisions. Another aim of uncertainty training is to facilitate awareness of uncertainty paradox mechanisms among people involved in risk regulation. Furthermore, risk assessment bodies, such as EFSA, should not only include experts on issues relevant with regard to specific uncertain risks, but should also welcome uncertainty tolerant experts who are aware of mechanisms associated with the uncertainty paradox in order to organize resistance to the production of plausibility proofs. In addition to this, it might prove fruitful to organize realms where risk producers, risk assessors, risk managers, and risk protestors meet, next to the indirect communication through formal reports. Such two-way exchanges might help to discuss uncertainties in a different way, and might enable risk regulators to gain an understanding of what science can and cannot provide. Notwithstanding the fact that currently we see some ways to counteract uncertainty intolerance, we think that further research is still needed to better understand uncertainty intolerance both on the individual and collective level. Such insights are needed to better target training and to develop strategies to change arrangements and incentives that favor uncertainty intolerance.

On the basis of our research, we feel confident to conclude that the uncertainty paradox is deeply ingrained in current risk regulation arrangements and the broad sociopolitical order.

The main challenge for risk governance seems therefore to be how to break (out of) the uncertainty paradox and to rethink the role of science and expertise in risk regulation (compare Wynne 2001; Levidow et al. 2005; Jasanoff 2005). Insights into, and broader awareness of mechanisms that bring about, and sustain, the uncertainty paradox are only first, but necessary steps. When looking at the current debate on EU GMO regulation, we observe that most critics continue to frame EFSA's role in terms of the uncertainty paradox: EFSA is expected resolve diverging scientific opinions and is still cast as “a body responsible for supplying *unimpeachable* scientific advice and guidance” (Randall 2006, p. 413, emphasis added). It is not recognized that the problems arise from the great burden placed on science as the basis for decisions (Levidow et al. 2005). In this way, an artificial certainty that glosses over any uncertainty regarding risks of GMOs is asked for, which only encourages and reinforces “the self-delusions of institutional science” (Wynne 2001, p. 457) and the “lack of reflexivity about the quality of the knowledge it provides” (Wynne 2001, p. 458). This direction further reifies the uncertainty paradox. Surely, we must stress that in the context of GMOs, the new approach for GMO cultivation that the Commission launched in 2010 addresses the political sensitivities of Member States that do not want to cultivate GMOs on their territory that we also observed in our case studies and recognizes explicitly the need to balance between maintaining the EU system of authorizations based on scientific assessment of health and environmental risks and the freedom of Member States to address specific national, regional or local issues raised by the cultivation of GMOs (European Commission 2010; see Poli 2010). On the other hand, it may be wondered whether this is motivated by the desire to shatter the uncertainty paradox as it does not seem coincidental that such an approach would free the EU institutions from being challenged before the WTO courts and confer unambiguously upon Member States themselves the responsibility to justify possible trade barriers before the WTO. The obligations of the WTO agreements seem indeed to reinforce the need for further study and understanding of EU risk regulation and the role of the various actors and provisions herein, also at the global level.

Recent research on EU regulation on nanotechnology seems to suggest that the uncertainty paradox is present also in this area. Although in this area the regulatory provisions expressly include ethical and other concerns as concerns to be taken into account in the decision-making, Maria Lee concludes that in practice this has

- ▶ not led to the inclusion of ethical concerns in the chemicals or cosmetics regulation, and even in respect of food, decisions are framed largely around risk and safety. These institutional innovations (carving out a space for “risk management”, public participation, expertise in areas other than risk assessment) begin to express the breadth of the decisions to be taken on nanotechnology and other emerging technologies (Lee 2010, p. 820).

She underlines that such innovations “fail to grapple with the basic issue, which is that conventionally we regulate only on the basis of risk. Superficial changes go nowhere when the decision is so heavily constrained by the regulatory context, dominated by a narrow approach to risk assessment. We are faced with a very serious failure of accountability: either decisions are being attributed to science and risk when actually they are political; or the issues that decision-makers say they are taking into account are simply deemed irrelevant” (Lee 2010).

So the next step is to more systematically compare risk regulation regimes in various domains (see Fig. 45.1). Most analyses, including ours, tend to concentrate on a particular technology, while studies systematically comparing risk regulation regimes are lacking. Such

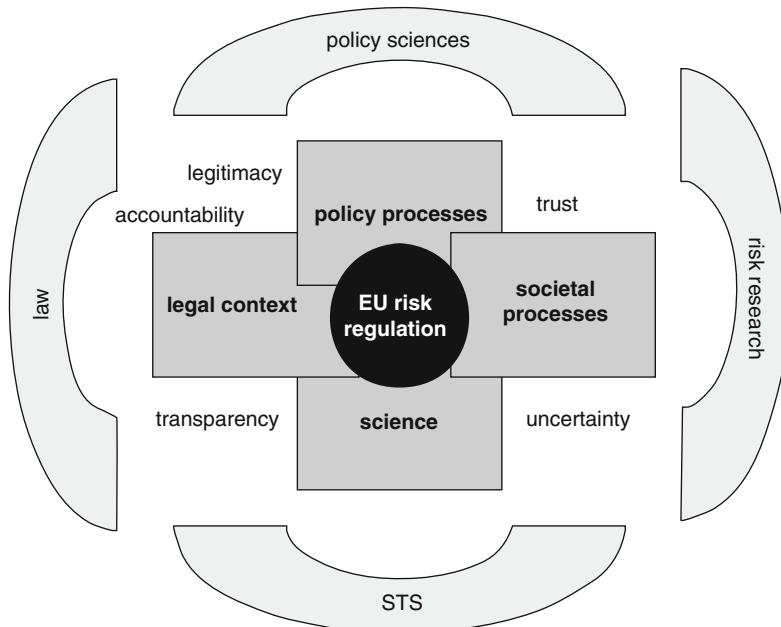

Fig. 45.1

An interdisciplinary research agenda for EU risk regulation

comparative research would enable to examine which problematic patterns seem to be widespread across domains, while differences in dealing with uncertainty might provide a basis for developing strategies to deal with uncertainty in responsible ways. We view four closely intertwined topics of particular importance: (1) the role of science and expertise in policy and decision-making; (2) the question of how to deal with uncertainty and trust; (3) the role of the precautionary principle; and (4) stakeholder participation.

Surely, a central topic will be the examining and rethinking of the role of science and expertise in policy- and decision-making pertaining to innovation, trade, and uncertain risks. In our current research, we have indicated that there is a need to rethink the current arrangements, provisions, expectations, and working styles. In the upcoming years, we hope that further case studies will provide insights into questions such as how and which legal requirements shape the role of science in the decision-making context and what features of science-based decision-making can or may enhance or decrease societal and political support.

As a second theme, we would like to point to the study of the issue of trust. We already highlighted that in situations of uncertainty, trust in the decision-making process is of particular importance. At the same time, due to major regulatory scandals, the current societal climate in which risk governance takes place has been qualified as post-trust (Löfstedt 2005). As far as we know, research examining the relationship between ways to deal with uncertainty and levels of trust is currently lacking. It seems therefore time to thematize the relation between uncertainty and trust.

A third theme on our research agenda is the study of the precautionary principle. Although much research has already been done in this area (see very recent Wiener et al. 2010; Zander 2010), more research seems necessary as regards the precise scope for precautionary action allowed by the trade rules of the WTO. In this context, we view further research and synthesis as necessary as to the role of the precautionary principle in case law and in societal debates. Such research is needed not just to evaluate what is adequate and responsible use of the principle but also to establish what is needed to endorse such best practices.

A fourth theme concerns stakeholder participation. Many writings on risk governance suggest the inclusion of stakeholders as an important step forward (Dreyer and Renn 2009; van Asselt and Renn 2011). However, whether and how stakeholder participation contributes to or rather obstructs decision-making that involves scientific uncertainty has not been investigated yet. It is for example known (van Asselt and Petersen 2003) that stakeholders may also stimulate a quest for certainty. It seems therefore necessary to critically examine how and in which contexts stakeholder participation could contribute to responsible governance of innovation in view of uncertain risks.

This agenda would in our view need to look into specific cases as well as comparative studies based on an interdisciplinary approach. These cases will lead to new empirical insights that will provide a further basis for an empirically informed theory development. On the other hand, also theoretically informed empirical research is needed to test claim pertaining to the uncertainty paradox, uncertainty intolerance, boundary work, and politicization of uncertainty. Although these notions in our view facilitate a more theoretical perspective on risk regulation, as any theoretical proposition they need to be tested. We argue that interdisciplinary research is indispensable to get a better understanding of the problems at stake and possible solutions. Lawyers, policy scientists, and risk scholars tend to put “science” in a black box and take knowledge claims as well as claims about independent expertise for granted, which is problematic in situations characterized by scientific uncertainty. The STS view is needed in order to appreciate what we emphasized above, the “less transparent, politically significant boundary work” (Jasanoff 2005). Social sciences help to question the often “utopic” view on the role of experts, putting them on a pedestal and considering scientific advice as simple facts, as the social science discipline teaches how science is made. Social sciences thus help the legal discipline in the thinking about the legal position of experts. It also helps to understand why certain cases of multiple complexity such as GM authorization may lead to complex regulatory processes but do not resolve the political dispute. The legal view is needed to understand the legal context that frames what actors can (and cannot) and should (and may not) do. The legal science helps for example to get a more realistic view on participation, as the legal discipline requires answers to questions such as who should participate, where and when, and thus plays a part in the thinking about process design and the shaping of participation. Policy sciences are needed in order to understand the policy processes in which regulators operate, which also frames the regulators’ room for maneuver. The risk perspective is needed to understand the kind of policy dossiers regulators deal with. Risk research provides insight into the specific requirements pertaining to risk dossiers, such as trust, participation of stakeholders (from innovators to protestors), and societal processes which may arise around risk (such as social amplification and attenuation of risk). While issues of accountability, legitimacy, democracy, and transparency addressed in legal and policy sciences refer to societal actors in the abstract, both in STS and risk research, the role of societal actors in real situations is explicitly considered. Interdisciplinary law–social sciences research has already yielded new insights

into risk regulation, both on an empirical and theoretical level. This type of research has therefore the potential to significantly contribute to risk theory. At the same time, this type of research also will raise new issues and new research questions that require further interdisciplinary research.

**Abstract:** Technocracy is an idea that has a long history. The idea of rule by experts goes back to ancient Greece, while the idea of rule by scientists or engineers is several centuries old. Formal mathematics, empirical studies, and natural scientific approaches are primary. A recent version of technocracy claims that the technicians do not literally rule but frame the choices of the leaders of industry and government. Technocracy can also be an attitude toward society or a tendency within individual institutions. Technocratic risk management is that version of risk management that emphasizes purely scientifically determined, objective measures of risk and ignores, downplays, or attempts to discredit public fears or estimates of risk that do not correspond to the scientific probabilities of death, disease, and injury. For a technocrat risk communication is either purely descriptive information or an attempt to undermine public fears or concerns with risk that differ from those of the specialists. Technocratic risk management contrasts with democratic or participatory risk evaluation. Despite the fact that no full technocracy exists, technocratic elements may be present in various forms of deliberative democracy and risk management involving public or citizen participation.

## Introduction

---

The term “technocracy” means rule by technocrats or technical experts. Technocracy is similar etymologically to “plutocracy” (rule by the wealthy) and “democracy” (rule by the common people or *demos*). Some people misidentify technocracy with importance of or rule by technical devices. Indeed artificial intelligence, in its more ambitious projected versions, would allow technocracy as rule by technical experts to transform into rule by computers.

The ideal of risk management in technocracy would be for experts in risk management to make objective, scientific risk analyses, and have the results of their analyses acted upon by government and citizens. Citizens would be ordered or persuaded to accept the results of the risk analysis experts and reject their own opinions and intuitions insofar as they disagreed with those of the experts.

Certainly contemporary industrial societies are far from manifesting the ideal form of risk management in a technocracy. The reports of risk management experts are not always unbiased, but sometimes or often influenced by political and economic interests. The opinions of the experts have been challenged by many organizations and publics in recent decades. Widespread distrust of scientific expertise has grown. Conflicting claims of expertise are sometimes made.

Nevertheless, the great number of government committees, commissions, and corporate departments that issue risk assessments and attempt to manage risks, the frequent appeal to risk analyses in public debate, and the number of policies that depend upon risk analyses and risk management show a strong but not all-powerful tendency in contemporary society. Further, even if the society does not always or often function as a full technocracy, the technocratic *attitude* is present in many evaluations and communications of risk. This attitude is one that the only relevant estimates of risk are objective, scientific ones, that the experts know best, that the public ought to trust the statements of experts and follow the directives of the experts.

## History

### Philosophical Concepts and Historical Bases of Technocratic Thought

Two aspects of risk management are relevant to technocracy: (1) The rationality involved in traditional risk analysis is the formal and instrumental rationality that is advocated by and characteristic of technocratic thought. (2) The role mathematical analysis and empirical surveys used by experts, which often is opposed to and contradicted by ordinary popular opinion and intuition concerning risks, where expert scientific opinion trumps popular beliefs is characteristic of technocracy.

Although the term technocracy was occasionally used in the 1890s with various meanings, it was not until the 1920s that the term became widely used and the notion became widely known. An engineer, William Henry Smyth, coined the word in close to its later sense in 1919 (Bell 1973, p. 349 n8). The rise of the Progressive Movement in the USA in the early twentieth century, with its demands for reform and for “social engineering” an engineering-like control of social institutions gave rise to stronger demands for a full technocracy around the time of World War I and the succeeding two decades.

Although significant used of the term technocracy is only a century old, the general notion of rule by experts goes back to ancient Greece and the notion of rule by specifically technological experts goes back four centuries.

Both Socrates and Plato in the fifth and fourth century BCE called for rule by experts. Socrates was highly critical of Athenian democracy, which chose many officers by lot. He argued that just as one would go to a medical expert for cures, to a skilled carpenter to have a house built, or a skilled navigator to pilot a ship, so one should go to an expert in political rule for guidance of the state. Plato in the *Republic* sketched out an ideal state that was ruled by philosopher kings trained in mathematics. Plato was influenced by the Pythagoreans both in his belief that mathematical knowledge was the exemplar of rational knowledge and that rulers should be trained in mathematics. The followers of Pythagoras claimed that the world is made of numbers and that numbers are the key to knowledge. The Pythagorean movement combined this philosophical claim with a religious and political movement whose adepts learned secrets of number theory (Von Fritz 1977). In the *Republic* (Plato [c 380 BCE] 1992) the rulers studied higher mathematics (including musical theory and astronomy) for 10 years before they became apprentice administrators. However, for the earlier Plato, mathematics only provided training in mathematics as abstract, logical reasoning as a preliminary for training in philosophy. In the *Republic* dialectic, or philosophical reasoning, is higher than mathematical knowledge. However, toward the end of his life, Plato in the *Philebus* (Plato [c 355 BCE] 1975) wrote of a “science of normative measure,” a kind of mathematical ethics, perhaps developed as an answer to the growing influence of the leading mathematician Eudoxus, who taught a kind of utilitarian ethics which was gaining supporters in Plato’s academy. Plato also began to discuss “ideal numbers,” which were higher and more abstract than ordinary numbers. According to a report of the music theorist Aristoxenus, Plato, toward the end of his life, announced a public “lecture on the good.” The audience who expected uplifting moral edification instead found the lecture focusing on higher mathematics and becoming more and more difficult. The majority of the audience left, in boredom and dismay (Aristoxenus and Pearson 1990; Findlay 1974; Gaiser 1980; Kramer 1990). Speucippus and Xenocrates, Plato’s immediate

successors as second and third heads of the Academy, moved toward identifying all abstract forms with numbers, whether ordinary numbers for Speucippus or ideal numbers for Xenocrates, for whom even the soul was a number. It was these views that Plato's greatest student, Aristotle identified with the Plato's Academy and rejected.

The two sides of Platonic doctrine of concern here, the identification of mathematics with a higher form of knowledge and the notion of rule by experts, were revived but were for the most part separately during the early modern period of the seventeenth century. On the one hand, the so-called rationalists, René Descartes, Gottfried Leibniz, and Baruch Spinoza developed the notion of mathematical reasoning as the highest form of reasoning and a model for philosophy. Descartes used his constructive analytic geometry, which he had discovered, as a key to and model for knowledge. Leibniz, who invented an early mathematical logic, identified God's knowledge and creation of the universe with a kind of logical reasoning, surveying all possible worlds, and based on the principles of noncontradiction and identity. Leibniz thought that he could develop a "universal characteristic," a mathematical logical language representing the essential concepts in all thought, and that could settle all disputes by simple logical deductions (Leibniz [1680] 1966). Leibniz claimed that in the future, if there was a dispute in any area, the opponents would say simply, "Come. Let us calculate." Leibniz also used the principle of continuity, based on the differential calculus that he also invented, as a model for the range of objects in the universe (Leibniz [1680] 2001). Spinoza, though not a supreme mathematical inventor as were Descartes and Leibniz, used the logic structure of Euclid's geometry, with theorem and proof, as his model for exposition in the *Ethics* (Spinoza [1677] 2000).

The other strand of early modern thought contributing to later technocracy is Francis Bacon.

Bacon in England in the earlier part of the seventeenth century contributed to the notion of technological and scientific rationality as the source of later British empiricism. He was the main proponent and propagator of the inductive method in science. Bacon was also a very early proponent of the role of scientific advisors in increasing the wealth and welfare of the nation. Bacon presented an ideal society, "The New Atlantis" in which inventors, engineers, and what would later be called scientists, advised the kingdom and increased the wealth, health, and welfare of the state through their studies of nature, chemical experiments, and development of machinery. Bacon's advisors in "Salomon's House" did not literally rule, but functioned as high-level advisors. In some cases they kept secret from the ruler some devices that they considered too dangerous (Bacon [1624] 1989).

Rather surprisingly, Bacon, in strongest contrast to the European rationalists, rejected the importance of mathematics (Quinton 1980; Jardine 1973; Dijksterhuis 1961). While both Descartes and Bacon ridiculed the traditional logic of Aristotle and the medieval schoolmen, Descartes replaced it with geometrical construction, and Bacon replaced it with empirical induction. Bacon's contempt for mathematics as useless formalism like the quibbles of the medieval professors, and the hypothetical nature of the Copernican system led him to reject the Copernican theory of the sun as center of the solar system as not empirical (Jardine 1973).

Later followers, such as Robert Boyle and Isaac Newton, combined the inductive, experimental method with mathematics.

Only in the nineteenth century did the two components of Plato's original notion of rule by experts become reunited. The French social thinkers and philosophers, Henri de Saint Simon and August Comte, hangers-on at the engineering school, the *École Polytechnique*, envisioned

a society ruled by experts in physics, engineering, and the social sciences in the modern sense. St. Simon, who coined the terms “physicist” and “industrialism” among many others, envisioned a “Council of Newton” composed of scientists, engineers, and other experts who would rule and plan society. After the reaction to Napoleon and the monarchist restoration, St. Simon included bankers in a place of honor among his experts (Saint-Simon 1952; Manuel 1962). Bankers, like physicists, dealt with numbers. St. Simon’s shifts concerning what professions would be represented in the ruling council foreshadow twentieth century disagreements within technocratic thought of the place of natural scientists versus social scientists as the ruling technocrats.

August Comte, unlike St. Simon, was actually enrolled at the *École* for several years, studying the leading mathematical physicists of the day, such as Carnot, Laplace, and Lagrange, but was expelled for his antimonarchist political views. Comte literally wished to replace religion with science and envisaged a hierarchical society similar to the Catholic Church, but with scientists as high priests, and perhaps himself as sort of positivist Pope. Comte coined the name sociology for what he considered the master science.

Comte was not only a major figure in the prehistory of technocracy, but the major figure in the origin of the doctrine of positivism. Comte entitled his major works with the name “positive,” positive philosophy and positive polity. Positive for Comte was natural scientific knowledge. Comte interpreted the natural sciences as purely predictive, not explanatory. He claimed that knowledge (and with it society) evolved through “three stages,” the theological, the metaphysical, and the positive. In the first stage, religious explanations of phenomena are given, gods, spirits, and demons, gradually evolving unity of God from fetishism (with spirits in everything) to polytheism, to monotheism. In the second stage, the metaphysical, explanations are given in terms of powers and essences. Finally, in the positive stage, laws of sequence are used to predict. A science that claims to explain the essence of things is still partially mired in the metaphysical stage. Comte’s view, less elaborately presented and without its historical sequence account is presented in much contemporary scientism. Science is seen as the highest form of knowledge.

For the early twentieth century logical positivists, empirical science is really the only form of knowledge. Ethics, religion, and metaphysics are all cognitively meaningless. The attitudes of Comtean positivism and logical positivism live on among those today that see science as the highest or the only form of genuine knowledge. Likewise those who disparage the claims of the humanities to offer some sort of valuable understanding of the world are heirs of the positivist tradition (Comte [1830] 1988). The logical positivists also emphasized the sharp separation between facts and values, taken over by technocratic theories, with facts objective and values subjective, noncognitive emotional expressions.

The logical positivists or Vienna Circle of the 1930s combined the positivistic thesis that science was the highest, indeed the only, form of genuine knowledge, with the mathematical logic that had been developed by Bertrand Russell a few decades earlier. They made the linguistic and logical foundations of the empiricist approach to science far more rigorous than had the earlier positivists, claiming that statements for which empirical verification was impossible were meaningless. The logical positivists dropped the Comte’s historical thesis concerning the evolution of knowledge and Comte’s detailed planning of a social utopia. Many of the logical positivists originally combined their scientific worldview with support of social democratic politics. However, upon fleeing Nazi Germany and Austria for the USA as immigrants, and residing in America as somewhat insecure foreigners during the McCarthy

anticommunist campaign, dropped any explicit social doctrines and retreated to “the icy slopes of logic” (Reisch 2005).

Technocratic tendencies in St. Simon were absorbed into Marxism and Soviet Communism by the fact that Karl Marx’s collaborator Friedrich Engels incorporated many phrases and much terminology of St. Simon in his expositions of Marxism. Engels’ presentations were much easier to read than those of Marx and had a great influence on the socialist and communist movements. Thus Lenin and Stalin focused on phrases in the writings of Engels which actually originated with St. Simon, for instance “society as one great factory,” “administration of things and not of men,” “artists as engineers of the soul” (Hayek 1955). Soviet Marxism had a strong technocratic trend, partly from earlier non-Marxist Russian utopians, but also from the St. Simonian strain in Marxism (Bailes 1978).

## Twentieth Century Western Technocracy

---

During the first three decades of the twentieth century engineers professionalized. Particularly in USA the engineering professions issued official statements concerning the importance of engineers for the progress and prosperity of society. By the 1920s the claims of these professional manifestos reached their height. Engineers were portrayed as the paradigm of objective and rational thinkers (Layton 1971, p. 63). Most working engineers shied away from the actual technocracy organizations and parties, but their vision of their role was quite similar to that of the militant technocratic campaigners.

The major figure in American technocracy was the economist Thorstein Veblen (brother of leading geometer, Oswald Veblen). Veblen contrasted the “predatory spirit” of businessmen with the “instinct for workmanship” of the engineers. He saw business practices as mainly wasteful and engineering as tending to quality products and efficient use of resources (Veblen [1921] 1983). Veblen at the height of the Russian Revolution even once proposed “a soviet of engineers” to rule society (Dowd 1964). Veblen’s ideas fit with the Progressive Movement’s emphasis on “social engineering” and efficiency. Veblen’s “institutional economics” influenced many in President Franklin D. Roosevelt’s “brains trust” was much as did the ideas of John Maynard Keynes. Stuart Chase, a follower of institutionalism and efficiency theory apparently coined the term “New Deal,” used to designate Roosevelt’s program.

In contrast with this indirect influence on the New Deal, the political organization that called itself Technocracy, Inc., after a brief spurt of popularity in the early Great Depression, collapsed in ridicule into a small fringe organization after the very poor public performance of its leader, a self-styled engineer who turned out to lack a degree (Elsner 1967). He turned out to be a charismatic “coffee house engineer” like the many self-proclaimed but untalented coffee-house poets. Technocracy as an organization survived into the new millennium, but only as a tiny, virtually unknown organization.

Despite the virtual disappearance of the openly political Technocracy organizations, technocracy as an idea or trend continued to influence thought during the later twentieth century in Europe and the USA. Gunnar Myrdal, the Swedish economist was a major proponent of technocratic planning (Myrdal 1960). Karl Mannheim, once he moved to Britain from Hungary, defended an important role for intellectuals in “democratic planning,” although Mannheim’s idea of the intellectual or social scientist was not that of the pure technician or pure empiricist.

The Manhattan Project during World War II in the USA, led by the physicist J. Robert Oppenheimer, led to a leading role for nuclear physicists as policy advisors due to the highly technical and secret nature of the relevant physics and engineering of nuclear weapons and missiles. After Oppenheimer's fall from political grace during the Cold War nuclear arms race, other leading physicists with more strongly anticommunist views such as Edward Teller, father of the H-bomb, and John von Neumann became major government advisors (Bird and Sherwin 2005; Goodchild 2004; Heims 1980; Herken 2002). The rise of game theory (also stemming from von Neumann) led to the rise of nuclear strategy experts, including figures such as Bernard Brody, Hermann Kahn, and Daniel Ellsberg (Kaplan 1983; Poundstone 1992). It was not really until the 1960s that the defense intellectuals and researchers at the RAND corporation were fully invited into the Defense Department by Robert S. McNamara of the "Whiz Kids," a name for his analysts that had previously been applied to the post-World War II Ford Motor Company executives, including McNamara.

During the 1960s and 1970s a number of writers in sociology such as Daniel Bell in the USA and Ralph Dahrendorf (1967) in Germany portrayed modern politics as a matter of what Karl Popper called "piecemeal social engineering." Bell proclaimed *The End of Ideology* (1960) in the title of one book, claiming that ideological fanaticism had been replaced by social scientific tinkering and pragmatism. Economists, apparently successful during the boom of the 1950s and 1960s with Keynesian methods to fine-tune the economy likewise proclaimed the replacement of traditional political ideologies with planning by experts. A group of social scientists, including Daniel Bell (1973) and Zbigniew Brzezinski (1970) propounded the importance of scientific and technical experts (including social scientists like themselves) in managing society.

The theory of technocracy was tied to the theory of postindustrial society. It was claimed that industrial society centered on manufacturing was steered by capitalists, but that postindustrial society with its emphasis on service industries, knowledge and information would be ruled by technocrats. Not all advocates of the postindustrial society thesis were technocrats, but most of the late twentieth-century social science technocrats were postindustrial theorists.

A more subtle form of technocracy was propounded by the institutional economist John Kenneth Galbraith (strongly influenced by the writings of Veblen). According to Galbraith, the stratum of technical experts, such as economists, accountants, engineers, and managers, which he called the "technostructure," do not literally rule society, as do the scientist-priests or engineer-planners in the utopias of St. Simon, Comte, and Veblen, but rather frame the choices and supply the information on the basis of which corporate CEOs, military generals, or politicians make their decisions. Thus, according to Galbraith's account, corporations and governments of industrial societies are guided by the technostructure although the decisions are officially made by the leaders, who in some cases are little more than figureheads or the public face of the organization. This sense of technocracy may be relevant to government risk analysts. In the financial industry, some hedge fund leaders are themselves financial risk analysts by training, while in other firms the risk analysts are advisors in the technostructure. Galbraith's claims about how the technocratic managerial firm has replaced traditional capitalism (Galbraith 1967), downgrading the importance of profits for long-run stability, have been criticized effectively both by economists and by the developments of subsequent decades. Insofar as Galbraith's noncapitalist managers, more concerned with technological rationality than with profits were replaced by initiators of capitalist buyouts and managers whose remuneration consists in stock options, the notion that the top managers are technocrats

and not concerned primarily with profits has been largely discredited. Nevertheless, at levels below the top managers, risk analysts and risk managers important are part of the techno-structure in Galbraith's sense and have gained increased importance in government agencies and private corporations since Galbraith presented his thesis.

## Twentieth Century Critics of Technocratic Rationality

---

The main forms of technocratic rationality stem from the legacy of on the one hand Plato and the seventeenth century rationalists, and on the other hand Bacon and the British empiricists. Both of these forms of rationality are used and valued in technocratic risk analysis. Highly formalistic mathematical models in risk analysis of technological projects and even more so in financial risk analysis are valued and pursued. Empirical evidence from surveys and physico-chemical and biomedical experimental analyses are also central to modern risk management.

A partial list of procedural goals of technocratic rationality includes analysis, planning and precise calculation, as well as impersonal, standardized, and precise criteria (Gendron 1977, p. 58).

The formal mathematics and logic valued by the rationalists, Descartes, Leibniz, and Spinoza discussed above is combined with emphasis on observation and empirical evidence emphasized by the British empiricist followers of Bacon such as John Locke and John Stuart Mill. Risk benefit analysis itself mirrors the structure of the utilitarian ethics of Jeremy Bentham. Utilitarianism is a form of consequentialism. Only consequences, not motivations, intentions, or principles, count for evaluating actions and policies, in contrast to Christian ethics of intentions or Kant's ethics of principles. Risk calculations are made of the positive and negative consequences of project for all parties affected. While Bentham calculated results in terms of pleasure and pain, risk benefit analysis generally calculates results in terms of money. The early mathematical micro-economics of Francis Y. Edgeworth and Stanley Jevons is based on utilitarian ethics of satisfaction. Even today a few economics texts start with measure in terms of "utils" (units of satisfaction or utility in Bentham's sense) before transferring to monetary measures. Thus there is a natural, historical link between microeconomics and utilitarian ethics and of both with risk benefit analysis. With few exceptions (and these very tentative ones such as that of Cranor), consequentialist ethics, or ethics that evaluates acts or policies in terms of causal consequences, is implicitly embraced by risk analysts. Indeed risk analysts explicitly speak of analysis of consequences (Rechard 1999). A number of the traditional problems for risk benefit analysis, such as those of justice, and human dignity or worth mirror or parallel problems for Bentham's utilitarianism. Competing theories of ethics, such as Christian ethics, Kantian ethics, or various ethics that emphasize intentions, as well as intuitionist ethics, that rejects the possibility of formal calculations in ethics, or even of formal rules for ethics, are generally ignored by risk analysts while working within their specialty. The few recent attempts to develop non-consequentialist risk analysis are sketchy and preliminary (Cranor 2007).

## The German Romantic Idealist Reaction Against Technical Rationality

---

Within German philosophy from the late eighteenth century Romantic Movement to the present there have been several tendencies of thought that reject the technocratic model of reason such as formalistic rationalism and British empiricism. This model would include

the methods of quantitative risk analysis. The appeal purely to empirical data concerning risk and purely mathematical analyses and calculations concerning risk are seen as involving an inadequate model of reason. The alternative, more informal and philosophical, notion of reason is an outgrowth of the reflections in the late eighteenth and early nineteenth century on dialectics as a form of reason higher than calculation or technical reasoning. In the twentieth century, particularly through so-called Critical Theory, these conceptions have influenced philosophy in the rest of the world. Immanuel Kant ([1781] 1996), despite his valuing the certainty and universality of mathematics and the fundamental principles of theoretical physics, also dealt with those areas wherein human reason runs, or attempts to run, beyond the bounds of reasoning dealing with common sense objects or with the objects of science. Kant called this sort of reason about everyday and scientific objects “understanding” (a term that acquired a very different meaning in the social science of the late nineteenth century). Kant described understanding as dealing with objects as delimited, bounded entities in space and time. Kant’s “Aesthetic” (dealing with sensory experience) dealt with the most fundamental forms of sensory perception, space and time, while his “Analytic” dealt with the fundamental categories that govern thought both commonsensical and science about objects. However, Kant, in his “dialectic” dealt with the tendency of reason to attempt to go beyond the bounds of sense in metaphysics and to deal with purported entities which were not objects in the being delimited, finite, and bounded or in space and time. The prime examples of these non-objects or pseudo-substances which reason wished to treat as objects are the universe as a whole, the soul, and God. In treatment of the universe as a whole, understanding attempts to extrapolate from its reasoning about finite spatiotemporal objects to the infinite. This leads to antinomies in which it possible to disprove claims both that the universe is finite and that it infinite in space and similarly to disprove both that the universe is eternal and that it has an origin in time. (These antinomies resemble and may have influenced the early understanding of the antinomies or paradoxes of mathematical naïve set theory.) In the case of the soul, understanding runs beyond its bounds in attempting to treat an unobservable, non-spatiotemporal object as a sort of physical object and runs into logical fallacies or paralogisms. In the case of God, understanding attempts to deal with something both infinite in numerous attributes (omniscient and omnipotent) and non-spatiotemporal, leading to fallacious proofs of the existence of God. If one takes the “low” view of Kant’s reason, it simply understands run amuck, spinning its wheels, venturing beyond its allotted capabilities. For Kant mere “thinking” is the use of the forms of understanding without any empirical or sensory input.

Kant himself had attempted to limit the claims to unlimited metaphysical knowledge by the rationalists; however, his successors, claiming to follow Kant, nevertheless reinstated the claim that total knowledge is possible. Philosophers after Kant, such as Friedrich Schelling and Georg W. Hegel, took a “high” view of Kant’s Reason. Kant had also considered reason the faculty of the critique of knowledge itself as well as the setter of ultimate goals for the unification of knowledge. Schelling turned Kant’s reason into a sort of aesthetic faculty of intuition, possessed in the highest form by geniuses, reversing Kant’s claims as to the centrality of discursive, sequential thought and his claims about the modest powers of the understanding. Hegel took Kant’s dialectic, which had been a kind of logic of illusion, and made it into a positive means of gaining knowledge of the infinite. Hegel claimed that for reason to know its supposed limits it had in some sense to pass beyond them. For Hegel, like the earlier rationalists, the infinite is in a sense prior to the finite. Hegel then claimed that dialectical reason could grasp the universe and its development in totality. Furthermore, since for Hegel reality is “spirit” the dialectic is

not just a means of reasoning but the dynamic and structure of reality itself. Marx took over this notion of the dialectic but denied that reality is spirit, claiming it is concrete natural reality. These notions of dialectical reason were used by the Frankfurt School to contrast with technocratic reason and to offer an alternative to purely calculative or purely means-end reasoning.

One of the major schools criticizing technocracy and the empirical/formal rational notion of reason in the twentieth century was the Frankfurt School of Critical Theory. Max Horkheimer (1972), Theodor Adorno (Horkheimer et al. [1948] 2002), and Herbert Marcuse (1964) took over Hegel's notion of Reason and Hegelian version of the Marxist dialectic to criticize technocratic reason. Horkheimer and Marcuse reviewed numerous works of logical positivism in an almost wholly negative manner, seeing positivism as reflecting the rise of technocratic reason and the decline of critical reason. They contrasted Hegelian, critical reason, with "instrumental reason," the means/end reason of technology and social tactics. The sociologist Max Weber et al. ([1914] 1968) had claimed that instrumental action involving means and ends cannot determine ultimate ends. For Weber the ultimate ends cannot be rationally justified. They are the outcome of an irrational, existential decision. Weber claimed that the main trend of modern, western societies was rationalization of all fields of activity (Weber [1904] 2001) (Weber et al. [1914] 1968). Bureaucracy, with its strict roles and chains of command, was a crucial form of this rationalization of society. Nevertheless the ultimate goals were based on irrational choices, and social solidarity was maintained by irrational charisma. There has been only limited application of Weberian rationalization theory to environmental issues (Murphy 1994).

Horkheimer and Marcuse claim, in contrast, that there can be reasoning about ultimate values. The claim of sociologist Max Weber and the existentialist philosophers that values cannot be rationally justified, but must be the result of a nonrational decision or leap, as well as the claim of the logical positivists that value statements are "cognitively meaningless" are both contributors to the "eclipse of reason." Critical theorists see these trends as contributing to what Adorno calls "the administered world," a world totally controlled by technocratic planners, in which popular opposition or critical objections by intellectuals are suppressed or co-opted. Although the first generation critical theorists did not discuss and apparently were not aware of risk analysis, they would have seen technocratic risk analysis as a prime example of this technocratic administration, in which the decisions by technical experts overrule popular opinion and humanistic claims. The elimination of questions of ends and values from rational discussion allows the implicit values of those in control to go unchallenged.

Marcuse goes so far as to claim that formal and instrumental rationality should be replaced with dialectical rationality. He hints at the replacement of present science and technology by a new "liberated" version, perhaps influenced by Marx's phrase "the liberation of nature" and Ernst Bloch's utopian and occultist development of the conception. These hints are not followed up, and most likely could not be by Marcuse. Indeed, in his later writings, Marcuse sees natural science used in a free and cooperative society as liberating, and not in need of such a total transformation.

Jürgen Habermas of the "second generation" of critical theory in a lengthy article on Marcuse entitled "Technology and Science as Ideology" (Habermas 1970) qualifies Marcuse's earlier identification of science and technology as such as oppressive and as means of social control. Habermas claims that the problem is not, as it was for Horkheimer and the Marcuse of *One Dimensional Man* (1964) instrumental reason, or physical science and technology as such

but rather the application of such means-end reasoning and orientation toward control to the social and human sciences. For Habermas, scientism is the misapplication of natural science and technological methods to the human sciences (Habermas 1973).

Habermas, who is highly eclectic, incorporates the distinction between the natural and human sciences that was developed in late nineteenth century German historical and social thought. This tradition was in strong opposition to positivism, both in its earlier, Comtean, version, and in its later logical positivist version. Habermas's lines of criticism of positivism and the misuse of or overreaching by science often called scientism and his linking these tendencies to technocratic rule via the authority of mathematics and physical science clearly apply to quantitative risk analysis as a means to technocratic authority.

Late nineteenth century neo-Kantians of the Southwest German School distinguished between the natural science and human sciences. Wilhelm Windelband distinguished nomothetic (lawful) sciences from idiographic (individual) sciences. According to Windelband, history and cultural sciences focus on unique individuals (are idiographic), while the natural sciences focus on laws (are nomothetic). Heinrich Rickert added to this the claim that natural sciences are value-free while the human sciences incorporate values and are value-oriented (Rickert [1896–1902] 1986, [1899] 1962). Much of the late twentieth century psychological studies of risk tend to treat humans as rational decision makers whose choices follow a formal calculus, and treat human behavior along the lines of the physical sciences. Also many technocratic risk analysts, such as the early Starr and Whipple (Starr and Whipple 1980), profess their own total value-neutrality.

Another distinction made by Wilhelm Dilthey is between natural sciences that deal with causes and the human sciences that deal with meanings (Dilthey et al. [1883] 1989). According to Dilthey the human sciences use “understanding” as opposed to causal explanation. “Understanding” (*Verstehen*, in a very different sense from Kant’s use) involves rethinking or reliving the experience of others, a kind of empathetic participation (although the roles of intellectual rethinking and empathetic refeeling were debated in later discussions of *verstehen*). The sociologist Max Weber attempted to combine *verstehen* in understanding the values and goals of actors and cultures with a causal analysis of social and historical events, nevertheless keeping the two methods separate.

Habermas, in his contrasting the (appropriate) instrumental reason of causal analysis in the natural science with the, for him, inappropriate uses of it in political understanding, contrasts Wilhelm Dilthey’s hermeneutics or interpretation of meaning with the instrumental, natural science approaches of positivism and pragmatism. Hermeneutics was originally the interpretation of biblical texts. Friedrich Schleiermacher in the early nineteenth century generalized it to the interpretation of literary texts in general, and Wilhelm Dilthey at the end of the nineteenth century generalized it to interpretation of human history and culture in general. Hans-Georg Gadamer developed Dilthey’s hermeneutics using concepts from the phenomenologist Martin Heidegger, purging the psychological orientation of Dilthey’s earlier attempts. In contrast to the logical positivists, who advocated the development of a unified science structured deductively and sharing the methods of the physical sciences, the hermeneutic approach claims not only the different hermeneutic method for the human sciences but the philosophical priority of the hermeneutic approach to that of causal or natural scientific analyses. Clearly the contrast between instrumental reason and hermeneutics parallels the contrast between strictly quantitative and utilitarian risk benefit analysis and qualitative and cultural accounts of risks.

Habermas claims that technocracy and scientism in their illicit application of engineering control and instrumental reason to society are ideologies of bureaucratic and administrative society. In his subsequent writings, Habermas contrasts the social system (which can be analyzed by systems theory) with the *lifeworld* which is understood through personal experience. For Habermas creeping technocracy is manifested in the invasion or colonization of the lifeworld by the system, that is, personal experience in face-to-face contacts of humans is superseded by scientific or pseudoscientific accounts based on the approach of the physical sciences. This process includes political and administrative as well as epistemological aspects. Bureaucratic and government regulation of many aspects of personal life through social welfare, educational, and other bureaucracies manage aspects of personal, subjective life. Cass Sunstein's *Nudge* (Thaler and Sunstein 2008) advocating subtle governmental framing of decisions and directing of lifestyle habits and beliefs is a more recent and subtler program for this. Within Sunstein's "libertarian paternalism" agents make choices, but the choices have been framed in such a way that the framers (nudgers) get the choices they want made. The critical theorists would have had a field day with this form of apparent freedom that is guided or manipulated.

Certainly the replacement of the lay public's estimates of risk with the results of quantitative, scientific, empirical estimates of risk by risk managers, and the use of risk communication to shape public attitudes and behavior would be a more recent aspect of this "invasion of the lifeworld by the system" that Habermas decries, whether rightly or wrongly. Habermas discusses the systems theory of the 1960s but does not discuss risk analysis and management as such. The conflict between public perceptions of risk and the scientific estimations of risk fits nicely into the critical theorists' contrast of popular democracy with technological and bureaucratic administration and with Habermas' contrast of system of lifeworld.

Habermas's critique of technocracy and technocratic reason thus grows out of the conceptions of a dialectical reason that supposedly reaches beyond the range and competency of purely technocratic reasoning, with its emphasis on formalism and detached and neutral science.

## Current Research

---

### Two Contemporary Students of Critical Theory: Giving More Credit to Technocratic Reason

---

Two more recent writers on risk trained in critical theory and making intellectual appeals to its texts diverged in various ways from the founders. William Leiss, who began studying under Marcuse and whose first book, *The Domination of Nature* (Leiss 1972) was a survey of theories of technological domination of nature based on critical theory, went on to be heavily involved in the study of risk management in Canada. Leiss even in his early work was critical of Marcuse's utopian hopes for an "emancipatory science," supporting Marcuse's later views that ordinary science deployed by a democratic and cooperative society would help human emancipation. Leiss supports the objectivity of science (Leiss 2001). His studies of the BSE (Bovine Spongiform Encephalopathy) or "mad cow" problem in Britain and Canada with its devastating effects on the cattle industry make him a severe critic of the failed risk management and risk communication, involving initial silence or denial by the British and Canadian governments and the failure to effectively communicate risks until too late (Leiss 2004). Leiss is far more sympathetic to scientific risk analysis than one presumes the early critical

theorists would have been, though he puts far more emphasis on the democratic aspect of risk communication than the technocratic risk managers would. In a number of respects Leiss is more accepting and favorable toward scientific risk analysis than the first-generation critical theorists would have been. Indeed he mentions that Habermas seemed early to suggest that there was more to the critique of scientific rationality than that of scientism and technocracy, but gave up on that theme (Leiss and Chociolko 1994). However, Leiss focuses on the issues of communication and controversy, not on a technocratic pronouncement on scientifically measured risks.

Another figure influenced by critical theory is the sociologist Ulrich Beck. His *Risk Society* (Beck 1992) is an academic best seller in Germany. His own sociological theory of “reflexive modernization” has been contrasted with Habermas’ theory of early modernization and the rise of the public sphere. Beck refers to and used the work of Adorno and Horkheimer. His works are written in an engaging and fluent style, made apt citations of literary works, and claim to present an alternative to other postmodern theories. Striking aphorisms and *obiter dicta* abound. The problem is with the logical coherence of the striking and often insightful theses. Beck’s claim that we are living in a “risk society” early captured the trend toward greater and greater importance for risk analysis in contemporary society and politics. However, he generalizes this notion to the extent of claiming that the distribution of bads (risks) has replaced the distribution of goods of classical capitalism, and that class distinctions are no longer relevant to risk. In this last respect his theory resembles other, competing theories of postmodernism. Classical, competitive capitalism has been replaced by something else. For other postmodernists it is postindustrial society, in the earlier postindustrial theorists of the 1970s with a technocracy, while for the postmodern social theorists of the 1980s and 1990s, especially after the collapse of the USSR with universal neoliberal capitalism. Beck offers the alternative of the risk society. One of his claims is that in past societies risks were in the form of natural disasters, plagues, and wars, but that in modern society the risks are primarily produced by technology itself. This may have appeared true in the period of Chernobyl, Bhopal, and the Challenger disaster, but the first decade of the new millennium, with Indonesian Tsunami, Chinese earthquakes, Icelandic volcano soot, and New Orleans US Katrina hurricane show that natural disasters still have an important place, though often, as in the case of Katrina, or of poorly constructed Chinese school buildings, social and political factors exacerbated the natural disaster.

Beck certainly is among the critics of technocracy and partisans of more democratic treatment of risks. However, his account of science is ambiguous. He does point out correctly several features of the changing role of science. One is that countermovements, particularly in ecology, have their own scientists, such as Rachel Carson and Barry Commoner (Carson 1962). Another is that the hegemony and authority of science is being contested, in part by critiques using science itself. Beck’s description of the society of conflicting experts sponsored by opposing interest groups and institutions as a kind of pluralistic technocracy. Just as classical theories of representative democracy and authoritarian rule were replaced by the theory of pluralism of competing groups, so centralized technocracy in Beck is replaced by a competition and circulation of technocrats, similar to the circulation of elites in Wilfredo Pareto and Gaetano Mosca’s theories of rule by elites or by a “political class” in which social transformations are merely replacements of one elite by another.

Beck states that science has lost its role as a servant of truth. However, he does not spell this out. Some of his theses seem similar to those of the social epistemologist Steve Fuller, in his

book *Science*, that science has become so tied to government and corporate institutions that it resembles more the science of medieval China than it does the independent and largely amateur science of the Europe of centuries past (Fuller 1997). However, Beck does not explicate what the status of science is. It could be purely instrumental, predictive, and manipulative, as the critical theorists (as well as Moritz Schlick the leader of the logical positivist Vienna Circle) claimed it to be. Some of his examples point to the ability of ordinary citizens with their “local knowledge” to outdo technical experts in the discovery of risks. However, he often points out how the countermovements have their own experts and need to put their claims in scientific risk management form in order to gain a hearing from the government agencies. However, his emphasis on the central role of science in society seems not to call for an elimination of technical risk analysis. Beck perceptively captures and incorporates many trends of contemporary society but does not seem to have well-worked proposals for how to handle them (though, neither do most other social theorists).

### Technocratic Science Versus “Mythic and Magical Thinking”

---

Another contrast of scientific and technological rationality is that with so-called “primitive” or “magical” thinking (Malinowski 1954, Wilson 1970). This contrast is sometimes used by defenders of quantitative, scientific risk analysis against popular attitudes toward and evaluations of risk. Popular thought is sometimes castigated as primitive and magical in contrast with the advanced, scientific results of risk analysis. A sophisticated development of this claim and contrast by is the work of Mary Douglas, someone who has achieved great eminence in the study of taboos in indigenous societies, in collaboration of political theorist Aaron Wildavsky, *Risk and Culture: An Essay on the Selection of Technical and Environmental Dangers*. In their cultural theory of risk, Douglas and Wildavsky make the analogy between popular fears of the risks of environmental dangers such as nuclear power, chemical additives, air pollution, electromagnetic radiation, and so forth with noncivilized people’s notion of taboo, uncleanness, and danger. According to Douglas and Wildavsky there is an objective issue of the reality of risks. They claim that environmentalists are not responding to real risks in the environment, but are resisting and resenting authority. They compare environmentalists’ concerns for purity of water and air to indigenous societies’ beliefs about purity and dirt (Douglas and Wildavsky 1982). Douglas had earlier written a highly influential anthropological work, *Purity and Danger: An Analysis of Concepts of Pollution and Taboo*, discussing these doctrines in indigenous African and other cultures that she had studied. While use of the terms “primitive,” “tribal,” and “magical thinking” are often bandied about by opponents of popular environmental fears or critics of drugs or procedures in mainstream medicine, Douglas, as an anthropologist, wishes to claim that magical and mythical thought are part of so-called modern or advanced cultures as well as indigenous ones. However, Douglas in her joint work with Wildavsky disdains and castigates environmentalists clearly as marginal, sectarian, and “primitive,” while treats the judgments of technocrats of the core institutions of government and corporations as rational, not prone to mythical thought. This totally contradicts the perspective of Douglas’ other works, but supports the technocratic understanding of risk management (Douglas 1985).

One problem with contrasting the (correct) scientific-bureaucratic estimates of risk with the (magical or irrational) popular conceptions of risk accounted for by cultural theory is the

issue of the entry of magical thinking into scientific and technological thought as it is actually pursued by real people in institutions as opposed to the ideal forms of scientific and technological thought. Douglas herself admits that residents of modern societies engage in mythic or taboo thought. Can this apply to scientists and risk analysts themselves? This problem is similar to that of the sharp contrast between value-free risk analysis and the value-laden popular conceptions of risk. Just as scientific investigations can incorporate values in several senses, values within scientific method, values involved in worldviews that support scientific paradigms, and values involved in the interests of social institutions or professions, (Mayo and Hollander 1991) so apparently rational and objective scientific thought, and even more so the reception of its authority by the public, including intellectuals not specialists in the relevant science, can manifest aspects of magical thinking. We have seen in the prehistory of technocracy section how the father of positivism, Comte, simply transposed the hierarchy of the Catholic Church with a hierarchy in which the priestly role was taken by scientists.

The authority of scientists, although in recent decades under attack, can have aspects of the reverence for magicians. This was true of nuclear scientists in the early days of the Cold War (Kowarski 1971). Similarly it was true of medical spokespeople. However, this reverence for nuclear physicists and medical doctors in the 1950s has been undermined by the end of the Cold War and various patients' rights movements.

## Technocracy Versus the Magical and Occult Attitude

---

The technocratic trend in risk management contrasts the objectivity, universality, and publicity of science with the secrecy and particularity of prescientific, magical, and mythic thought, often attributing the latter to opponents of technocratic approaches.

The ideal of science is one of universalism, openness to criticism, sharing of data, organized skepticism, and disinterestedness. Karl Popper (Popper 1945, 1962) in philosophy and Robert King Merton (Merton 1947, 1973) in sociology presented these as, respectively, ideal and acting norms of science.

Science with its openness and publicity was traditionally contrasted with the secrecy of magic and alchemy. The very name "occultism" embodies this contrast. However, with the growth of secrets of military research and secrets of corporate research and development this stark contrast of previous centuries between scientific openness and occultist secrecy has been undermined (Kaplan 1983). Writers such as Lewis Mumford (Mumford 1967) have compared the military scientists with the priests of the ancient empires. Alvin Weinberg, head of Oak Ridge Laboratories, is credited with the term "nuclear priesthood" for the engineer custodians of long-lived nuclear waste (Weinberg 1972, Lapp 1965). Similarly a work on the US Federal Reserve and its monetary fine-tuning was entitled "Secrets of the Temple" (Greider 1987).

Risk benefit analyses of technological projects usually make their results, if not their evidence and methods, fully public. This hardly fits with the image of scientist as occult figure. However, quantitative financial risk analysts, so-called quants, did at the opening of the twenty-first century have a kind of prestige partially based on mystery.

The mathematics involved in hedge fund risk analysis (for instance, Wiener processes from Brownian motion, Feynman path integrals from quantum mechanics, and the Ito calculus and its even more complex progeny) is of a sort accessible only to those with graduate educations in math and physics, which most of the quants possess (Lindsay and Shachter 2007; S Patterson

2010). There was a mystique and prestige of advanced mathematics in convincing ordinary investors as well as less mathematically adept bank officials that this sophisticated mathematical apparatus gave assurance of safety. Further, the computer programs used by financial risk analysis “quants,” including high speed trading programs, impressed investors; some were very sophisticated ones with technological complexity and power (Leinweber 2009). In addition, the actual details of the risk formulae and computer programs of most hedge funds are carefully guarded trade secrets, protected by all sorts of computer safeguards from hackers and industrial spies in less competing hedge funds. Of course, events such as the credit crunch in the mortgage securities market of 2007–2008 and the surprising and unexplained “flash crash” of computerized trading in the spring of 2010 demonstrated to many that the claims of mathematical and technological trustworthiness of the formulae and programs were mostly overrated. The complex formulae had assumptions, and a number of the assumptions used were false. The historical memory of the young, ex-physicist quants did not go back to the crash of 1987 let alone to that of 1929. Most of the quants, trained in mathematics, computer programming, the physical sciences, and many of those trained in highly formal economic theory lacked any sense of history, society, or institutions (Skidelsky 2009). Measurements such as value-at-risk (VAR or VaR) turned out to be inaccurate, based on insufficient data from the recent past, and assuming uncertainty can always be probabilistically estimated using mathematical models (Taleb 2010, p. 225n, 2004, p. 289n). Assumptions that different kinds of assets have independent and uncorrelated probabilities turned out to be wrong. In crises many assets’ values showed themselves to be highly interdependent and correlated (Cassidy 2010, pp. 274–278; Triana 2009). The faith of not only naïve individual retirement fund investors but apparently sophisticated European bank officials was based on the mathematical and technological incomprehensibility of the hedge funds’ risk analysis and management apparatus, a kind of occultist faith in complex, arcane, mathematics. Perhaps the greatest harm that the defunding of the Texas Superconducting Supercollider did was not the loss of technological spin-offs, but the driving of unemployed particle physicists into the financial markets, where their impressive but misapplied mathematics mislead even sophisticated institutional investors.

### The “Science Wars” and Technocratic Risk Management

---

The so-called Science Wars in the 1990s (Lingua Franca 2001) were triggered by natural scientists feeling that science no longer had the prestige and respect that it had during the previous few decades. The cancelation of funding for the superconducting supercollider in Texas was symbolic for physicists. Paul Gross and Norman Levitt both defend a somewhat unarticulated positivism, clear mainly in its rejection of social constructivism and theories of the objects of science as subjective. In some respects, the science warriors’ defense of science veers into a defense of scientism and in its denunciation of any who question the pronouncements of technical experts, a kind of technocracy. Gross and Levitt blame the antinuclear movement, the ecology movement, the women’s movement, and Afrocentrism were blamed in part for undermining of faith in science. Paul Gross, author of the chapter on ecology movements in *Higher Superstition*, emphasizes the debunking of claimed environmental risks by citing the example of Alar (Gross and Levitt 1994, p. 163) and being rather skeptical of global warming (p. 158). Sociological studies of the politics of science and literary studies of the rhetoric of scientific papers were seen as undermining the majesty and mystique of science.

The mathematician Norman Levitt, one of the leading and most aggressive polemicists in the science wars castigated Sheila Jasanoff (Jasanoff 1986, 2005) for criticizing establishment risk benefit analyses and supporting popular input into risk management. He notes she supported what he claims is a quack medical movement, clinical ecology, and, according to his own account of unrecorded remarks, creation science in the classroom (Levitt 1999, pp. 222–229). Despite these feelings by certain natural scientists that they were getting no respect, aspects of the scientific mystique remained strong in areas such as genetic explanations of human cultural behavior in sociobiology and evolutionary psychology, widely propagated in the popular media, interest in personal genetic screening, and popular fascination with theoretical physicists' and cosmologists' explanations of the origin of the universe.

## Psychology of Risk and Technocracy

---

The early or classic works on risk analysis were developed by people with an engineering or scientific training. They were mainly developed in reaction to what were seen as excessive, irrational fears of nuclear reactors and nuclear power on the part of the public (Shrader-Frechette 1985a, b). The Electric Power Research Institute sponsored research and education in this area in the USA. Another major motivation for early developments in scientific risk management was what was perceived as irrational fear of pesticides and lab-made chemicals in food. Bruce Ames famously compared the risk of a number of foods and environmental influences (Ames et al. 1987). A famous case not involving nuclear power often appealed to was that of alar-tainted apples in contrast with numerous other foods. This became (though some still dispute the account) a code word for excessive caution concerning tiny risks and costly but unnecessary regulation (Glickman and Gough 1990).

The work of Daniel Kahneman and Amos Tversky (Kahneman et al. 1982; Kahneman and Tversky 1973) concerning the erroneous probability judgments humans make has been used by those with a technocratic bent to disparage popular concerns about risks. Kahneman and Tversky's striking experiments show that humans estimate strongly different probabilities of events, depending how the problem is phrased, in terms of gain versus loss. Human intuitive judgments ignore the conjunction rule in probability and are biased by the base point from which they make estimates. An extreme conclusion from Kahneman and Tversky's work is that of the linguist Noam Chomsky, that although humans have innate and high-functioning linguistic and arithmetic modules, humans lack a probability module (and, according to Chomsky, in some of his speculations, also lack an ethical module).

Even mild or partial technocrats such as Cass Sunstein and Mary Douglas appeal to these results to claim that popular movements concerning nuclear power, food additives and pesticides, and so forth are mistaken and irrational.

It was thought by the early, engineering trained risk management experts that simply informing the public of the correct, scientifically ascertained probabilities would dispel widespread apprehension concerning nuclear plants and pesticides. This proved, of course, to be false. The next tack taken by more technocratically inclined risk managers was to attempt to reassure the public by discussion and to understand the factors other than actual probability of death, illness, or injury that determined the public's fears and estimates of risk. Paul Slovic (Slovic et al. 1981; Slovic 2000) has been a leading figure in estimating these other factors in the public perception of risk.

Involuntary, catastrophic, unknown, novel, long-term, and low-benefit risks were estimated as less risky than voluntarily undertaken, noncatastrophic, well-known, familiar, and high-benefit risks. The more technocratic approach to the psychology of risk then took these other factors into account in terms of dealing with the public, but saw them as mistaken and distorting of the real risks in terms of mortality, morbidity, or injury. The least technocratic risk management policies took these factors into account in evaluating actual designated risks. However, incorporating the psychology of risk (as well as social theories of popular risk estimation) can be used simply as more scientific data concerning objective human behavior to be combined with the natural scientific data concerning physical and biological sources of risk. This social scientific data can then be used to steer the public in the desired direction, either by government directives, commands, and punishments at the authoritarian extreme, or by economic incentives and other “libertarian paternalist” “nudges” lacking explicit coercion, framing of the decision situation by “choice architecture” at the other, less explicitly coercive, extreme.

Gerd Gigerenzer (Gigerenzer 2000) has written extensive criticisms of Kahneman and Tversky’s approach, claiming that humans have “quick and dirty” or rather “fast and frugal” “simple heuristics that make us smart” for rapid decisions that function quite well in real life. He has criticized the omniscient model of an individual with unlimited search time and memory. He claims that his account of human judgment is “rationality for mortals” (Gigerenzer 2008). Although Gigerenzer has written extensively about medical diagnosis and counseling, he has not directly tackled technological or economic risk analyses. Since Gigerenzer’s and colleagues’ work cannot any longer be simply ignored, technocratic risk managers can reply by granting Gigerenzer that our simple decision procedures may have evolved for survival, and that they often function effectively where everyday snap decisions are demanded, but that humans are prone to major errors and fallacies when using these approaches. Kahneman and Tversky among others make a distinction between System I reasoning involving these intuitive “gut” decisions and System II reasoning involving logical deduction and explicit discursive reasoning. Thus some credit is given to our evolved intuitive procedures, but they are discounted as useful in scientific risk estimation. It is claimed that we ought to switch to System II reasoning in dealing with societal risks.

Gigerenzer points out that Kahneman’s own studies show that even professional statisticians who are not prone to the fallacies in textbook, formal probability problems, commit some of the same fallacies as statically untutored when dealing with concrete, real-life problems (Kahneman et al. 1982, pp. 23–31, 46–47). In the same vein, Gigerenzer found that physicians are often almost as bad as patients at interpreting statistical data concerning risks of side effects of medicines or medicines or medical procedures (Gigerenzer 2007). This fact can be used to support anti-technocratic doubts about the infallibility of experts. However, no one, to this author’s knowledge, has advocated using Gigerenzer’s “gut feelings” to deal with technological risk management.

On the other hand, it should be noted that physicians, working engineers on dangerous projects, and financial analysts estimating risks of investments often do appeal to “gut feelings” in making their final decisions, even when scientific and mathematically structured inputs are available. Richard Feynman once claimed that one does not really have full grasp of an equation in physics until one can make intuitive estimates of solutions without doing calculations. There is, of course, a century-old body of writings on the role of intuition and “gut feelings” in judgment in physics and chemistry (Duhem [1914] 1954; Polanyi 1958). This would suggest that even in mathematical, technical-scientific risk analysis System I reasoning has a role.

The intuitive reasoning of mathematicians does not show that the intuitive judgments of risk by the public are trustworthy or accurate. However, it does show that professional risk analysts may use intuitive, unconscious processes in finding solutions to equations and in making judgments concerning what assumptions to accept or what alternatives to include in their analyses.

### Citizen Investigations of Risk and “Local Knowledge”

---

In science and technology studies of traditional non-Western or indigenous science the “local knowledge” of geography, botany, weather, navigation of hunter-gatherers or non-literature peoples in general is contrasted with the “universal” knowledge of natural science that originated in the West. Western science or mainstream modern science is claimed to be universal in several senses, it uses universal laws, unrestricted in space and time for explanation. It is universal in applying to and being pursuable by peoples of all cultures. Science studies people and anthropologists sympathetic to ethno-science or indigenous knowledge have turned this contrast on its head by claiming that modern, mainstream science is itself “local knowledge, not universal knowledge, and its locality is the laboratory” (Harding 1998; Latour 1987). The laboratory can be reconstructed in distant locations, can travel, but it is claimed that laboratory knowledge with its purified substances, frictionless motion in a vacuum, purebred strains of model organisms, itself really local and special, not universal. The local knowledge idea can be applied to conflicts between citizens and scientific risk managers (Jasanoff 1986, 2005). Local citizens may have detailed anecdotal and practical knowledge of terrain, ocean currents, flora, or weather that risk management experts called in from a distant location may lack. Local citizens have identified toxic waste sites denied to exist by corporate experts (Lash et al. 1996). Louisiana fishermen showed justified skepticism concerning claims by representatives and risk communicators of both the BP Corporation and the US government that oil from the Deepwater Horizon Gulf of Mexico oil spill of April 2010 would not reach shore. (The Minerals Management Service’s risk management plan at the time referred to protection of walruses in the subtropical Louisiana waters that even the most ignorant citizen there would know did not exist.)

### The Introduction of Technocratic Attitudes and Tendencies in Some Apparently Non-Technocratic Treatments of Risk

---

The anthropological treatment of risk is at face value non- or anti-technocratic. The role of community tradition, community attitudes and worldviews, belief systems, and myths would seem to go against the Comtean or positivist priority of scientific rationality. It does so in many inquiries such as those of Brian Wynne (Wynne 1982). However, Dame Mary Douglas, despite holding to the universality and centrality of cultural taboos and conceptions of purity and impurity, in her collaboration with Adam Wildavsky, at least, applies the “primitive” or mythic account to the so-called sectarians of the ecology and health movements but not to the “center” of corporate and governmental opinion (Douglas and Wildavsky 1982). Thus this anthropological treatment of risk comes close to the technocrats vision of rational leaders and irrational, pre-civilized public. A consistent application of the anthropological approach can, and often

does, treat the rulers and technocrats themselves as possessing cultural worldviews, traditions, and myths that belie the rational and objective self-image of the technocrats.

Ulrich Beck is supportive of the ecological, health, and other countermovements in contemporary society. He claims that in reflexive modernity the countermovements have their own scientific experts. Although there is a pluralism of expert centers and expert claims, it is in a sense a pluralism of mini-technocratic centers. Although Beck claims that science has given up its claim to be serving truth, it is science to which Beck believes all factions must appeal. The notion of nonscientific, psychological, or anthropological constructions of risk is given little credence.

Third, Cass Sunstein in particular, but some of the other proponents of deliberative democracy as well, give a prominent and even dominant role to the technocrats. Sunstein himself claims that deliberative democracy must have a preponderant role for technocratic opinion. The deliberative side of deliberative democracy allows for time to ponder and evaluate scientific surveys and claims. Sunstein goes further, claiming that the government can act to “distract” the public from fears and opinions that conflict with objective, scientific risk-benefit analysis. He also advocates that the government surreptitiously support “independent” experts to give their opinions and evaluations supporting programs supported by the government. He even advocates the sending of undercover government agents into groups that support irrational conspiracy theories (apparently judged as such by him) to question and undermine these theories. Sometimes the government must undertake wasteful expenditures to eliminate minor risks if the public has great fear of them. This is done on a purely utilitarian consideration that the fears themselves can create great harms in public’s behavior and must be dealt with.

Thus even in a number of contemporary apparently non-technocratic approaches and views, such as the anthropological approach to risk, the self-reflexive critical society of reflexive modernization, and deliberative democracy, technocratic directions and tendencies are present.

## The Public's Problem in Identifying Technical Experts

---

Given that in technocracy the opinions of experts ought to be believed and followed, the problem arises – “Who are the experts?” (Crease and Selinger 2006).

This problem is apparently easy to solve in a totalitarian society, where the experts are simply those designed as such by the rulers or the government. For instance, in Marxist–Leninist societies, dialectical and historical materialism was considered not just a political theory or a philosophy, but a *science* of society and of nature. The ruling party itself acted on this “science” of Marxism–Leninism, and it had the authority to designate the experts in particular fields (Bailes 1978).

However, in a more open society, the problem of identifying the experts is not quite that simple. Certainly there is the whole process of professionalization and credentialing, which sociologists have studied in great detail. An expert is a member of a research institution, university, or government committee which has been accredited by the relevant accrediting bodies. There is a tacit social contract between the professional societies and the society at large. The implicit contract gives the professional body a monopoly on certain services in return for society’s gaining the services of the members of the professional body. The members of the profession are granted a certain self-determination and autonomy (Lowrance 1976). Academic freedom is an extreme example of this professional autonomy, although recently subject to controversy and constraint, and not always followed in the past.

The public often listens to “experts” who are indeed experts in one field of science (and have gained media attention) but who are not particularly expert on the field on which they pronounce in the mass media. An example of this is Steven Hawking’s pronouncements on climate change.

Hawking is a renowned cosmologist and astrophysicist, but his statements on the dangers of climate change are regarded by many in the media and the public as expert on climate because of his skills in relativity theory, black holes, and cosmology, which are unrelated to the issue in question (Connor 2007). Perhaps an even more extreme example of this was the public talks and pronouncements of William Shockley on racial differences in IQ. Shockley was an inventor of the transistor and a brilliant engineer, but his pronouncements on race and IQ were based on no research of his own. Unlike Arthur Jensen or Philip Rushton, who use statistics and surveys to defend their controversial so-called race realism, Shockley defended his position purely by obiter dicta (Shurkin 2008).

Clearly science in a normative sense can differ from science in an institutional or sociological sense at a given time, although retrospectively the poor science may be normatively rejected.

Since the seventh decade of the twentieth century widespread public criticism and opposition to experts has arisen. This was stimulated by the role of scientists, both natural and social, in the Vietnam and other recent wars, the public fears of nuclear power despite expert risk analysts assuring the public of its relative safety, and various health controversies, such as concerning AIDS, and food controversies such as BSE. The genuine expertise of experts has been called into question. Counter-experts, supported by ecology groups or opponents of genetic engineering have appeared. In court the situation is more complex. A variety of experts and alleged experts have been called upon as expert witnesses. In the controversy over recovered memory in child molestation, the expertise of some court-designated “experts” has been strongly denied by other social scientists and writers.

Some, like Ulrich Beck, in his *Risk Society* and Anthony Giddens, claim that with ecology and health movements and controversies scientific expertise has been severely fragmented, and the citizen must decide which of the numerous competing expert views on a topic to follow.

However, being credentialed as an expert and actually following the norms of science can be quite different things. There is a difference between the descriptive, sociological question of whether someone has status in scientific or technological professions as social institutions, and the normative issue of whether some member group within those institutions are following rationally legitimate or valid procedures. Sir Cyril Burt is an extreme example of the possibility of dichotomy between public reputation or authority and genuinely scientific quality of research. Burt was highly respected in his profession of psychometrics. He edited the most prestigious journal in the field, *The British Journal of Statistical Psychology*, advised the London Council on the tracking of students, founded Mensa, and received a knighthood. However, toward the end of his life a few raised doubts about his later data and articles. Shortly after his death many became convinced that his later work was fraudulent, with invented data to support his positions. Burt even wrote articles critical of Burt under pseudonyms, to which he then brilliantly replied (Hearnshaw 1979).

This raises the question of how to judge and trust experts. One form of the problem involves how the layperson can judge whether or not a self-proclaimed or even court-designated expert really is an expert. Another form of the problem involves the judgment by professionals and experts concerning other experts in other fields. Conflicts of professional turf and territory can bias the opinion of one sub-profession of another. Toxicologists or laboratory

microbiologists, for instance, may have differing opinions versus epidemiologists concerning a toxic substance or microbe.

There is also a problem concerning the relevant expertise of counter-experts of the sort that Beck and Giddens discuss. In the antinuclear movement and the opposition to biotechnology laboratories in some cities, some very eminent scientists lent their prestige and testimony to the opposition to corporations and government. However, sometimes the expertise of what the countermovement activists sometimes call “our experts” is not directly related to the specific issues involved. Linus Pauling, Nobelist expert in quantum chemistry, was the leading scientific spokesperson against nuclear testing, but was not himself privy to much of the secret data concerning the tests, while those, such as Edward Teller, who were privy, were defenders of the tests. For instance Mikio Kaku, a very able particle physicist and popularizer of science, and Barry Commoner, an organic chemist widely read and published on ecological issues, spoke against nuclear power. Both have some expertise relevant to the issues but are not nuclear engineers or students of low-level radiation. Similarly George Wald, a Nobel Prize winning biochemist lent his voice and prestige in opposition to genetic engineering labs, but was not himself a genetic engineer. (In this case several radical molecular biochemists involved in gene isolation, Jon Beckwith and Jonathon King also lent their voices.) Noam Chomsky, certainly the most eminent linguist has written against race difference IQ theories, but is not himself a psychometrician or statistician. David Layzer, a physicist, has training perhaps even further from the IQ debate. Richard Lewontin, who is expert on biostatistics also wrote extensively against racial IQ theories and studies, with more relevance. However, most working nuclear engineers support the value and relative safety of nuclear power, and most working psychologists of group differences in IQ believe in group differences in IQ (Snyderman and Rothman 1988). Otherwise they would not be working in that field.

Citizens attempt to judge the experts. This is often done on the basis of prestige, such as Nobel Prizes, even if not in the relevant field. Also inductive evidence is often reasonably used by the public in terms of the past track record of the relevant risk management experts. Philosopher of science, Wesley Salmon (1963) considers such inductive arguments valid forms of positive ad hominem or appeal to authority. However, if safety estimates were given in the past that later are admitted to be vastly lower than now accepted, citizens totally distrust the experts. Of course much smaller disagreements among experts or revisions of estimates are sufficient to make many members of the public total skeptics about science. Small errors or revisions have been successfully publicized by global warming skeptics, for instance. Likewise, insulting and aggressive statements about climate skeptics in private e-mails written by researchers, hacked, leaked and widely publicized have led many in Britain to doubt the whole, huge body of climate research.

One irony with respect to the special status of technical experts in technocracy is that several recent theories of expertise (Collins and Evans 2009; Collins 2010; Dreyfus 2008) base genuine expertise on tacit, non-explicit skills, involving language, embodiment, and social relationships, not on the explicit formal rules that are involved in technocratic rationality and technocratic expertise.

---

## Further Research

Research for the future concerning risk management in technocracy includes continuing surveys of public opinion concerning trust in technical on various issues, and analyses of the

components of trust and their weight. Empirical surveys or interviews of government and corporate officials to determine the amount of faith they have in the reports of their own technosphere would also be desirable, but more difficult to undertake. Perhaps slightly easier to undertake would be anonymous surveys or interviews with technical experts concerning their own opinion of how much acceptance the public, and institutional leaders, respectively have in their advice.

However, much of the further research on the issue of risk management in technocracy will consist not in empirical surveys and questionnaires, but in conceptual analysis of the nature of technocracy and the appropriateness of the term to contemporary societies and institutions. Certainly no nation is a complete or perfect technocracy. Technocratic and anti-technocratic tendencies exist to varying degrees in different nations, governmental departments, and branches of industry. We need to evaluate to what extent is the term technocracy relevant or applicable to contemporary societies and institutions, as a useful descriptive and analytical too, not as a kind of insult or accusations, as critical theorists and ecological activists sometimes use the term, or as the elder President George H.W. Bush used against his opponent Michael Dukakis during his presidential complain.

The main conceptual and empirical issues involve to what extent technocracy, not in the Platonic or Comtean sense of literal rule of experts, but in the weaker and more indirect sense of Galbraith's "technosphere." If technocracy is alive and well today at all, it is in this form.

To determine the extent to which the technosphere influences major societal decisions, one needs to estimate to what extent the alternative between which executives, generals, corporate offices, and other leaders choose are fully structured or provided by the technosphere. Using conceptual analysis, one might pose the counterfactual question: How would executives have decided if the input of the technosphere was not present? Of course, there are great difficulties with counterfactual history or social science, insofar as rigorous and accurate laws of the sort supporting counterfactuals in the natural sciences are generally not available. Some historians totally deny the usefulness or conceptual content of historical counterfactuals. Nevertheless, in recent years there has been a great deal of serious discussion of historical counterfactuals in the social sciences (Ferguson 2000; Lebow 2010). Sketching historical scenarios and tracing out plausible consequences of the absence of certain expert advice for executive decisions would be a valuable enterprise.

Another conceptual issue is the degree of technocratic versus participatory approach in various forms of risk deliberation. Deliberative democracy involves discussion of issues and programs. In deliberations concerning risk, experts have various possible roles. Sunstein (2002) would claim that experts should have a predominant role in risk deliberations, for Sunstein does not consider fears not concerned with death, disease, or injury (such as involuntary, unfamiliar nature of the risk) as irrelevant. Sunstein considers technocracy a central part of deliberative democracy. Others would consider citizen participation in discussion and evaluation of the expert opinions to be essential to genuine democracy. Radical critics of the present order see technocracy and democracy as totally opposed (Feenberg 1999). The dominant American form of public deliberation involves experts for the opposing parties (workers versus owners, neighborhood residents versus initiators of local technological project, environmental activists versus corporations or government). Many European forms of deliberation involve nonconfrontational, nonpublic discussion (Renn 2004). These different approaches have different possibilities for developing in the direction of technocratic dominance or democratic involvement. The confrontational, court-like testimonials, cross

examinations, and rebuttals of opposing experts can evolve into what was earlier dubbed a kind of pluralistic technocracy. The public's opinions can be sidelined. On the other hand, the nonpublic nature of the nonconfrontational discussion behind closed doors can lead to dominance by experts in the conversation and sidelining of the informally arrived at and nonpublic policy conclusions of the discussion.

Another largely conceptual but partly empirical issue is to what extent we evaluate various risk communication strategies as technocratic. Clearly the direct informational or warning approach is technocratic. However, there are degrees of understanding or empathy of the public fears concerning risk, whether justified or not. It is a matter of drawing the line between technocratic communication and genuine participatory communication.

Some questions for conceptual and empirical investigation are:

1. To what extent is technocratic risk management necessary in any industrial society?
2. To what extent is technocratic risk management replaceable by "democratic planning" of some sort not run by technocratic experts, but not totally uniformed about objective risks?
3. When technocrats incorporate risk perception research into their models, to what extent can they take perceived risks into account and acknowledge them without ceasing to be technocrats?
4. Similarly, when technocrats make risk communication a major part of their task, what are the parameters of simply propagandizing, persuading, or engaging in democratic deliberation?
5. To what extent have risk managers been able to recognize and acknowledge their own political and professional biases in their effect on risk estimates?
