# Preface

Risk has become one of the main topics in fields as diverse as engineering, medicine, and economics, and it is also studied by social scientists, psychologists, and legal scholars. But the topic of risk also leads to more fundamental questions such as: What is risk? What can decision theory contribute to the analysis of risk? What does the human perception of risk mean for society? How should we judge whether a risk is morally acceptable or not? Over the last couple of decades, questions like these have attracted interest from philosophers and other scholars into risk theory.

This handbook provides an overview into key topics in a major new field of research. It addresses a wide range of topics, from decision theory, risk perception, to ethics and social implications of risk, and it also addresses specific case studies. It aims to promote communication and information among all those who are interested in theoretical issues concerning risk and uncertainty.

This handbook brings together leading philosophers and scholars from other disciplines who work on risk theory. The contributions are accessibly written and highly relevant to issues that are studied by risk scholars. We hope that the *Handbook of Risk Theory* will be a helpful starting point for all risk scholars who are interested in broadening and deepening their current perspectives.

The editors:

Sabine Roeser (Editor-in-Chief), Rafaela Hillerbrand, Per Sandin, and Martin Peterson

# Acknowledgments

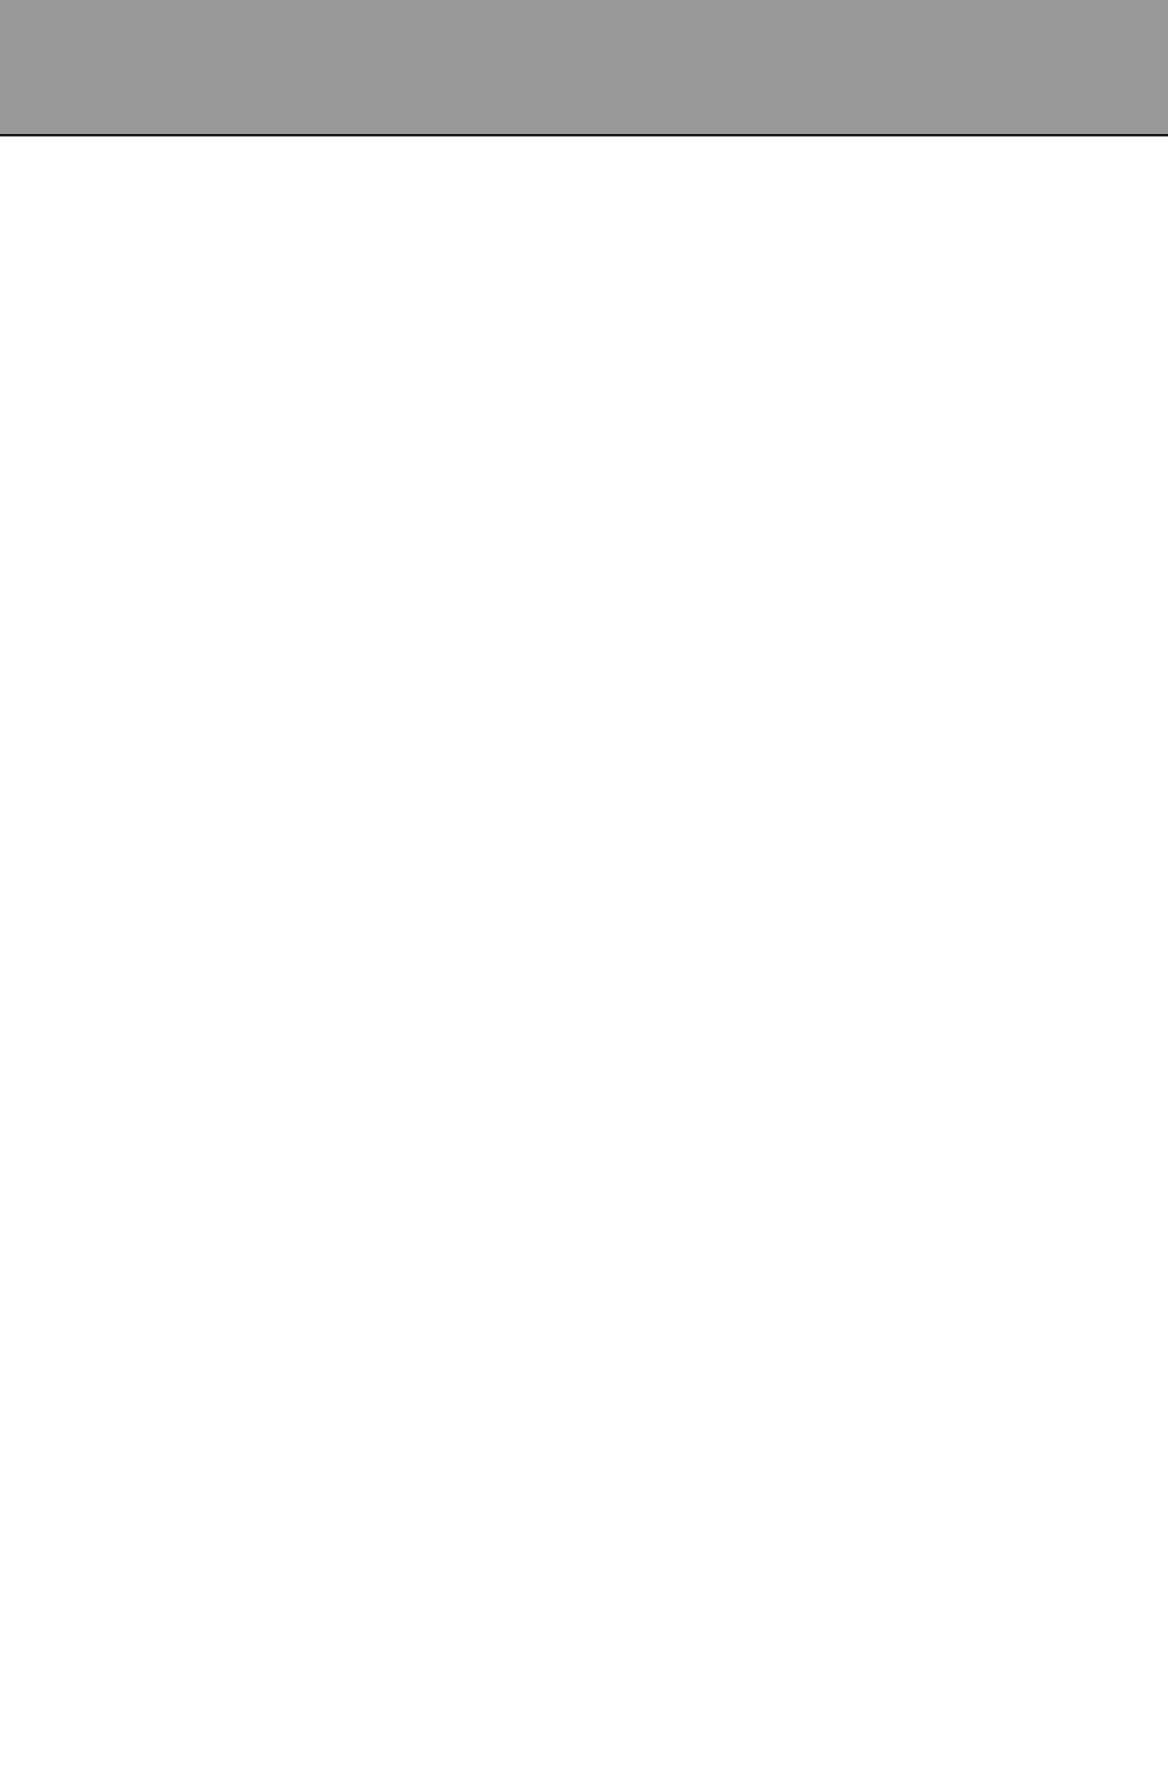

Sabine Roeser's work for the *Handbook of Risk Theory* has been conducted at the philosophy departments of TU Delft and Twente University and was sponsored by the Netherlands Organization for Scientific Research (NWO), with VIDI-grant number 276-20-012.

Rafaela Hillerbrand's work on this volume was supported by the excellence initiative of the German federal and state governments and conducted at the Human Technology Centre (HumTec) and the Institute of Philosophy, RWTH Aachen University. Thanks to all members of the research group eet - ethics for energy technology for insights into risks from various disciplines. Special thanks to Andreas Pfennig, Nick Shackel, and Peter Taylor for numerous fruitful discussions on the topic.

Per Sandin's work for this handbook was done in the Department of Plant Physiology and Forest Genetics, Swedish University of Agricultural Sciences, Uppsala and in the Department of Philosophy and History of Technology, Royal Institute of Technology, Stockholm.

Martin Peterson has conducted his work for the handbook at the philosophy department of TU Eindhoven. Sabine Roeser and Martin Peterson are members of the 3TU. Centre for Ethics and Technology, a center of excellence of the federation of the three technical universities in the Netherlands (Delft, Eindhoven, and Twente).

We are very grateful to the contributors of this handbook. In addition, we would like to thank Katie Steele, Linda Soneryd, and Misce Wester, each of whom provided expert reviews for a chapter. We would like to thank the staff at Springer for the excellent collaboration, specially Ties Nijssen, Jutta Jaeger-Hamers, and Christine Hausmann.

# Table of Contents

Preface .....	v
Acknowledgments .....	vii
Editors .....	xiii
List of Contributors .....	xv

## Volume 1

1 Introduction to Risk Theory .....	1
Sabine Roeser · Rafaela Hillerbrand · Per Sandin · Martin Peterson	

### Part 1 General Issues in Risk Theory

2 A Panorama of the Philosophy of Risk .....	27
Sven Ove Hansson	
3 The Concepts of Risk and Safety .....	55
Niklas Möller	
4 Levels of Uncertainty .....	87
Hauke Riesch	

### Part 2 Specific Risks

5 The Economics of Risk: A (Partial) Survey .....	113
Louis Eeckhoudt · Henri Loubergé	
6 Interpretation of Forensic Evidence .....	135
Reinoud D. Stoel · Marjan Sjerps	
7 Risks and Scientific Responsibilities in Nanotechnology .....	159
John Weckert	
8 Risk and Risk-Benefit Evaluations in Biomedical Research .....	179
Annette Rid	
9 Understanding and Governing Public Health Risks by Modeling .....	213
Erika Mansnerus	

<b>10</b>	<b>Management of the Risks of Transport</b>	<b>239</b>
	<i>John Adams</i>	
<b>11</b>	<b>Risk and Spatial Planning</b>	<b>265</b>
	<i>Claudia Basta</i>	
<b>12</b>	<b>Intergenerational Risks of Nuclear Energy</b>	<b>295</b>
	<i>Behnam Taebi</i>	
<b>13</b>	<b>Climate Change as Risk?</b>	<b>319</b>

## Introduction

---

Risk is an important topic in contemporary society. People are confronted with risks from financial markets, nuclear power plants, natural disasters and privacy leaks in ICT systems, to mention just a few of a sheer endless list of areas in which uncertainty and risk of harm play an important role. It is in that sense not surprising that risk is studied in fields as diverse as mathematics and natural sciences but also psychology, economics, sociology, cultural studies, and philosophy. The topic of risk gives rise to concrete problems that require empirical investigations, but these empirical investigations need to be structured by theoretical frameworks. This handbook offers an overview of different approaches to risk theory, ranging from general issues in risk theory to risk in practice, from mathematical approaches in decision theory to empirical research of risk perception, to theories of risk ethics and to frameworks on how to arrange society in order to deal appropriately with risk.

Risk theory provides frameworks that can contribute to mitigating risks, coming to grips with uncertainty, and offering ways to organize society in such a way that the unexpected and unknown can be anticipated or at least dealt with in a reasonable and ethically acceptable way. This handbook reflects the current state of the art in risk theory, by bringing together scholars from various disciplines who review the topic of risk from different angles.

## Part 1: General Issues in Risk Theory

---

Theoretical reflection about risk gives rise to various general issues. What is the relation between risk research and philosophy? What can the two disciplines learn from each other? How are the concepts of risk and safety interrelated? Which different levels of uncertainty can be distinguished? Part one of this handbook discusses these general issues in risk theory.

### Sven Ove Hansson: A Panorama of the Philosophy of Risk

---

Sven Ove Hansson's chapter provides for an overview of the contributions that different philosophical subdisciplines and risk theory can provide for each other. He starts out with discussing the potential contributions of philosophy to risk theory. These contributions concern terminological clarification, argumentation theory, and the fact–value distinction. It is philosophy's “core business” to provide for terminological clarification. In the area of risk theory, philosophical theories can shed light on the multifaceted concepts of risk and safety. Philosophical argumentation theory can draw attention to common fallacies in reasoning about risk. In the philosophical tradition, there are intricate debates about the relationship between facts and values that can contribute to more careful and nuanced discussions about facts and values in risk analysis, for example, by making implicit value judgments explicit. These are areas in which existing philosophical theories can be applied rather straightforwardly. However, there are other issues in risk theory that give rise to new philosophical problems and require new philosophical approaches in virtually all areas of philosophy. This is due to the fact that most traditional philosophical approaches are based on deterministic assumptions. Thinking about risk and uncertainty requires radically different philosophical

theories. Hence, the topic of risk can lead to new philosophical theories that are at the same time directly practically relevant, as our real-life world is one that is characterized by risk and uncertainty.

## Niklas Möller: The Concepts of Risk and Safety

---

Niklas Möller provides for an analysis of the concepts of risk and safety. Möller distinguishes three major approaches in empirically oriented risk theory: the scientific, the psychological, and the cultural approach, respectively. Philosophical approaches connect with each of these approaches in specific ways. Möller then distinguishes between at least five common usages of the notion “risk” and shows how each usage can be connected to a different approach in risk research. He emphasizes the importance of distinguishing between factual and normative uses of the notion of risk. Möller continues with the question whether safety is the antonym of risk. He argues that this is not necessarily the case; for example, these words can have different connotations. Möller then discusses various ethical aspects of risk that are elaborated on in more detail in Part 5 of this handbook, on Risk Ethics. Möller’s unique contribution to risk ethics is to argue that risk is a “thick concept”; that is, a concept that does not only have descriptive aspects that are the subject of scientific investigations, but that also has normative or evaluative aspects, which require ethical reflection. Möller discusses and rejects, on philosophical grounds, various claims by social scientists to the socially constructed nature of risk that is supposed to follow from its inherently normative nature.

## Hauke Riesch: Levels of Uncertainty

---

Risk science seems to be a paradigm of interdisciplinary research: Risk unites disciplines. But every discipline seems to denote something else with the umbrella term risk. This dilemma is the starting point of Hauke Riesch’s contribution on the “Levels of Uncertainty.” Hauke Riesch analyzes various uses of the terms risk and uncertainty. He attributes differences not so much to imperfect or sloppy use of the terms. Rather, he argues that these differences are a symptom of the fact that different scientists are interested in different aspects of risk. Therefore, there is not much point in criticizing someone for using vague or different notions of risk. Riesch conceptualizes risk as uncertainty of an event happening whose outcome may be severe. Riesch argues that concerning the uncertainty aspect of risk we can distinguish the following six questions which are not mutually independent: Why are we uncertain? Who is uncertain? How is uncertainty represented? How do people react to uncertainty? How do we understand uncertainty? What exactly are we uncertain about? Within this multidimensional map, Riesch divides the objects of uncertainty into five layers: uncertainty of the outcome, uncertainty about the parameters as well as uncertainty about the model itself, uncertainty about acknowledged inadequacies and implicitly made assumptions, and uncertainty about the unknown inadequacies. These layers relate to different concerns of different disciplines. The expert discourse commonly focuses on one of these levels, but this distorts the way people perceive particular risks, because higher level uncertainties still exist. Riesch illustrates through various case studies – lottery, bad eating habits, CCS (carbon capture storage), and climate

change – how all five levels of uncertainty are always present, but differently important. Riesch's multidimensional classification provides some useful information for risk communication in order to convey information on other levels of uncertainty that people find important.

## Part 2: Specific Risks

---

What brings about reflections on risk is the necessity to react to real natural or anthropogenic hazards. The second part of this book addresses natural, technological, and societal risks from the perspective of the natural and social sciences by also incorporating insights from the humanities and mathematical sciences.

### Louis Eeckhoudt and Henri Loubergé: The Economics of Risk: A (Partial) Survey

---

Louis Eeckhoudt and Henri Loubergé give a historical overview of how risk thinking has developed in the mainstream model of economics, that is, that of expected utility theory. The authors argue that despite Daniel Bernoulli's foundational work on this model in the eighteenth century, those ideas were not formulated in precise terms until von Neumann and Morgenstern's Expected Utility Theorem in the late 1940s. These ideas were further developed by Friedman and Savage, Arrow, and Pratt. Eeckhoudt and Loubergé introduce the concept of general equilibrium and discuss issues of risk distribution among individuals. The authors end their discussion with brief illustrations of applications of the theory from the fields of finance and insurance.

### Reinoud D. Stoel and Marjan Sjerps: Interpretation of Forensic Evidence

---

Reinoud D. Stoel and Marjan Sjerps write about the interpretation of forensic evidence. Since absolute certainty regarding the guilt of a suspect is unattainable, the question has to be put in terms of probability. They go on to describe how this issue can be approached using the Likelihood Ratio and how this applies to both forensic experts and legal decision makers. They propose further research focusing on methods for computing quantitative Likelihood Ratios for different forensic disciplines and also how different pieces of evidence combine, for example, using Bayesian networks.

### John Weckert: Risks and Scientific Responsibilities in Nanotechnology

---

John Weckert writes about the risks of nanotechnology, and using this field as an example he discusses scientists' responsibility. He presents four generations of nanotechnology and the risks associated with each generation. In particular, he emphasizes five risks that have been discussed in relation to nanotechnology: health/environmental risks related to nanoparticles, "grey goo," threats to privacy, cyborgs, and the possibility of a "nanodivide" between the

developed and the developing world. He goes on to delineate two models of science, the linear and the social mode, where the latter focuses on the inevitable value-ladenness of science. He also discusses four different interfaces between science and ethics. As regards the responsibility of scientists involved in nano research, he argues that these responsibilities differ between the different risks, and that on the linear model scientists are not free from responsibility. Weckert calls for more interdisciplinary research in the future, based on sound science and knowledge of actual technological developments.

### **Annette Rid: Risk and Risk-Benefit Evaluations in Biomedical Research**

---

Annette Rid critically reviews recent debates about risk-benefit evaluations in biomedical research. To determine whether potential new interventions in clinical care, new drugs, or basic science research in biomedicine have a net benefit, risks that participants take have to be balanced against the positive effects for potential patients and society as a whole. Rid presents and evaluates the four existing ethical frameworks for risk-benefit evaluations in medical ethics: component analysis, the integrative approach, the agreement principle, and the net risks test. She contends that net risks tests are superior to alternative approaches, but fail to offer guidance for evaluating the ethical acceptability of risks that participants are exposed to for research purposes only. This leaves two of the fundamental problems of risk-benefit evaluations in research largely unaddressed: How to weigh the risks to the individual research participant against the potential social value of the knowledge to be gained from a study, and how to set upper limits of acceptable research risk. Discussions about the “minimal” risk threshold in research with participants who cannot consent go some way to specifying upper risk limits in this context. However, these discussions apply only to a small portion of research studies.

### **Erika Mansnerus: Understanding and Governing Public Health Risks by Modeling**

---

Erika Mansnerus discusses how risk is perceived and expressed through the computational models that are increasingly used to govern and understand public health risk. She discusses a case study on infectious disease epidemiology to illustrate how models are used for explanation-based and scenario-building predictions in order to anticipate the risks of infections. Mansnerus analyzes the tension that arises when model-based estimates exemplify the population-level reasoning of public health risks, but have restricted capacity to address risks on an individual level. Mansnerus provides an alternative account in order to overcome the limitations of computational tools in the governance of public health risks. This richer picture on risk goes beyond the pure probabilistic realm of mathematical risk modeling.

### **John Adams: Management of the Risks of Transport**

---

John Adams discusses whether transport safety regulations indeed reduce risks of, for example, fatal car accidents. With the exception of the seat belt law, major reductions in road fatalities

over the past decades cannot be linked to changes in transport safety laws in a straightforward way. So what is the use of these laws and why do they fail? Adams introduces the reader to two models of how risk managers may deal with risks, a cost–benefit model and a model underlying risk compensation strategies. Both models focus on different risk. The former focuses on what Adams terms “risks perceived through science” and models road users as ignorant, obedient objects. In contrast, the alternative model pictures road users as vigilant and responsive subjects and thus can also take into account directly perceived risks and what Adams terms “virtual risks.” Adams applies Mary Douglas’ cultural theory of risk to road safety issues in order to provide an explanation of why different societies perceive risks very differently. Adams shows how this leads to two very different strategies to manage and reduce the risks of transport in the two countries with the best road safety records worldwide, the Netherlands and Sweden.

## Claudia Basta: Risk and Spatial Planning

---

Claudia Basta challenges the way societies currently deal with site-specific hazardous technologies. The location of hazardous facilities is rarely an uncontroversial issue. Basta describes how this issue is dealt with in selected European countries and explains their differences as a reflection of nonexplicit, but retraceable, underlying ethical theories. Basta suggests a possible synergy between spatial planning practices and ethical theories by proposing a theoretical framework which may guide spatial planning processes before and beyond unavoidable contextual features. In particular, following the Rawlsian theory of justice (Rawls 1971) as transposed to spatial planning theories by Moroni, Basta proposes an understanding of “spatial safety” as a primary spatial good. Spatial planning practice is thus perceived primarily as a practice of distributing the maximum possible amount of the primary good of spatial safety in society equally up to the lowest societal level. She contends that approaching any siting controversy as a NIMBY (not-in-my-backyard) case is not only incorrect, but also dangerously instrumental. The case study of a planned CCS facility at Barendrecht illustrates this point.

## Behnam Taebi: Intergenerational Risks of Nuclear Energy

---

Behnam Taebi discusses the intergenerational risk of nuclear waste disposal. The accident in the Fukushima II nuclear power plant in Japan in 2011 gives rise to a renewed discussion about the civic use of nuclear power. In addition to the risk of a nuclear meltdown, nuclear power plants put seemingly unduly high burdens on future generations: The longevity of the toxic and radioactive waste seems to require geological disposals that are faced with immeasurable uncertainties concerning the stability of rock formation over large timescales (a few thousand years). The relatively new technological possibility of Partition and Transmutation (PT) may provide an alternative to that and put long-term surface storage in a new light. Taebi not only examines this new technology as an alternative to geological disposal, but also addresses central aspects of intergenerational ethics, namely the principles of intergenerational equity. Taebi scrutinizes the notion of diminishing responsibility over time, which is an important notion in

nuclear waste policies, and rejects the moral legitimacy of distinguishing between future people. In this sense Taebi not only provides a thorough account on how to deal with long-life radioactive waste, but also reflects on our present obligations toward future generations.

### Rafaela Hillerbrand: Climate Change as Risk?

---

Rafaela Hillerbrand analyzes the types of uncertainties involved in climate modeling and discusses whether common decision approaches based on the precautionary principle or on the maximization of expected utility are capable of incorporating the uncertainty inevitably involved in climate modeling. The author contends that in the case of decision making about climate change, unquantified uncertainties can neither be ignored, nor can they be reduced to quantified uncertainties, by assigning subjective probabilities. These insights reveal central problems, as they imply that the commonly used elementary as well as probabilistic decision approaches are not applicable in this case. The chapter argues that the epistemic problems involved in modeling the climate system are generic for modeling complex systems. Possible parts of future research to circumvent these problems are adumbrated.

### Amy Donovan: Earthquakes and Volcanoes: Risk from Geophysical Hazards

---

The recent earthquake in Japan revealed the vulnerability of a high-tech society to natural hazards. Amy Donovan calls for a genuinely interdisciplinary study of volcano and seismic risk if we want to be better forewarned against such risks. A wide range of disciplines, spanning both social and physical sciences, is involved in research into geophysical hazards, in order to predict, prepare for, and communicate about events like the one in Japan. However, only few holistic approaches to geophysical risks exist. Most information comes from the natural sciences that tend to focus on hazard assessment, while the social sciences focus on vulnerability reduction and risk communication. The contribution of Amy Donovan fills this gap. Donovan examines the social context both of the scientific research of the natural hazards, and of the hazards themselves, proposing a holistic and context-based approach to understanding risk. In the context of seismic risk, the uncertainty of the scientific methods coupled with the procedures involved in mitigating these risks and the need to involve populations in the preparation, leads to a snowballing of uncertainty and indeterminacy from the scientific domain through the policy domain and into the wider public.

## Part 3: Decision Theory and Risk

---

As illustrated by the interdisciplinary nature of the contributions to this handbook, risk theory is a very broad field of research. Eight chapters explore the links between risk theory and *decision theory*.

Very briefly put, decision theory is the theory of rational decision making. A key assumption accepted by nearly all decision theorists is that it is essential to distinguish between

*descriptive* claims about how people actually make risky decisions, and *normative* claims about how it would be rational to take such decisions. In recent years, the term decision theory has primarily been used for referring to the study of normative claims about rational decision making. In what follows, we shall follow this convention and reserve the term “decision theory” for the study of normative hypotheses about what rationality demands of us.

The notion of rationality researched in decision theory is best described as means–ends rationality. The rational decision maker has certain beliefs about what the effects of various risky options could be, and also has a set of desires about what he or she wants to achieve. The key question is then how we should best combine these beliefs and desires into a decision.

This so-called belief–desire model of rationality goes back at least to the Scottish eighteenth-century philosopher David Hume. According to Hume, the best explanation of why people behave as they do – and are willing to accept the risks they do accept – is that we all have certain beliefs and desires that determine our actions (cf. Hume 1740/1967). In the belief–desire model, a basic criterion of a rational decision is that it must accurately reflect the agent’s beliefs and desires, no matter what these beliefs and desires happen to be about. But how should such a theory of rationally permissible structures of beliefs and desires be spelled out in detail?

The mainstream view among contemporary decision theorists is that rational agents are allowed to let whatever beliefs and desires they so wish guide their decisions, as long as those beliefs and desires are compatible with the principle of maximizing expected utility. The principle of maximizing expected utility takes the total value of an act to equal the sum total of the values of its possible outcomes weighted by the probability for each outcome. The values assigned to an outcome are determined by the decision maker’s desires, whereas the probabilities are determined by his or her beliefs about how likely the outcomes are to materialize.

An important step in the development of modern decision theory was the development of axiomatic accounts of the principle of maximizing expected utility. The first such axiomatization was sketched by Frank Ramsey in his paper *Truth and Probability*, written in 1926 but published posthumously in 1931. Ramsey (1931) formulated eight axioms for how rational decision makers should form preferences among uncertain prospects. One of the many points in his paper is that a decision maker who behaves in accordance with the eight axioms will act in a way that is *compatible* with the principle of maximizing expected value, in the sense that he or she will implicitly assign numerical probabilities and values to outcomes. Note that it does not follow from this that the decision maker’s choices were *actually triggered* by these implicit probabilities and utilities. This indirect approach to rational decision making is extremely influential in the contemporary literature. In 1954, Leonard Savage put forward roughly the same idea in his influential book *The Foundations of Statistics* (Savage 1954).

An equally important book in the recent history of decision theory is John von Neumann and Oskar Morgenstern’s book *Theory of Games and Economic Behavior* (1944). They used the notion of a “lottery” for developing a linear measure of an outcome’s utility. In von Neumann and Morgenstern’s vocabulary, a lottery is a probabilistic mixture of outcomes. For instance, an entity such as “a fifty-fifty chance of winning either \$1,000 or a trip to Miami” is a lottery. The upshot of their utility theory is that every decision maker whose preferences over a very large set of lotteries conform to a small set of axioms implicitly assigns numerical utilities to outcomes, and also implicitly acts in accordance with the principle of maximizing expected utility.

The chapters in this section discuss various aspects of, ideas behind, and problems with decision theory in the context of risk.

## Claus Beisbart: A Rational Approach to Risk? Bayesian Decision Theory

---

Claus Beisbart's contribution clarifies the concept of utility maximization as the core notion of rationality in Bayesian decision theory. For Bayesians, a rational approach to risk depends on the agents' utilities and subjective probabilities that measure the strength of their desires and beliefs, respectively. Two questions are commonly put forward by critics of Bayesian decision theory: Why do or why should rational agents maximize expected utility? And how can the strength of an agent's desire and belief be measured? The classical answers by Bayesians to these questions are commonly put in the form of representation theorems. These theorems show that – under certain assumptions – an agent's beliefs and desires can indeed be represented in terms of numerical probabilities and utilities. Beisbart presents several different ways to obtain a presentation theorem: the classical approach of von Neumann-Morgenstern, its modification by Anscombe and Aumann, the approach of Ramsey, Bolker-Jeffrey theory, and Savage's account, the latter possibly being closest to how risk is actually dealt with in technology assessment. The chapter concludes with a discussion of major controversies concerning Bayesian decision theory.

## Karsten Klint Jensen: A Philosophical Assessment of Decision Theory

---

Karsten Klint Jensen starts his chapter with drawing a distinction between classical decision theory and modern axiomatic decision theory. He then goes on to give an overview of Savage's axiomatization of the principle of maximizing expected utility. This all leads up to a discussion of what *sort of problem* decision theory really aims at solving. Several possible answers are considered. Jensen points out that the perhaps most plausible interpretation of what modern decision theories are up to is to try to develop theories of what counts as personal good and how such personal goods can be aggregated intrapersonally.

## Peter R. Taylor: The Mismeasure of Risk

---

Peter R. Taylor challenges the classical approaches in risk management and risk assessment, thereby mainly, but not exclusively, focusing on how the insurance industry deals with risk. Taylor argues that already our embosomed definition of risk, which pictures risk as a quantitative measure combining, in one way or the other, harm and likelihood of the hazardous event, falls short of describing realistic events like the recent disasters that caught world headlines – tsunamis, volcanic ash clouds, or financial crashes. It is argued that simple measures of risk that, like for example in the Bayesian approach, focus merely on the mean expected harm, may be poor guides for dealing with real-world risk. Taylor outlines how a more complex risk assessment may incorporate what Rumsfeld termed the unknown unknowns or Taleb the black swans: that is, events that are not considered in the probability space. Taylor shows how model risk, that is, the risk that the underlying model of the, say, physical hazard is simply inadequate, may be quantified and how multiple measures and thresholds may be implemented. The author further examines if we could also tackle what he calls ROB, "risk outside the box," that is, risks that are not considered by the underlying risk model.

## Nils-Eric Sahlin: Unreliable Probabilities, Paradoxes, and Epistemic Risks

Nils-Eric Sahlin's chapter focuses on the quality of the information on which a decision is based. By definition, if the information at hand when a decision is taken is unreliable, then the epistemic uncertainty is high. Suppose, for instance, that for one reason or another tomorrow's weather is important for a decision that you are about to take. Now consider the scenario in which you have received a detailed weather forecast from a professional meteorologist according to which the probability for rain tomorrow is 50% and compare this with a scenario in which your 3-year-old son, who knows nothing about meteorology, tells you that he thinks the probability for rain tomorrow is 50%. Intuitively, you as a decision maker seem to be better off from an epistemic point of view in the first scenario compared to the second, but exactly how should this difference be accounted for from a decision theoretical point of view? How do we take intuitions about epistemic risks into account in our theories of rational decision making? This is the key question that drives Sahlin's chapter.

## Till Grüne-Yanoff: Paradoxes of Rational Choice Theory

Till Grüne-Yanoff's chapter gives an overview of some of the many well-known paradoxes that have played an important role in the development of decision theory. The very first such paradox was the St Petersburg paradox, formulated by the Swiss mathematician Daniel Bernoulli (1700–1782), who worked in St Petersburg for a couple of years at the beginning of the eighteenth century. The St Petersburg paradox, which is still being discussed by decision theorists, is derived from a game known as the St Petersburg game: A fair coin is tossed until it lands heads up. The player then wins  $2^n$  dollars, where  $n$  is the number of times the coin was tossed. Hence, if the coin lands heads up in the first toss, the player wins 2 dollars, but if it lands heads up on, say, the fourth toss, the player wins  $2^4 = 2 \cdot 2 \cdot 2 \cdot 2 = 16$  dollars. How much should a rational person be willing to pay for getting the opportunity to play this game? Clearly, the expected monetary payoff is infinite, because  $\frac{1}{2} \cdot 2 + \frac{1}{4} \cdot 4 + \frac{1}{8} \cdot 8 + \dots = 1 + 1 + 1 + \dots = \sum_{n=1}^{\infty} \left(\frac{1}{2}\right)^n \cdot 2^n = \infty$ . However, to pay, say, a million dollars for playing a game in which one is very likely to win just 2, 4, or 8 dollars seems absurd. As Grüne-Yanoff points out, it is not as easy to resolve this and other paradoxes as many people have thought.

## Paul Weirich: Multi-Attribute Approaches to Risk

Paul Weirich considers the special type of situation that arises if many different features of a decision are considered to be relevant by the decision maker. In a single-attribute approach to decision theory, all possible outcomes are compared on one and the same scale. Imagine, for instance, that you are about to buy a new car. Some cars are more expensive than others, but they are also safer. How many dollars is it worth to pay for extra safety? The multi-attribute approach attempts to avoid the idea that money and human welfare are somehow directly commensurable by giving up the assumption that all outcomes have to be compared on a common scale. In a multi-attribute approach, each type of attribute is measured in the unit the decision maker considers to be most suitable for the attribute in question. Money is

typically the right unit to use for measuring financial costs, whereas other measures are required for measuring car safety.

### **John R. Welch: Real-Life Decisions and Decision Theory**

---

John R. Welch discusses another important area of decision theory, concerning the question of how we can apply decision theory to real-life decisions. As everyone who reads the other chapters on decision theory will quickly discover, decision theorists make many quite unrealistic idealizations about the decision problems they are discussing, which seldom or never hold true in real-life applications. In recent years, decision theorists have become increasingly aware of this limitation, and in response to this have started to develop more realistic decision theories that deal better with the ways in which we actually take decisions in real life. Welch gives a very instructive overview of this emerging literature.

### **Stefan T. Trautmann and Ferdinand M. Vieider: Social Influences on Risk Attitudes: Applications in Economics**

---

In the last chapter on decision theory, Stefan T. Trautmann and Ferdinand M. Vieider discuss the links between decision theory and two of the key disciplines on which much work in decision theory draws, namely, economic theory and psychology. Trautmann and Vieider identify and discuss four distinct types of social influences on economic decisions under risk: (1) observations of other agents' outcomes; (2) observations of the decision maker's outcomes by other agents; (3) direct effects of the decision maker's choices on other agents' outcomes; and (4) direct dependencies of the decision maker's outcomes on other agents' choices.

## **Part 4: Risk Perception**

---

Where the previous section discussed normative or rational decision theory, the present section discusses risk from the point of view of empirical decision theory, or to use a more common notion, risk perception. In the 1970s, the psychologists Amos Tversky, Daniel Kahneman, and Paul Slovic started to investigate the ways in which people as a matter of fact make decisions under uncertainty or risk. It turned out that these decisions deviate significantly from rational decision theory. It might not be too surprising that laypeople's intuitive judgments about risk and statistics deviate from mathematical methods. However, surprisingly, also the judgments of experts turned out to be subject to numerous heuristics and biases. These findings gave rise to a whole research industry in mistakes people make in their risk judgments (cf., e.g., Gilovich et al. 2002), which eventually earned Kahneman the Nobel Prize in economics in 2002. The common framework to explain these phenomena is Dual Process Theory (DPT) which states that there are two systems with which people make judgments: system 1 is intuitive, spontaneous, and evolutionary prior; system 2 is rational, analytical, and comes later in our evolution. System 1 helps us to navigate smoothly through a complex world, but system 2 is the one that provides us with ultimate normative justification.

However, there are alternative approaches to risk perception that challenge this picture to some extent. Paul Slovic and various social scientists have argued that there is no "objective"

measure of risk, that all approaches to risk, also those of experts, involve normative and partially arbitrary or subjective assumptions. Slovic and his colleagues have conducted studies that show that laypeople do not so much have a wrong understanding of risk but rather a different understanding of risk that might provide for valuable insights (cf. Slovic 2000). Dan Kahan has combined Slovic's psychometric approach with Mary Douglas's cultural theory to account for cultural values in risk perception. The psychologist Gerd Gigerenzer (2007) has conducted studies that show that intuitive risk judgments can actually be more reliable than mathematical approaches to risk. For example, experts' intuitions, but also laypeople's heuristics, can be superior to formal approaches.

This section consists of chapters that discuss various aspects of risk perception.

## Dylan Evans: Risk Intelligence

---

Dylan Evans presents new empirical research that shows that risk intelligence perceived as the ability to estimate probabilities correctly is rare. Previous calibration tests have mainly been used to measure expert groups like medics and weather forecasters. However, Dylan presents tests of over 6,000 people of all ages and a variety of backgrounds and countries. Like other work in the psychology of judgment and decision making, Evans' own work shows that most people are not very good at thinking clearly about risky choices. They often disregard probability entirely, and even when they do take probability into account, they make many errors when estimating it. However, some groups of people have an unusually high level of risk intelligence. Evans outlines how lessons can be drawn from these groups to develop new tools to enhance risk intelligence in others.

## Nicolai Bodemer and Wolfgang Gaissmaier: Risk Communication in Health

---

The chapter by Nicolai Bodemer and Wolfgang Gaissmaier studies risk communication in the health-care sector. A major problem for doctors who wish to help their patients to make well-informed medical decisions is that patients often find it difficult to understand the information presented by the doctor. Bodemer and Gaissmaier point out that purely qualitative information, such as saying that the risk is "large" or "quite small," often does not work well: the beliefs that the patients end up with if they receive purely qualitative information is often badly calibrated with the true risk. Numerical representations often make it easier for patients to correctly understand the magnitude of a risk. However, some numerical representations tend to be easier to understand than others. In particular, Bodemer and Gaissmaier argue that doctors should try to avoid using conditional probabilities if they wish to be understood, and instead use natural frequencies.

## Lennart Sjöberg: Risk Perception and Societal Response

---

Lennart Sjöberg discusses research on risk perceptions of experts and laypeople. Sjöberg first reviews the most well-known models of risk perception, that is, the psychometric model by

Paul Slovic and others, and Cultural Theory as developed by Mary Douglas and Aaron Wildavsky (1982). Sjöberg argues that the empirical evidence for these models is problematic. These approaches leave 80% of the variance in risk perception unexplained. Sjöberg presents approaches that have more explanatory power. One tool is the risk sensitivity index with which risk attitudes can be measured. Sjöberg goes on to discuss the role of affect and emotion in risk perception. He points out ambiguities in the use of these notions in studies on risk perception; for example, affect sometimes refers to emotions and sometimes to values. He emphasizes that the psychometric model only employs one emotion, that is, dread, and it is rated for others rather than for the respondent. Sjöberg also discusses social trust, epistemic trust, and antagonism as important dimensions in risk perceptions. He reviews studies that show that risk perceptions of experts and laypeople mainly diverge when experts have responsibilities for risk, which can be explained by self-selection and social validation that lead to lower risk perceptions amongst experts. Sjöberg emphasizes that there will probably never be an ultimate consensus on risk in an open society. He warns for the risks of risk denial.

---

### **Melissa L. Finucane: The Role of Feelings in Perceived Risk**

Melissa L. Finucane discusses the role feelings play in risk perception. She starts with a historical review of the development in research of feeling in risk perception, which is usually placed within the framework of Dual Process Theory. She then discusses different functions of feelings that have been identified in the context of risk, such as providing for accessible information, motivation, and moral and evaluative knowledge. Finucane presents frameworks that question the dichotomies underlying Dual Process Theory and provides for alternative views, for example, that “risk as analysis” (system 2) and “risk as feeling” (system 1) can be combined into what Finucane calls “risk as value.” Finucane goes on by reviewing empirical evidence for the role of feelings in risk perception. One example is the role of emotional images on risk perception. Another example is psychophysical numbing, referring to diminishing sensitivity as numbers of, for example, victims of a disaster increase. This phenomenon can explain why we fail to respond appropriately to large humanitarian or environmental disasters. Finucane also discusses biases in gambles that are due to feelings, and the influence of moods on risk perception. She concludes by pointing out directions for future research, by taking into account available empirical tools for research into feelings, and alternative approaches to risk that go beyond purely quantitative models but also include values and feelings.

---

### **Ross Buck and Rebecca Ferrer: Emotion, Warnings, and the Ethics of Risk Communication**

Ross Buck and Rebecca Ferrer discuss the relation between emotion, warnings, and the ethics of risk communication. They describe the common approach to risk communication which focuses on factual, statistical information. Appeal to emotions is considered to be unethical because it is supposed to be a form of manipulation. Buck and Ferrer challenge this approach. Emotions are already widely used in marketing, often overruling the more sober information on risk, for example, in the context of tobacco and alcohol consumption. They review empirical studies from decision theory and neuropsychology that show the importance of

emotions in decision making. Some of these studies support the framework of Dual Process Theory, others suggest the possibility of an interaction between the affective and the analytical system, and yet others indicate that affect and cognition are intertwined. The authors argue that effective and ethically sound risk communication has to take into account and anticipate the various ways in which emotions can play a role in risk decisions. They present work on the role of emotion in communication about safe sexual behavior and on emotion intervention strategies and emotional education to illustrate this.

### **Dan M. Kahan: Cultural Cognition as a Conception of the Cultural Theory of Risk**

---

Dan M. Kahan discusses two approaches to risk perception: Mary Douglas's and Aaron Wildavsky's cultural theory, and cultural cognition of risk. The latter is a combination of the former with Paul Slovic's psychometric approach to risk. Kahan first provides for a rough outline of cultural theory and its developments. According to cultural theory, cultural worldviews can be fit in a matrix with two axes called "group" and "grid." The group axis ranges from individualism to solidarity, the grid axis from hierarchy to egalitarianism. What distinguishes cultural cognition from other versions of cultural theory is that it allows for a certain way to measure cultural worldviews, a focus on the social and psychological measures that explain the way culture shapes risk perceptions, and a focus on practical applications. The chapter addresses each of these points. It reviews various studies by Kahan and colleagues that show how influential people's cultural worldviews are on the kinds of risks they find salient and which experts they find trustworthy. One way to mitigate that effect is to have experts proclaim unexpected viewpoints, for example, a leftist looking expert making typical right-wing claims. However, Kahan notes that to do this would be ethically dubious. A solution would be to include a plurality of viewpoints in public debates, as this also leads to less predictable views amongst people.

### **Britt-Marie Drottz-Sjöberg: Tools for Risk Communication**

---

Britt-Marie Drottz-Sjöberg studies risk communication projects. She presents different risk communication tasks and derives several general conclusions. Tools for risk communication combine theoretical and applied insights. Drottz-Sjöberg discusses examples which show the influences of social and historic events on a communication setting or a conflict situation and how they shape a risk communication project. She also analyzes how values, attitudes, and feelings influence thinking and behavior within groups. The examples provide for heuristics for the improvement of risk communication. Drottz-Sjöberg also discusses the RISCOM model of transparency. She shows that risk communication always takes place in a social setting, involving various interests, power relations, and actors' own agendas. However, the aim to communicate about specific risks, nevertheless, can be focused on clarification, understanding, and learning. Drottz-Sjöberg describes tools for risk communication that aim at achieving clarity in dialogues, which are characterized by openness and interaction regarding risk issues, in order to enhance problem solving and democracy.

## Part 5: Risk Ethics

---

There is a growing consensus amongst risk scholars that risk is not a purely quantitative notion but also involves qualitative, normative, and ethical considerations. The dominant approach in risk analysis and risk management is to define risk as the probability of unwanted outcomes, such as annual fatalities, and to apply cost–benefit (or risk–benefit) analysis to determine which of various alternative technologies or activities is preferable. However, the question as to which unwanted outcomes to take into account already involves ethical considerations. Furthermore, cost–benefit analysis compares aggregates, whereas it is ethically significant how costs and benefits are distributed within a society. Social scientists and philosophers argue that ethical considerations such as justice, fairness, equity and autonomy have to be taken into account in assessing the acceptability of risk.

Interestingly, the same considerations can be found in the risk perceptions of laypeople that have been studied by Paul Slovic and others and which are discussed in the section on risk perception. Apparently, the intuitive responses to risk by laypeople include ethical aspects. The question arises why these considerations do not figure in the approaches of experts. This might be due to the fact that expert approaches are by definition focused on quantitative data and mathematical tools. Although these approaches can be helpful to a certain degree, they can lead to a tunnel vision that excludes other important considerations. In the context of risk it turns out that laypeople intuitively have a broader perspective that does justice to ethical considerations that can be normatively justified through established ethical theories.

The chapters in this section discuss ethical aspects of risk in more detail.

### Douglas MacLean: Ethics and Risk

---

The point of departure in Douglas McLean's contribution is the widespread belief that traditional ethical theories have little, if anything, to say about risk. Numerous contemporary scholars argue that moral philosophers of the past have simply failed to recognize the ethical issues related to risk, and that this is therefore an area in which more theoretical work is needed. McLean claims that this mainstream picture is not entirely true: Although risk has not been one of the major topics of ethical reflection in the past, it is easy to find examples of scholars who have explicitly discussed ethical principles for risk decisions. The most prominent examples are John Stuart Mill, Jeremy Bentham, and Robert Nozick; the latter, for instance, devoted an entire chapter of his influential book *Anarchy, State, and Utopia* to ethical principles for risk decisions. This means that the ethics of risk has been extensively analyzed within at least two ethical traditions, namely, utilitarianism and theories based on natural rights.

### Carl F. Cranor: Toward a Premarket Approach to Risk Assessment to Protect Children

---

Carl F. Cranor critically discusses risk legislation, specifically the postmarket approach to risk that is currently common in the USA and many other countries. In contrast with this, Cranor argues in favor of a premarket approach on which risks are assessed before products enter the market, similar to legislation concerning pharmaceuticals. Most industrial chemicals are

allowed to enter the market without any testing. Tests are done afterwards, which often leads to strategic behavior, such as claims concerning supposed insufficient evidence about risks. This happened in the case of the tobacco industry, which delayed legislation against smoking for decades. For 70% of the chemicals used for products, there are no toxicity data at all. Cranor reviews evidence of significant amount of traces of dangerous industrial chemicals that can be found in the population. He specifically focuses on health risks for children to give special force to his argument. Given the special vulnerability of small children and fetuses, they should be given additional protection. Legislation should require testing before chemicals are used in consumer products. This will lead to a paradigm shift in legislation as much as in scientific practice.

### **Sabine Roeser: Moral Emotions as Guide to Acceptable Risk**

---

Sabine Roeser explores the role emotions do and can play in debates about risky technologies. Most authors who write on risk and emotion see emotions as a threat to rational decision making about risks. These authors endorse Dual Process Theory, according to which emotion and reason are distinct faculties that have opposite tasks. However, based on recent developments in emotion research, an alternative picture of risk emotions is possible. According to various psychologists and philosophers who study emotions, emotions are a source of practical rationality. They are appraisals or judgments of value that have a cognitive aspect. These ideas can be applied to risk emotions. Emotions such as sympathy and compassion help to grasp morally salient aspects of risk, such as fairness, justice, and autonomy. This view allows for fruitful insights on how to improve public debates about risk, by taking emotional concerns of the public, but also of policy makers and experts, seriously. This approach leads to morally better judgments about risks, by doing justice to emotional-ethical concerns. In addition, as all parties will be taken seriously, it can also help to overcome the gap between experts and laypeople that currently so often leads to a deadlock in discussions about risky technologies.

### **Allison Ross and Nafsika Athanassoulis: Risk and Virtue Ethics**

---

Allison Ross and Nafsika Athanassoulis propose a virtue ethics approach to risk assessment. They argue that it is superior to consequentialist or deontological approaches to the moral assessment of risk. For example, consequentialist approaches to risk are not sensitive to morally salient aspects of risk such as recklessness, fairness, and equity. Risk assessment cannot be left to scientific experts. Risk-taking is both unavoidable and potentially morally problematic. Hence, it requires context-sensitive and reflective judgments. Ross and Athanassoulis argue that it is important to focus on the role of character and patterns of behavior in moral risk assessments. Such patterns should not be understood as the result of arbitrary, automatic processes but as the product of dispositions which constitute somebody's character. Character dispositions are developed through education, habituation, and reflection. They combine desires, emotions, and thoughts that are attuned to decision making about risk in specific circumstances. The authors argue that only virtue ethics with its emphasis on character provides for a framework for sensible and reflective risk judgments. They illustrate this with a hypothetical time-travel experiment in which an agent has to decide about risks for himself or herself and others.

## Philip J. Nickel and Krist Vaesen: Risk and Trust

---

Philip J. Nickel and Krist Vaesen discuss philosophical conceptions of the relationship between risk and trust. They distinguish between three main approaches. The first is a Hobbesian approach. This approach understands trust as a kind of risk assessment about the expected behavior of other people and the estimated benefits of cooperation. This approach comes close to expected utility theory, which is commonly used in formal decision theoretical approaches to risk. The second approach to risk and trust is in direct opposition with such a calculative risk assessment. On this approach, one willingly relies on people based on, for example, habitual, social, or moral reasons. On the third approach, trust is seen as a morally loaded attitude, in which one expects the trusted person to fulfill certain moral obligations. This allows for cooperative behavior in which there are no interpersonal risks. Nickel and Vaesen examine how these three approaches explain relationships between the concepts of risk and trust, also based on empirical research, specifically on cooperative breeding. They suggest that the notion of trust might help overcome the current gap between technocratic and social approaches to risk, if experts are more aware of their moral responsibilities rather than simply providing the public with information, which might create fears.

## Ibo van de Poel and Jessica Nihlén Fahlquist: Risk and Responsibility

---

Ibo van de Poel and Jessica Nihlén Fahlquist discuss the relationship between risk and responsibility. The authors start with noting that even though it is very common to link these two concepts in our daily practice, there is hardly any academic literature on it. They first discuss different conceptions of and connections between risk and responsibility. Van de Poel and Nihlén Fahlquist then elaborate on specific topics concerning responsibility for risk. They discuss the responsibility of engineers to contribute to risk reduction. They elaborate on the role of values and responsibility in risk assessment, risk management, and risk communication. An important distinction is the one between individual and collective responsibility for risk. The authors illustrate this with a case study from traffic safety. Van de Poel and Nihlén Fahlquist suggest various topics for future research, centered around the so-called problem of many hands in relation to climate change. The authors propose three possible lines of research to address this problem, which are responsibility as virtue, procedures for distributing responsibility, and institutional design.

## Madeleine Hayenjelm: What Is a Fair Distribution of Risk?

---

Madeleine Hayenjelm's chapter discusses the question as to what a fair distribution of risk is, partially based on insights from John Rawls's theory of justice. Hayenjelm starts out by reviewing what the objects of fairness are in the context of risk distributions. It is commonsensical that goods should be increased and risks should be diminished. This is also the underlying rationale of risk-cost-benefit analysis. However, such a consequentialist approach to risk overlooks issues of fair distribution, by only focusing on aggregate risks and benefits. Goods and risks should be distributed fairly. This can give rise to moral dilemmas. Hayenjelm discusses problems with equal distributions of probabilities of harm by focusing on a thought

experiment from James Lenman. She then reviews conditions under which deviations of equal distributions are justified and can still be fair. She suggests that this requires the justification of specific risky activities, and that higher risks for specific people should be mitigated by consent, precaution, and compensation.

### **Lauren Hartzell-Nichols: Intergenerational Risks**

---

Lauren Hartzell-Nichols discusses the notion of intergenerational risks – long-term threats of harm that will affect future people – using the example of climate change. She begins by noting that there is comparatively little material on intergenerational risk, and identifies two philosophical problems that are relevant for the issue: Parfit's Non-Identity Problem and Gardiner's Pure Intergenerational Problem. She introduces a distinction between *de re* and *de dicto* badness that can be illuminating. Hartzell-Nichols presents three current approaches to addressing intergenerational risks: (1) cost–benefit analysis, (2) precautionary principles, and (3) approaches based on intergenerational justice, for example, as discussed by Darrel Moellendorf, Henry Shue, Simon Caney, and Steven Vanderheiden. She argues why the two former approaches are problematic. Hartzell-Nichols finally notes that the debate on intergenerational risks point to the larger problem of anthropocentric versus non-anthropocentric ethics.

### **Marko Ahteesuu and Per Sandin: The Precautionary Principle**

---

Marko Ahteesuu and Per Sandin discuss the precautionary principle (PP). The PP is often conceived of as a decision-making principle that calls for early measures to avoid and mitigate hazards in the face of uncertainty, in particular, in the context of environmental problems. Ahteesuu and Sandin trace the PP to three sources: (1) the general idea of precaution, (2) nonjudicial codes of conduct and arguments from precaution, (3) and legal documents. They present three ways of conceiving of the PP: as a rule of choice, a procedural requirement, or as an epistemic principle, and the distinction between weak and strong versions of the PP. Ahteesuu and Sandin also discuss a number of common arguments against the PP, such as that it is ill-defined, self-refuting, or counterproductive. They end with observing that formal methods of inquiry have been insufficiently used in the study of the PP. Some topics that also warrant further research are the normative underpinnings of the principle, the status of the principle in risk analysis, and the relationship between the PP and stakeholder/public engagement.

### **Colleen Murphy and Paolo Gardoni: The Capability Approach in Risk Analysis**

---

Colleen Murphy and Paolo Gardoni discuss the way in which the capability approach might provide for fruitful insights concerning ethical aspects of risk and vice versa. The capability approach has been founded by the economist Amartya Sen and the philosopher Martha Nussbaum and has been extremely influential in the context of development. The capability approach allows to focus on a broader range of capacities, functionings, and achievings than

conventional approaches to development that mainly focus on the availability of goods, but not on what people can do with these goods. The authors discuss three ways in which the capability approach can contribute to risk theory: by focusing on capabilities rather than resources or utility, by focusing on threshold levels of capabilities instead of decision procedures, and by focusing on unacceptable or intolerable risks, which avoids the shortcomings of cost–benefit analysis. On the other hand, there are two ways in which risk theory can contribute to the capability approach, by focusing on security as an important dimension of capability, and by allowing a novel way to assess capabilities that looks further than actual functionings achievements.

## **Part 6: Risk in Society**

---

Given the importance of risk management in modern society, there are several aspects of risk that might, at one point, have seemed to be of mere theoretical interest, but now have vastly important implications for people's lives. The stock and insurance markets rely on methods developed by mathematicians, philosophers, and decision theorists. Increasingly complex technological systems rely on probabilistic methods for safety assessment; methods that could never have been developed without the prior work of risk theorists. In some instances the road from theory to application is short and straight, in other cases long and winding.

As citizens and human beings, we are increasingly required to relate to issues where risk theory is directly relevant in our everyday lives. We are asked to compare insurance policies, invest in the stock market, participate in referendums whether our country should rely on nuclear power or not, and make all kinds of choices where information about likelihood and consequences feed to us from a plethora of different sources.

This has not always been the case. Risk analysis and risk management, as we understand those activities today, are comparatively novel disciplines. We have seen a significant expansion of the field during the last 50 years or so, and the intellectual tools used are modern inventions, where “modern” means at least “post-Renaissance.” The most important of these tools – the mathematical analysis of chance events – is in essence a seventeenth-century invention (or perhaps discovery). It was pioneered by thinkers like Pascal, Descartes, and Bayes, and later refined. Pretty soon, it received its applications in the insurance business. The industrial revolution and the increased scope of the consequences of technology – from steam engines to nuclear power plants to genetically modified organisms and climate change – called for rapid development in the field.

Today, risk consciousness permeates nearly every area of societal life. This has not gone unnoticed by risk theorists, and it has given rise to a number of new disciplines, such as the psychology, sociology, and philosophy of risk. The contributions to this section discuss what Ulrich Beck has famously called “risk society,” or in other words, the ways society does and should cope with risk.

### **Rolf Lidskog and Göran Sundqvist: Sociology of Risk**

---

Rolf Lidskog and Göran Sundqvist begin by reviewing the historical background of general sociology. The focus of sociology is the relationship between society and the individual, and

this holds also for sociology of risk. The authors sketch the history of the sociology of risk and how it started from experts' recognition that public perceptions of risk differed from those of experts, and the attempts to explain this. They then go on to present three central sociological contributions in which risk occupies a prominent place – those of Mary Douglas, Ulrich Beck (1992), and Niklas Luhmann. Then they present five thematic areas which are subject to intense discussion in contemporary sociology of risk: organizational risk, the relation between experts and public, framing and risk, the epistemological status of risk, and governmentality and risk.

### Misse Wester: Risk and Gender: Daredevils and Eco-Angels

---

Misse Wester notes that empirical risk studies show consistent, systematic differences in risk perception between women and men, with focus on environmental issues and disasters. She identifies three different models to explain these differences that have been proposed in the literature: differences in knowledge of and familiarity with science, biological and social differences, and cultural differences. She argues that each model has problems of its own. She hypothesizes that knowledge plays an inferior role in risk perception in comparison to values, ideology, or cultural belonging and calls for further research in this area. She also calls for further research in the form of critical examination of the function of stereotypes in risk issues, and in the form of investigation of empirical studies of how women and men, respectively, are actually affected by crises and risk on a concrete level.

### Tsjalling Swierstra and Hedwig te Molder: Risk and Soft Impacts

---

Tsjalling Swierstra and Hedwig te Molder discuss a bias in current discourse about impact of technology. Policy makers and experts focus on quantifiable and supposedly value-neutral risk, rather than on other, less obviously measurable impacts, such as emotions, values, and subjective experiences. The authors call this “hard” and “soft” impacts, respectively. They examine how this distinction is theoretically and practically construed, by using two case studies. The first case study concerns an online forum for patients with gluten intolerance, and why some patients reject the idea of a pill that might cure them. The reason is that the pill would affect their identity. A second case study concerns how consumers are concerned about the naturalness of food. This concern is dismissed by experts as a private and invalid preference. The authors analyze how social structures shape the distinction between supposedly valid and invalid forms of and concerns about technological impacts. They distinguish how such impacts are evaluated, estimated, and caused. A better understanding of how the demarcation between hard and soft impacts is construed can contribute to overcoming this bias.

### Rinie van Est, Bart Walhout, and Frans Brom: Risk and Technology Assessment

---

Rinie van Est, Bart Walhout, and Frans Brom explore the relationship between risk assessment (RA) and technology assessment (TA), in particular, parliamentary TA, and how that has

evolved over the years since the early days of the Office of Technology Assessment in the USA in the 1970s. The disciplines differ, for instance, with regard to the concept of risk utilized. In RA, risk is typically understood as the product probability and the magnitude of consequences, while TA understands risk in a wider sense, as negative social impact. The authors consider two problems that occur in TA as well as in RA: the problem of representation, that is, who is allowed to define the risk problems under discussion. They discuss how participatory approaches have been developed to alleviate the problem. As a concrete illustration of present-day parliamentary TA, the authors recount the recent TA of nanotechnology carried out by the Rathenau Institute in the Netherlands, and its role in the country's governance of nanotechnology risks.

### **Marijke A. Hermans, Tessa Fox, and Marjolein B. A. van Asselt: Risk Governance**

---

Marijke A. Hermans, Tessa Fox, and Marjolein B. A. van Asselt write about risk governance, by which they mean attempts at an approach to deal responsibly with public risks which is broader in scope than the traditional categories of risk assessment, risk management, and risk communication, and utilizes several different notions of risk in addition to the classical idea of risk as a function of probability and consequences. They review the origins of the approach and the movement from early positivistic approaches to risk. The term “governance” became prominent in the 1980s, originally in studies of development, and was taken over by other subjects. Today the term “governance,” including in risk contexts, is used both in a descriptive and a normative sense, and the distinction is not always clear. Since 2003, considerable efforts have been made by the International Risk Governance Council (IRGC), an independent nonprofit Swiss-based foundation. The authors review current work and analyze it along three lines or principles, which they call “the communication and inclusion principle,” “the integration principle,” and “the reflection principle.”

### **Marjolein B. A. van Asselt and Ellen Vos: EU Risk Regulation and the Uncertainty Challenge**

---

Marjolein B. A. van Asselt and Ellen Vos introduce what they term “the uncertainty paradox,” referring to situations where uncertainty is acknowledged, but where the role of science is seen as providing certainty. The authors argue that it is not recognized that uncertainty undermines the traditional positivist model of knowledge. There are instances of uncertainty intolerance, where uncertainty is not acknowledged and there is unwillingness to produce uncertainty information. To illustrate this, the authors give examples from their analyses of several cases in regulation of risk in the EU, for instance, involving the European Food Safety Authority. They note that uncertainty intolerance is prevalent, but also that there is a tendency to equate uncertainty with risk. They suggest further research involving systematic comparison between risk regulation regimes in different domains. As particularly important topics, they mention the role of science and expertise in decision making and policy, how to deal with uncertainty and trust, the role of the precautionary principle, and stakeholder participation.

## Val Dusek: Risk Management in Technocracy

Dusek critically discusses technocratic risk management approaches. The idea underlying much of the current risk management in Western societies is the assumedly superior expert understanding of risk. Such technocratic tendencies in how we deal with risk can be seen in the large number of government committees, commissions, and corporate departments that issue risk assessments and attempt to manage risks. While several contributions to this handbook challenge the quantitative, Bayesian approach to risk assessment, Dusek critically examines the general attitude of mind underlying this approach. Dusek traces technocratic risk management back to the ideal of the superiority of technocratic rationality as advocated by Plato, the seventeenth-century rationalist as well as Francis Bacon and the British empiricists. He explicates and challenges the ideal of an expert rule, following the technology critique of the critical theory of the Frankfurter Schule and existential philosophy, Dusek does not reject risk analysis and risk management, but thinks that the technocratic trend in risk management which builds on the objectivity, universality, and publicity of science, has to be supplemented by other approaches such as the recent work of Gigerenzer.

## Conclusion

This *Handbook of Risk Theory* unites scholars from disciplines ranging from mathematics and the natural sciences to the social sciences, humanities, and philosophy. However, as diverse as the approaches and topics are, there is one issue that emerges from practically all contributions, namely that risk involves statistics as much as ethics and social values. There are as yet no final answers on how to deal with risk, nor will there probably ever be such answers, but there nevertheless is a consensus that risk should be approached from different perspectives, including those of stakeholders and the public. This requires “sound science” (broadly conceived, i.e., including social sciences, humanities and philosophy), as much as sound political institutions. When it comes to risk, theory and practice are closely intertwined.

**Abstract:** The role of philosophy in the development of the risk sciences has been rather limited. This is unfortunate since there are many problems in the analysis and management of risk that philosophers can contribute to solving. Several of the central terms, including “risk” itself, are still in need of terminological clarification. Much of the argumentation in risk issues is unclear and in need of argumentation analysis. There is also still a need to uncover implicit or “hidden” values in allegedly value-free risk assessments. Eight philosophical perspectives in risk theory are outlined: From the viewpoint of *epistemology*, risk issues have brought forth problems of trust in expertise and division of epistemological labor. In *decision theory*, the decision-maker’s degree of control over risks is often problematic and difficult to model. In the *philosophy of probability*, posterior revisions of risk estimates (in so-called hindsight bias) pose a challenge to the standard model of probabilistic reasoning. In the *philosophy of science*, issues of risk give us reason to investigate what influence the practical uses of knowledge can legitimately have on the scientific process. In the *philosophy of technology*, the nature of safety engineering principles and their relationship to risk assessment need to be investigated. In *ethics*, the most pressing problem is how standard ethical theories can be extended or adjusted to cope with the ethics of risk taking. In the *philosophy of economics*, the comparison and aggregation of risks falling to different persons give rise to new foundational problems for the theory of welfare. In *political philosophy*, issues such as trust and consent that have been discussed in connection with risk give us reason to reconsider central issues in the theory of democracy.

## Introduction

---

Philosophy is often seen as an unworldly discipline, dealing with abstract and contrived issues that have very little connection with real life. Concededly, philosophy has a long tradition of unabashedly delving into intellectual problems that have no immediate application. In this it does not differ from most other academic disciplines. But philosophy also has another side. It has a strong tradition, going back at least to Socrates and Aristotle, of probing into issues that societies and individuals need to understand better in order to solve practical problems. And just as in other disciplines, some of the progress made in studies driven by pure intellectual curiosity has turned out to provide us with indispensable tools for investigations aimed at solving practical problems. Examples of this can be found in the philosophy of risk as well as other areas of applied philosophy.

In what follows, a brief historical background (section [❶ Historical Background](#)) will be followed by a presentation of the major types of contributions that philosophy can make to risk research (section [❷ What Philosophy Can Contribute](#)) and an overview over eight philosophical perspectives on risk (section [❸ Philosophical Perspectives in Risk Theory](#)). Finally, some topics for further research will be summarized (section [❹ Further Research](#)).

## Historical Background

---

Modern risk research originated in studies from the 1960s and 1970s that had a strong focus on chemical risks and the risks associated with nuclear energy. From its beginnings, risk research drew on competence in areas such as toxicology, epidemiology, radiation biology, and nuclear engineering. Today, many if not most scientific disciplines provide risk analysts with specialized

knowledge needed in the study of one or other type of risk – medical specialties are needed in the study of risks from diseases, engineering specialties in studies of technological failures, etc. In addition, several disciplines have supplied overarching approaches to risk, intended to be applicable to risks of different kinds. Statistics, epidemiology, economics, psychology, anthropology, and sociology are among the disciplines that have developed general approaches to risk.

Philosophers did not have a big role in the early development of risk analysis. Most of the philosophical contributions to the area were in fact outsiders' criticisms of risk analysis. There was a strong tendency in the early development of risk analysis to downplay value issues. Risk assessments were presented as objective scientific statements, even when taking a stand on value-laden issues such as risk acceptability. Most of the early philosophical work on risk had as its main purpose to expose the value-dependence of allegedly value-free risk assessments (Thomson 1985b; MacLean 1985; Shrader-Frechette 1991; Cranor 1997; Hansson 1998). This was an important task, and it was also undertaken with some success. Although hidden value assumptions are still common in risk assessments, there is now much more awareness of their presence. Philosophers who took part in these discussions certainly contributed to the steps that have been taken to keep facts and values apart as far as possible in the assessment of risk, in particular attempts to divide the risk-decision process into a fact-finding risk-assessment part and a value-based risk-management phase (National Research Council 1983).

In the 1990s, philosophers increasingly discovered many other risk-related issues in need of philosophical clarification. Philosophers have studied the nature of risks, the specific characteristics of knowledge about risk, the ethics of risk taking, its decision-theoretical aspects, the implications of risk in political philosophy, and several other areas. It is too early to write the history of these developments, but a pattern emerges in which most of the major subdisciplines of philosophy turn out to have important risk-related issues to deal with. These developments will be introduced in section  [Philosophical Perspectives in Risk Theory](#), but before that we are going to look more closely at the nature of the philosophical contribution.

## What Philosophy Can Contribute

---

Philosophy is unique in having potential connections with virtually every other academic discipline. Philosophical concepts and methods have proven to be applicable to a wide variety of problems in other academic disciplines. When you probe into almost any field of learning, interesting problems of a philosophical nature tend to emerge. Unfortunately, this potential is underused, largely due to intellectual isolation and to the “two-cultures” phenomenon that separates philosophers from empirical scientists.

The contributions of philosophy to other disciplines and to interdisciplinary cooperations can be of many kinds, but experience shows that there are certain ways in which philosophy has particularly often turned out to be useful. Three of them are especially important in risk research:

- *Terminological clarifications:* Philosophy has a long tradition of constructing precise definitions and developing new distinctions, often beyond the limits of what can readily be expressed with current linguistic means. Armed with standard tools and distinctions from philosophy, philosophers can often contribute to conceptual clarification in other disciplines.

- *Argumentation analysis:* Arguments, as we express them in scientific or social debates, tend to depend on unstated assumptions. Using the tools of logic and conceptual analysis philosophers can often exhibit hidden assumptions and clarify the structure of arguments.
- *The fact–value distinction:* Factual input from science has a large and increasing role in debates on social issues. This applies to virtually all branches of science: economics, behavioral science, environmental science, climatology, medical science, technological sciences, etc. But even if scientists try to make their statements as value-independent as possible, they do not always succeed in this. Philosophical tools are useful in identifying the values that are inherent in science-based information.

In the following three subsections, we will have a brief look at each of these types of contribution, in order to show how philosophical method can contribute to investigations of risk that are performed primarily by researchers in other fields.

## Terminological Clarification

---

As in many other research areas, the terminology in risk research is often imprecise. This applies even to key terms such as “risk” and “safety.” The word “risk” has been taken over from everyday language, where it is used (often somewhat vaguely) to describe a situation in which we do not know whether or not some undesired event will occur. In risk analysis, two major attempts have been made to redefine risk as a numerical quantity. First, in the early 1980s, attempts were made to identify risk with the probability of an unwanted event (Fischhoff et al. 1981; Royal Society 1983, p. 22). This usage has some precedents in colloquial language; we may for instance say that “the risk that this will happen is one in twenty.” Secondly, in more recent years, several attempts have been made to identify risk with the statistical expectation value of unwanted events. By this is meant the product of an event’s probability with some measure of its undesirability. If there is a probability of 1 in 100 that three people will die, then “the risk” is said to be 0.03 deaths. Currently, this is by far the most common technical definition of risk (International Organization for Standardization 2002; Cohen 2003).

From the viewpoint of philosophical definition theory (Hansson 2006b), this terminology is problematic in at least two ways. First, it conflates “risk” with “severity of risk.” It makes sense to say that a probability of 1 in 1,000 that one person will die in a roller coaster accident is “equally serious” as a probability of 1 in 1,000,000 that 1,000 people will die in a nuclear accident, but it does not make sense to say that these two are the same risk (namely 0.001 deaths). They are in fact risks with quite different characteristics.

Secondly, it is a controversial value statement that risks with the same expectation value of undesirable events are always equally serious. Some authors have claimed that serious events with low probabilities should be given a higher weight in decision making than what they receive in the expected utility model (O’Riordan and Cameron 1994; O’Riordan et al. 2001; Burgos and Defeo 2004). The identification of “risk” with expectation values has the unfortunate effect of ruling out this view on the severity of risk by means of a terminological choice. In order to achieve clarity in discussions on risk, we need to make a clear distinction between a risk and its severity, and we also need to avoid terminology that takes controversial standpoints on what constitutes risk severity for granted. Therefore, a term such as “expected damage” is much preferable to “risk” as a designation of the statistical expectation values employed in risk analysis (Hansson 2005).

Besides “risk,” several other terms used in risk studies are in need of terminological clarification. Prominent among these are “safety” and “precautionary principle.”

“Safety” has sometimes been defined as a situation without accidents (Tench 1985) and on other occasions as a situation with an acceptable probability of accidents (Miller 1988). In a recent philosophical analysis of the concept, it was shown that usage of the terms “safe” and “safety” vacillates between an absolute concept (“safety means no harm”), and a relative concept that only requires such risk reductions that are considered to be feasible and reasonable. It may not be possible to eliminate either of these usages, but it is possible to keep track of them and avoid confusing them with each other (Möller et al. 2006).

The “precautionary principle” is a principle for decision making under scientific uncertainty that has been codified in a several international treaties on environmental policies. Its major message is that policy decisions in environmental decisions can legitimately be based on scientific evidence of a danger, even if that evidence is not strong enough to constitute full scientific proof that the danger exists. There has been considerable controversy on the precise meaning of the principle. A careful philosophical analysis showed that the major definitions of the precautionary principle contain four major components, namely (1) a threat to the environment or to human health, (2) a degree of uncertainty that is sufficient for action (such as “even before scientific proof is established”), (3) the action that is then taken (e.g., “warn” or “forbid”), and (4) the level of prescription (e.g., “is mandatory”) (Sandin 1999). The first two of these can be summarized as the *trigger* of the precautionary principle, whereas the last two constitute the *precautionary response* (Ahteesuu 2008). Although this analysis does not resolve the controversies on the principle, it facilitates a precise understanding of these controversies.

## Argumentation Analysis

---

Ever since Aristotle, logical and argumentative fallacies have been an important topic in philosophy (Walton 1987). It is not difficult to find examples of traditional fallacies such as ad hominem in discussions on risk. In addition, there are fallacies that are specific to the subject matter of risk. The following is a sample of such fallacies:

Risk X is accepted.

*Y is a smaller risk than X.*

∴ Y should be accepted.

*Risk X is natural.*

∴ X should be accepted.

*X does not give rise to any detectable risk.*

∴ X does not give rise to any unacceptable risk.

*There is no scientific proof that X is dangerous.*

∴ No action should be taken against X.

*Experts and the public do not have the same attitude to risk X.*

∴ The public is wrong about risk X.

*A's attitude to risk X is emotional.*

∴ A's attitude to risk X is irrational.

For examples of the first five of these fallacies and clarifications of why they are fallacies, see Hansson (2004b). For the last of these fallacies, see Roeser (2006).

## The Fact-Value Distinction

---

As already mentioned, the task of uncovering hidden value assumptions in risk assessments often requires philosophical competence. Implicit value components of complex arguments have to be discovered, and conceptual distinctions relating to values have to be made. Often, other competences are required as well. A thorough understanding of the technical contents of risk assessments is needed in order to determine what factors influence their outcomes (Hansson and Rudén 2006). This is an area in which cooperations between philosophy and other disciplines can be very fruitful.

For the philosophical part of this work, two distinctions are particularly important. The first is the seemingly trivial but, in practice, often overlooked distinction between being value-free and being free of controversial values. There are many values that are shared by virtually everyone or by everyone who takes part in a particular discourse. Medical science provides good examples of this. When discussing analgesics, we take for granted that it is better if patients have less rather than more pain. There is no need to interrupt a medical discussion in order to point out that a statement that one analgesic is better than another depends on this value assumption. Similarly, in economics, it is usually taken for granted that it is better if we all become richer. Economists sometimes lose sight of the fact that this is a value judgment. Obviously, a value that is uncontroversial in some circles may be controversial in others. This is one of the reasons why values believed to be uncontroversial should be made explicit and not treated as non-values.

The other distinction is that between epistemic and non-epistemic values. Most of the values that we usually think of in connection with risk policies are non-epistemic. The epistemic values are those that rule the conduct of science. Among the most commonly mentioned examples of such values are the attainment of truth, the avoidance of error, simplicity, and explanatory power. It was Carl Hempel who pointed out that these should be treated as values, although they are not moral values (Hempel 1960; Levi 1962; Feleppa 1981; Harsanyi 1983). Epistemic values are not necessarily less controversial than non-epistemic ones, but these are different types of controversies that should be kept apart.

The following are three examples of values that are often implicit or “hidden” in risk assessments:

1. *Values of error-avoidance:* Two major types of errors can be made in a scientific statement. Either you conclude that there is a phenomenon or an effect that is in fact not there. This is called an error of type I (a false positive). Or you miss an existing phenomenon or effect. This is called an error of type II (a false negative). In scientific practice, errors of type I are the more serious ones since they make us draw unwarranted conclusions, whereas errors of type II only make us keep an issue open instead of adopting a correct hypothesis. As long as we stay in the realm of pure science, the relative weights that we assign to the two types of error express our epistemic values, and they need not have any connection with our non-epistemic values. However, when scientific information is transferred to risk assessment, values of error-avoidance are transformed into non-epistemic and often quite controversial values. Consider the question “Does Bisphenol A impair infant brain development?” In a purely scientific context, the level of evidence needed for an affirmative answer to this question is a matter of

epistemic values. (How close to certainty should we be in order to take something to be a scientific fact?) In a risk assessment context, the relevant issue is what level of evidence we need to act as if the substance has this effect. This is a matter of non-epistemic values. (How much evidence is needed for treating the substance as toxic to infants?) In a case like this, a focus on epistemic values will usually lead to more weight being put on the avoidance of type I errors than type II errors, whereas a focus on non-epistemic values can have the opposite effect.

The distinction between a scientific assessment and a judgment of what should be done given the available scientific information is both fundamental and elementary, but it is nevertheless often overlooked (Rudén and Hansson 2008). It is not uncommon to find scientists unreflectingly applying epistemic standards of proof in risk assessment contexts where they are not warranted. It should be said to their defense that this is often more difficult to avoid than what one would perhaps think. Scientists are educated to focus on type I errors, and the tools of science are often ill suited to deal with type II errors. As one example of this, standard statistical practices for the evaluation of empirical data that have been tailored to the epistemic issue need to be adjusted in order to deal adequately with the risk assessment situation in which type II errors are usually more important (Krewski et al. 1989; Cranor and Nutting 1990; Leisenring and Ryan 1992; Hansson 1995, 2002).

2. *The value of naturalness:* In public debates, risks associated with GMOs or synthetic chemicals are often denounced as “unnatural.” This argument is seldom used in risk assessments, but a converse version of it can sometimes be found, most often in connection to radiation. Radiation levels are frequently compared to the natural background with the tacit assumption that exposures lower than the natural background are unproblematic. In health risk assessments, this is a very weak argument. That something is natural does not prove that its negative effects on human health are small (Hansson 2003a). In ecological risk assessments, an argument referring to naturalness may be more relevant. If we want to protect the natural environment, then it is important to know what is natural. However, appeals to naturalness or unnaturalness are often made in a perfunctory way in discussions on ecological risk, and there is much need for clarification and analysis.
3. *Attitudes to sensitive individuals:* Risk assessments tend to focus on individuals with average sensitivity to the exposure in question. However, individual sensitivity differs and in many cases it is possible to identify groups of exposed persons who run a larger risk than others. According to the best available estimates, the radiogenic cancer risk is around 40% higher for women than for men at any given level of exposure. There are also small groups in the population who run a much higher risk. However, the recommended exposure limits are based on a population average rather than data for subpopulations (Hansson 2009a). From an ethical point of view, this is problematic. Exposing a person to a high risk cannot be justified by pointing out that the risk to an average person would have been much lower. Nevertheless, sensitive groups are often overlooked or disregarded in risk assessments, and the ethical implications of doing so are seldom discussed. It often takes careful study to reconstruct and analyze the underlying value assumptions.

## Philosophical Perspectives in Risk Theory

In the previous section, we encountered several ways in which philosophers can contribute to interdisciplinary risk studies. Such contributions can be seen as applications of philosophy,

mostly without much influence on the core of philosophical research. But the interaction between philosophy and risk studies does not end there. In recent years, it has become increasingly clear that risk has implications in many if not most of the philosophical subdisciplines. In what follows, we will have a look at several of these subdisciplines. In some of them, there is already an established tradition of studying risk. In others, little has yet been done, but interesting issues for future research can nevertheless be pointed out.

## Epistemology

---

Risks are always connected to lack of knowledge. If we know for certain that there will be an explosion in a factory, then there is no reason for us to talk about that explosion as a risk. Similarly, if we know that no explosion will take place, then there is no reason either to talk about risk. What we refer to as a risk of an explosion is a situation in which it is not known whether or not an explosion will take place. In this sense, knowledge about risk is knowledge about the unknown. It is therefore a quite problematic type of knowledge. It gives rise to several important epistemological questions that have not been much studied. Two of them will be mentioned here.

### The Limits of Epistemic Credibility

Some issues of risk refer to possible dangers that we know very little about. Recent debates on biotechnology and nanotechnology are examples of this. It is easy to find examples in which many of us would be swayed by considerations of unknown dangers. Suppose that someone proposed to eject a chemical substance into the stratosphere in order to compensate for the anthropogenic greenhouse effect. It would not be irrational to oppose this proposal solely on the ground that it may have unforeseeable consequences, even if all specified worries can be neutralized.

But on the other hand, it would not be feasible to take the possibility of unknown effects into account in all decisions that we make. Given the unpredictable nature of actual causation, almost any decision may lead to a disaster. We therefore have to disregard many of the more remote possibilities. It is easy to find examples in which it can be seen in retrospect that it was wise to do so. In 1969, *Nature* printed a letter that warned against producing polywater, polymerized water. The substance might “grow at the expense of normal water under any conditions found in the environment,” thus replacing all natural water on earth and destroying all life on this planet (Donahoe 1969). Soon afterward, it was shown that polywater does not exist. If the warning had been heeded, then no attempts would have been made to replicate the polywater experiments, and we might still not have known that polywater does not exist. In cases like this, appeals to the possibility of unknown dangers may stop investigations and thus prevent scientific and technological progress.

It appears to be an unavoidable conclusion that we should take some but not all remote possibilities seriously. But which of them? What about the warnings that global warming might soon be aggravated by feedbacks that lead to a run-away greenhouse effect totally beyond our control, the warnings that the greenhouse effect may not exist at all, the warnings that mobile phones might have grave health effects, and that high-energy physics experiments might lead to an apocalypse? We are in need of concepts and criteria to discuss such issues in a systematic way, but as yet very little research has been performed on how to assess epistemic credibility in cases like this (Hansson 1996, 2004d).

## The Legitimacy of Expertise in Uncertain Issues

In many issues of risk, we have seen wide divergences between the views of experts and those of the public. This is clearly a sign of failure in the social system for division of intellectual labor. However, it should not be taken for granted that every such failure is located within the minds of the nonexperts who distrust the experts. Experts are known to have made mistakes. A rational decision-maker should take into account the possibility that this may happen again. This will be particularly important in cases when experts assign very low probabilities to a highly undesirable event. Suppose that a group of experts have studied the possibility that a new microorganism that has been developed for therapeutic purposes will mutate and become virulent. They have concluded that the probability that this will happen is 1 in 100,000,000. Decision-makers who receive this report should of course consider whether this is an acceptable probability of such an event, given the advantages of using the new organism. But, arguably, this is not the most important question they should ask. The crucial issue is how much reliance they should put on the estimate. If there is even a very small probability that the experts are wrong, say a probability that we in some way estimate as 1 in a million, then that will be the main problem to deal with. In cases like this, reliance on experts creates serious epistemic problems that we do not yet seem to have adequate tools to analyze.

## Decision Theory

---

A risk (in the informal sense of the word) is a situation in which some undesirable event may or may not occur, and we do not know which. Probability theory is a tool for modeling such situations. However, it should not be taken for granted that all such situations can be adequately modeled in that way. In many cases, our knowledge is so incomplete that no meaningful probability estimates are obtainable. In other cases, the situation may have features that make it unsuitable for probabilistic modeling. This applies in particular to risks that depend on complex interactions between independent agents. We all try both to influence the choices that others make and to foresee them and adjust to them. Therefore, our choices will depend in part on how we expect others to react and behave, and conversely their choices will depend on what they expect from us. Such interpersonal interactions are extremely difficult to capture in probabilistic terms.

This applies not least to malevolent action, such as the actions of an enemy, a saboteur, or a terrorist. Such agents try to take their adversaries with surprise. It is in practice impossible – and perhaps even counterproductive – to make probability estimates of their actions. For most purposes, a game-theoretical approach that makes no use of probabilities is more adequate to deal with inimical actions than models that employ probability estimates.

The use of probabilistic models is also problematic in situations where we have to take a whole series of decisions into account. The crucial issue here is whether or not one should treat one's own future choices and decisions as under one's present control (Spohn 1977; Rabinowicz 2002). The consequences at time  $t_3$  of your actions at time  $t_1$  are not determinate if you have an intermediate decision point  $t_2$  at which you can influence what happens at  $t_3$ . In a moral appraisal of your actions at  $t_1$ , you have to decide whether to treat your actions at  $t_2$  as under your own control at  $t_1$  or as beyond your control at that point in time. In the former case, a decision at  $t_1$  can bind your actions at  $t_2$ ; in the latter case, it cannot do so. Consider the following two examples:

### Example 1

A nonsmoker considers the possibility to smoke for just 1 week and then stop in order to achieve a better understanding of why so many people smoke. When making this decision, should she regard herself as being in control of the future decision whether or not to stop after a week? Or should she make a probabilistic appraisal of what she will do in that situation?

### Example 2

A heavy cigarette smoker considers whether or not to try to quit. When making this decision, should she regard herself as being in control of future decisions whether or not to start smoking again? Or should she make a probabilistic appraisal of her future decisions? From such a viewpoint, quitting may seem to have a too meager prospect of success to be worth trying (Hansson 2007a).

Probably, most of us would recommend the non-control (probabilistic) approach to future decisions in Example 1 and the control (non-probabilistic) approach in Example 2. However, no general rule seems to be available to determine when a probabilistic approach to one's own future decisions is appropriate. Since most risk issues seem to require decisions on more than one occasion, this is a problem with high practical relevance. We have access to sophisticated decision-theoretical models that employ probabilities, but we do not have tools to determine when we should use these models and when we should instead use non-probabilistic approaches.

---

## Philosophy of Probability

An average person's yearly risk of being struck by lightning is somewhat below one in a million (Lopez and Holle 1998). Risks of that magnitude have often been considered "negligible." After the Deepwater Horizon oil spill in 2010, BP's chief executive, Tony Hayward, said that the risk of this spill had been "one in a million" (Cox and Winkler 2010). However, there was no sign that the public – or the public authorities – were willing to discuss BP's responsibility from the premise that the accident was almost as unlikely as being struck by lightning. The fact that the accident had occurred was generally taken as proof that the company had not taken sufficient measures to prevent it from happening.

This example reveals a common pattern in how we argue about probabilities in the context of risks. If the expected utility argumentation were followed to the end, then many accidents would be defended as consequences of a maximization of expected utility that is, *in toto*, beneficial. But, such an argument is very rarely heard in practice. Once a serious accident has happened, not much credence is given to the calculations showing that it was highly improbable. Instead, the very fact that the accident happened is taken as evidence that its probability was higher than estimated. Such reasoning has been disparaged by some as a fallacy, "hindsight bias" (Levi 1973; Fischhoff 1977). But it is not a fallacy.

Suppose that we know that a certain accident took place yesterday. Then the probability that it *did* happen was 1. Nevertheless, the probability that it *would* happen can have been much lower, say 1 in 100. As was observed by Blackburn in a different context, these are two distinctly different types of probabilities. "We can say that the probability of an event was high at some

time previous to its occurrence or failure to occur, and this is not to say that it is now probable that it did happen" (Blackburn 1973, p. 102).

A simple example serves to show that our estimates of past probabilities can legitimately be influenced by information about what happened after the events in question. Suppose that a die was tossed 1,000 times yesterday. My original belief about the chance of a six on the first toss was that it was 1/6. When I learn that all the 1,000 tosses yielded a six, I change my opinion and assign a probability close to 1 to the event to which I previously had assigned 1/6. This is sensible since it is much more plausible that a die is biased than that a fair die yields the same outcome in 1,000 tosses.

The same principle applies to the probabilities referred to in risk analysis, such as the probability of an accident. Suppose that a new type of nuclear reactor is built. Nuclear engineers argue persuasively that it is much safer than previous designs. They convince us that the probability of a core damage ("meltdown") is 1 in  $10^8$ . However, after the first reactor of the new type has been in service for only a couple of months, a serious accident involving core damage occurs. Probably, most people would not see this as an example of an extremely improbable event taking place. Instead, they would see the accident as a very strong indication that the probability estimate 1 in  $10^8$  was wrong. Just as in the example with the die, it would be perfectly rational to substantially revise one's estimate of the probability, perhaps from 1 in  $10^8$  to 1 in  $10^5$  or even higher. However, this is not an ordinary (Bayesian) revision of probabilities (A Bayesian revision refers to the probability that the accident actually took place, and thus takes us all the way from  $10^{-8}$  to 1). This is a nonstandard form of probabilistic revision. It can be accounted for in terms of second-order probabilities (Hansson 2009b, 2010b), but its properties and its implications in assessments of risk remain to be investigated.

## Philosophy of Science

In order to understand the relationship between risk assessments and scientific knowledge, it is useful to take intrascientific knowledge production as a starting point. The production of scientific knowledge begins with data that originate in experiments and other observations. Through a process of critical assessment, these data give rise to the scientific corpus (See [Fig. 2.1](#)). The corpus consists of that which is taken for given by the collective of researchers in their continued research and, thus, not questioned unless new data give reason to question it (Hansson 2007b). Hypotheses are included into the corpus when the data provide sufficient evidence for them, and the same applies to corroborated generalizations that are based on explorative research.

**Fig. 2.1**  
The knowledge-formation process in pure science

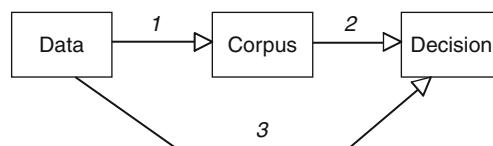

The scientific corpus is a highly complex construction, much too large to be mastered by a single person. Different parts of it are maintained by different groups of scientific experts. These parts are all constantly in development. New statements are added, and old ones removed, in each of the many subdisciplines, and a consolidating process based on contacts and cooperations among interconnected disciplines takes place continuously. In spite of its complex structure, the corpus is, at each point in time, reasonably well defined. In most disciplines, it is fairly easy to distinguish those statements that are, for the time being, generally accepted by the relevant experts from those that are contested, under investigation, or rejected. Hence, although the corpus is not perfectly well defined, its vague margins are fairly narrow.

The process that leads to modifications of the corpus is based on strict standards of evidence that are an essential part of the ethos of science. Those who claim the existence of an as yet unproven phenomenon have the burden of proof. In other words, the corpus has high entry requirements. This is essential to protect us against the importation of false beliefs into science.

But as we noted in section [❶ The Fact – Value Distinction](#), scientific information is often used not only to guide the progress of science but also to guide practical decisions. As one example of this, studies of the anthropogenic greenhouse effect are used both to achieve more reliable scientific knowledge about what happens to the climate and to determine what practical decisions to take in climate policies. In this and many other cases, two decisions have to be based on the same scientific information: the intrascientific decision concerning what to believe and an extrascientific (practical) decision concerning what to do. These are two different decisions, although they make use of the same scientific data.

[❷ Figure 2.2](#) illustrates the practical use of scientific information (Hansson 2004c). The obvious way to use science for decision-guiding purposes is to employ information from the corpus (arrow 2). In many cases, this is all that we need to do. The high entrance requirements of the corpus have the important effect that the information contained in it is dependable enough to be relied on in almost all practical contexts. Only on very rare occasions do we need, for some practical purpose, to apply stricter standards of evidence than those that regulate corpus inclusion.

However, the high entry requirements of the corpus also have another, more complicating implication. On some occasions, evidence that was not strong enough for corpus entry may nevertheless be strong enough to have legitimate influence in some practical matters. To exemplify this, suppose that a preservative agent in baby food is suspected of having a negative health effect. The evidence weighs somewhat in the direction of there being an effect, and most scientists consider it to be more probable that the effect exists than that it does not. Nevertheless, the evidence is not conclusive, and the issue is still open from a scientific point of view. Considering what is at stake, it would be perfectly rational for a food company or a government agency to cease the use of the substance. Such a decision would have to be informed by scientific information that did not satisfy the criteria for corpus entry. More generally speaking, it would not seem rational – let alone morally defensible – for a decision-maker

**Fig. 2.2**

The use of scientific data for decision-making

to ignore all preliminary indications of a possible danger that do not amount to full scientific proof. We typically wish to protect ourselves against suspected health hazards even if the evidence is much weaker than what is required for scientific proof. As was indicated in section **● The Fact – Value Distinction**, in order to guide the type of decisions that we want to make, these decisions have to be based on standards of evidence that differ from the criteria used for intrascientific purposes. Evidence that is weaker than the requirements for corpus entry cannot influence decisions in the “standard” way that is represented in **● Fig. 2.2** by arrows 1 and 2. In cases like this, we need to take a direct way from data to practical decision-making (arrow 3).

Just like the process represented by arrow 1, the bypass route represented by arrow 3 involves an evaluation of data against criteria of evidence. However, the two evaluation processes differ in being calibrated to different criteria for the required strength of evidence. The process of arrow 1 is calibrated to the standard scientific requirements, whereas that of arrow 3 is calibrated to criteria corresponding to the needs of a practical decision. However, the latter process is nevertheless in important respects a scientific one. From the viewpoint of philosophy of science, it is a challenge to clarify the nature of argumentation and decision processes like this that contain a mixture of scientific and policy-related components.

From a somewhat more practical point of view, it is essential to ensure that the bypass route does not lead to inefficient use of the available scientific information. In order to see what this requires, it is instructive to compare the processes represented by arrows 1 and 3. First of all, there should be no difference in the type of evidence that is taken into account. Hence, in the baby-food example, the same experimental and epidemiological studies are relevant for the intrascientific decision (arrow 1) and for the practical one (arrow 3). The evidence is the same, although it is used differently. Furthermore, the assessment of how strong the evidence is should be the same in the two processes. What differs is the *required* level of evidence for the respective purposes (Hansson 2008).

The term “precautionary principle” has often been used to designate the process illustrated by arrow 3 in our diagram (cf. section **● Terminological Clarification**). But the need for a special principle can be put in doubt. Once it is recognized that the principle applies to practical decisions, it will be seen that the importation of practical values that this route makes possible is not only legitimate but in many cases also rationally required. From a decision-theoretical point of view, allowing decisions to be influenced by uncertain information is not a special principle that needs to be specially defended. To the contrary, doing so is nothing else than ordinary practical rationality, as it is applied in most other contexts. If there are strong scientific indications that a volcano may erupt in the next few days, decision-makers will expectedly evacuate its surroundings as soon as possible, rather than waiting for full scientific evidence that the eruption will take place. More generally speaking, it is compatible with – and arguably required by – practical rationality that decisions be based on the available evidence even if it is incomplete.

Although the account given here is a reasonable ideal account, it is far from easy to implement in practice. If we want to take uncertain indications of toxicity seriously, then this has implications not only on how we interpret toxicological tests but also on our appraisals of more basic biological phenomena. If our main concern is not to miss any possible mechanism for toxicity, then we must pay serious attention to possible metabolic pathways for which there is insufficient proof. Such considerations in turn have intricate connections with various issues in biochemistry and, ultimately, we are driven to reappraise an immense number of empirical conclusions, hypotheses, and theories. Due to our cognitive limitations, this cannot

in practice be done. In practice, we will have to rely on the corpus in most issues and use the detour (arrow 3) only in a limited number of selected issues. It remains to clarify how such partial adjustments are best made.

## Philosophy of Technology

---

Since the nineteenth century, engineers have specialized in worker's safety and other safety-related tasks. With the development of technological science, the ideas behind safety engineering have been subject to academic treatments. However, most of the discussion on safety engineering is fragmented between different areas of technology. The same basic ideas or "safety philosophies" seem to have been developed more or less independently in different areas of engineering. Therefore, the same or similar ideas are often discussed under the different names for instance by chemical, nuclear, and electrical engineers. But a recent study has shown that there is much unity in this diversity. In spite of the terminological pluralism, and the almost bewildering number of similar or overlapping safety principles, much of the basic thinking seems to be the same in the different areas of safety engineering (Möller and Hansson 2008). In order to see what these basic ideas are, let us consider three major principles of safety engineering: inherent safety, safety factors, and multiple barriers.

### Inherent Safety

Also called primary prevention, inherent safety consists in the elimination of a hazard. It is contrasted with secondary prevention that consists in reducing the risk associated with a hazard. For a simple example, consider a process in which inflammable materials are used. Inherent safety would consist in replacing them by noninflammable materials. Secondary prevention would consist in removing or isolating sources of ignition and/or installing fire-extinguishing equipment. As this example shows, secondary prevention usually involves added-on safety equipment.

The major reason to prefer inherent safety to secondary prevention is that as long as the hazard still exists, it can be realized by some unanticipated triggering event. Even with the best of control measures, if inflammable materials are present, some unforeseen chain of events can start a fire. Even the best added-on safety technology can fail or be destroyed in the course of an accident.

An additional argument for inherent safety is its usefulness in meeting security threats. Add-on safety measures can often easily be deactivated by those who want to do so. When terrorists enter a chemical plant with the intent to blow it up, it does not matter much that all ignition sources have been removed from the vicinity of explosive materials (although this may perhaps have solved the safety problem). The perpetrators will bring their own ignition source. In contrast, most measures that make a plant inherently safer will also contribute to diverting terrorist threats. If the explosive substance has been replaced by a nonexplosive one or the inventories of explosive and inflammable substances have been drastically reduced, then the plant will be much less attractive to terrorists and therefore also a less likely target of attack (Hansson 2010a).

Most of the development of techniques for inherent safety has taken place within the chemical industry. Another major industry where inherent safety is often discussed is the nuclear industry, where it is referred to in efforts to construct new, safer types of reactors. A reactor will be inherently safer than those currently in use if, even in the case

of failure of all active cooling systems and complete loss of coolant, the temperatures will not be high enough to trigger the release of radioactive fission products (Brinkmann et al. 2006).

## Safety Factors

Probably, humans have made use of safety reserves since the origin of our species. We have added extra strength to our houses, tools, and other constructions in order to be on the safe side. The use of safety factors, i.e., numerical factors for dimensioning safety reserves, originated in the latter half of the nineteenth century (Randall 1976). Their use is now well established in structural mechanics and in its many applications in different engineering disciplines. Elaborate systems of safety factors have been specified in norms and standards (Clausen et al. 2006).

A safety factor is most commonly expressed as the ratio between a measure of the maximal load not leading to the specified type of failure and a corresponding measure of the maximal load that is expected to be applied. In some cases, it may instead be expressed as the ratio between the estimated design life and the actual service life. A safety factor is typically intended to protect against a specific integrity-threatening mechanism, and different safety factors can be used against different such mechanisms. Hence, one safety factor may be required for resistance to plastic deformation and another for fatigue resistance.

According to standard accounts of structural mechanics, safety factors are intended to compensate for five major categories of sources of failure:

1. Higher loads than those foreseen.
2. Worse properties of the material than foreseen.
3. Imperfect theory of the failure mechanism in question.
4. Possibly unknown failure mechanisms.
5. Human error (e.g., in design) (Knoll 1976; Moses 1997).

The first two of these can in general be classified as variabilities, that is, they refer to the variability of empirical indicators of the propensity for failure. They are therefore accessible to probabilistic assessment (although these assessments may be more or less uncertain). The last three failure types refer to eventualities that are difficult or impossible to represent in probabilistic terms and, therefore, belong to the category of (non-probabilizable) uncertainty. They are not easily amenable to probabilistic treatment. It is, for instance, difficult to see how a calculation could be accurately adjusted to compensate self-referentially for an estimated probability that it is itself wrong. However, these difficulties do not make these sources of failure less important. Safety factors are used to deal both with those failures that can be accounted for in probabilistic terms and those that cannot (Doorn and Hansson 2011).

## Multiple Independent Safety Barriers

Safety barriers are arranged in chains. The aim is to make each barrier independent of its predecessors so that if the first fails, then the second is still intact, etc. Typically, the first barriers are measures to prevent an accident, after which follow barriers that limit the consequences of an accident, and, finally, rescue services as the last resort.

The archetype of multiple safety barriers is an ancient fortress. If the enemy manages to pass the first wall, there are additional layers that protect the defending forces. Some engineering safety barriers follow the same principle of concentric physical barriers. Interesting examples of this can be found in nuclear waste management. The waste can for instance be put in a copper canister that is constructed to resist the foreseeable challenges. The canister is surrounded by a layer of bentonite clay that protects it against small movements in the rock and absorbs leaking radionuclides. This whole construction is placed in deep rock, in a geological formation that has been selected to minimize transportation to the surface of any possible leakage of radionuclides. The whole system of barriers is constructed to have a high degree of redundancy so that if one of the barriers fails the remaining ones will suffice. With the usual standards of probabilistic risk analysis, the whole series of barriers around the waste would not be necessary. Nevertheless, sensible reasons can be given for this approach, namely reasons that refer to uncertainty. Perhaps the copper canister will fail for some unknown reason not included in the calculations. Then, hopefully, the radionuclides will stay in the bentonite, etc.

The notion of multiple safety barriers can also refer to safety barriers that are not placed in a spatial sequence like the defense walls of a fortress but are arranged consecutively in a functional sense. The essential feature is that the second barrier is put to work when the first one fails, etc. Consider, for instance, the protection of workers against a dangerous gas such as hydrogen sulfide that can leak from a chemical process. An adequate protection against this danger can be constructed as a series of barriers. The first barrier consists in constructing the whole plant in a way that excludes uncontrolled leakage as far as possible. The second barrier is careful maintenance, including regular checking of vulnerable details such as valves. The third barrier is a warning system combined with routines for evacuation of the premises in the case of a leakage. The fourth barrier is efficient and well-trained rescue services.

The basic idea behind multiple barriers is that even if the first barrier is well constructed, it may fail, perhaps for some unforeseen reason, and that the second barrier should then provide protection. For a further illustration of this principle, suppose that a shipbuilder comes up with a convincing plan for an unsinkable boat. Calculations show that the probability of the ship sinking is incredibly low and that the expected cost per life saved by the lifeboats is above 1,000 million dollars, a sum that can evidently be more efficiently used to save lives elsewhere.

How should the naval engineer respond to this proposal? Should she accept the verdict of the probability calculations and the economic analysis, and exclude lifeboats from the design? There are good reasons why a responsible engineer should not act in this way: The calculations may possibly be wrong, and if they are, then the outcome may be disastrous. Therefore, the additional safety barrier in the form of lifeboats (and evacuation routines and all the rest) should not be excluded. Although the calculations indicate that such measures are inefficient, these calculations are not certain enough to justify such a decision. (This is a lesson that we should have learned from the *Titanic* disaster.)

The major problem in the construction of safety barriers is how to make them as independent of each other as possible. If two or more barriers are sensitive to the same type of impact, then one and the same destructive force can get rid of all of them in one swoop. Hence, three consecutive safety valves on the same tube may all be destroyed in a fire or they may all be incapacitated due to the same mistake by the maintenance department. It is essential, when constructing a system of safety barriers, to make the barriers as independent as possible. Often, more safety is obtained with fewer but independent barriers than with many that are sensitive to the same sources of incapacitation.

These three principles of engineering safety – inherent safety, safety factors, and multiple barriers – are quite different in nature, but they have one important trait in common: They all aim at protecting us not only against risks that can be assigned meaningful probability estimates, but also against dangers that cannot be probabilized, such as the possibility that some unforeseen event triggers a hazard that is seemingly under control. It remains, however, to investigate more in detail the principles underlying safety engineering and, not least, to clarify how they relate to other principles of engineering design.

## Ethics

---

Moral theorizing has mostly referred to the values of certain outcomes. The evaluation of uncertain outcomes is conventionally referred to decision theory, where it is treated as means-ends (instrumental) reasoning directed toward the attainment of given ends. Hence, moral philosophy refers primarily to human behavior in situations when the outcomes of actions are well defined and knowable. Decision theory takes assessments of these cases for given and derives from them assessments for situations involving risk and uncertainty. In this derivation, it operates, or so it is assumed, exclusively with criteria of rationality and does not add any new moral values. The dominating framework for these deliberations is expected utility theory.

Consider a person who risks a sleeping person's life by playing Russian roulette on her. In a moral assessment of this act, we need to consider (1) the set of consequences that will ensue if the person is killed, and (2) the set of consequences that will fall out if the person is not killed. In addition to this, we should also take into account (3) the act of risk imposition, which in this case takes the form of intentionally performing an act that may develop into an instance of either (1) or (2). In many people's moral appraisal of this misdeed, (3) has considerable weight. The act of deliberate risk-taking is perceived as a wrongdoing against the sleeping person, even if she is not killed and even if she never becomes aware of this episode or any disadvantage emanating from it. However, in the standard decision-theoretic approach, only (1) and (2) are taken into account (weighed according to their probabilities), whereas (3) is left out from the analysis.

This can be expressed with somewhat more precision in the following terminology: In a conventional decision-theoretical appraisal of this example, (1) and (2) will be replaced by their *closest deterministic analogs*. (1) is then evaluated as the act of discharging a fully loaded pistol at the sleeping person's head and (2) as that of letting off an unloaded pistol at her head. The composite act of performing what may turn out to be either (1) or (2) is assumed to have no other morally relevant aspects than those that are present in at least one of these two acts, both of which have well-determined consequences. The additional moral issues in (3), i.e., the issues concerning risk-taking per se, have no place in this account.

It is a general feature of this form of decision-theoretical analysis that if an act has moral aspects that are not present in the closest deterministic analog of any of its alternative developments, then these aspects are left out from the analysis. The crucial (but usually unstated) underlying assumption is that an adequate appraisal of an action under risk or uncertainty can be based on the values that pertain to its closest deterministic analogs. But as we saw from the Russian roulette example, this assumption has the disadvantage of excluding from our consideration the moral implications of risk-taking per se. This exclusion is unavoidable since risk-taking is by definition absent from the closest deterministic analogs that are used in the analysis.

The exclusion of risk-taking from consideration in most of moral theory can be clearly seen from the deterministic assumptions commonly made in the standard type of life-or-death examples that are used to explore the implications of moral theories. In the famous trolley problem, you are assumed to know that if you flip the switch, then one person will be killed, whereas if you do not flip it, then five other persons will be killed (Foot 1967). In Thomson's (1971) "violinist" thought experiment, you know for sure that the violinist's life will be saved if he is physically connected to you for 9 months, otherwise not. In Williams's (1973) example of Jim and the Indians, Jim knows for sure that if he kills 1 Indian, then the commander will spare the lives of 19 whom he would otherwise kill, etc. This is in stark contrast to ethical quandaries in real life, where action problems with human lives at stake seldom come with certain knowledge of the consequences of the alternative courses of action. Instead, uncertainty about the consequences of one's actions is a major complicating factor in most real-life dilemmas.

There are no easy answers to questions such as what risks you are allowed to impose on one person in order to save another or what risks a person can be morally required to take in order to save a stranger. These are questions that present themselves to us as moral questions, not as issues for decision-theoretical reckoning to take place after the moral deliberations have been finished. The exclusion of such issues from most discussions in moral philosophy has the effect of removing essential aspects of actual moral decision-making from our deliberations on moral theory. In order to include them, we have to give up the traditional assumption that the valuation of risk should take the form of applying decision-theoretical – and thus nonmoral – reasoning to values that refer to the moral evaluation of non-risky outcomes (in the form of closest deterministic analogs). Instead, we have to treat risk-taking per se as an object of moral appraisal.

The obvious way to develop an ethical theory of risk would be to generalize one of the existing ethical theories so that it can be effectively applied to situations involving risk. The problem of how to perform this generalization can be specified in terms of *the causal dilution problem*. It was presented by Robert Nozick (1974) as a problem for deontological ethics but is equally problematic for other moral theories.

► *The causal dilution problem (general version):*

Given the moral appraisals that a moral theory  $T$  makes of value-carriers with well-determined properties, what moral appraisals does (a generalized version of)  $T$  make of value-carriers whose properties are not well-determined beforehand?

In utilitarian moral theory, one fairly obvious approach to the causal dilution problem for utilitarianism is the following (Carlson 1995):

► *Actualism*

The utility of a (probabilistic) mixture of potential outcomes is equal to the utility of the outcome that actually materializes.

To exemplify the actualist approach, consider an engineer's decision whether or not to reinforce a bridge before it is being used for a single, very heavy transport. There is a 50% risk that the bridge will collapse if it is not reinforced. Suppose that she decides not to reinforce the bridge and that everything goes well; the bridge is not damaged. According to the actualist approach, what she did was right. This is, of course, in stark contrast to common moral intuitions.

But actualism is not the standard decision-theoretical solution to the causal dilution problem for utilitarianism. The standard approach is to maximize expected utility:

► *Expected utility:*

The utility of a probabilistic mixture of potential outcomes is equal to the probability-weighted average of the utilities of these outcomes.

This is a much more credible solution, and it has the important advantage of being a fairly safe method to maximize the outcome in the long run. Suppose, for instance, that the expected number of deaths in traffic accidents in a region will be 300 per year if safety belts are compulsory and 400 per year if they are optional. Then, if these calculations are correct, about 100 more persons per year will actually be killed in the latter case than in the former. We know, when choosing one of these options, whether it will lead to fewer or more deaths than the other option. If we aim at reducing the number of traffic casualties, then this can, due to the law of large numbers, safely be achieved by maximizing the expected utility (i.e., minimizing the expected number of deaths).

However, this argument is not valid for case-by-case decisions on unique or very rare events. Suppose, for instance, that we have a choice between a probability of 0.001 of an event that will kill 50 persons and a 0.1 probability of an event that will kill one person. Here, random effects will not be leveled out as in the safety belt case. In other words, we do not know, when choosing one of the options, whether or not it will lead to fewer deaths than the other option. In such a case, taken in isolation, there is no compelling reason to maximize expected utility.

Even when the leveling-out argument for expected utility maximization is valid, compliance with this principle is not required by rationality. It is quite possible for a rational agent to refrain from minimizing total damage in order to avoid imposing high-probability risks on individuals. This can be exemplified with an example involving an acute situation in a chemicals factory (Hansson 1993). There are two ways to repair a serious gas leakage that threatens to develop into a disaster. One of the options is to send in the repairman immediately. (There is only one person at hand who is competent to do the job.) He will then run a risk of 0.9 to die due to an explosion of the gas immediately after he has performed the necessary technical operations. The other option is to immediately let out gas into the environment. In that case, the repairman will run no particular risk, but each of 10,000 persons in the immediate vicinity of the plant runs a risk of 0.001 to be killed by the toxic effects of the gas. The maxim of maximizing expected utility requires that we send in the repairman to die. This is also a fairly safe way to minimize the number of actual deaths. However, it is not clear that it is the only possible response that is rational. A rational decision-maker may refrain from maximizing expected utility (minimizing expected damage) in order to avoid what would be unfair to a single individual and infringe her rights. Hence, we have to go beyond expected utility theory in order to do justice to important moral intuitions about the rights of individuals.

As already mentioned, the causal dilution problem was originally formulated for rights-based theories by Robert Nozick. He asked: "Imposing how slight a probability of a harm that violates someone's rights also violates his rights?" (Nozick 1974, p. 7). In somewhat more general language, we can restate the question as follows:

► *The causal dilution problem for deontological/rights-based moral theories:*

Given the duties/rights that a moral theory *T* assigns with respect to actions with well-determined properties, what duties/rights does (a generalized version of) *T* assign with respect to actions whose properties are not well-determined beforehand?

A rights-based moral theory can be extended to indeterministic cases by just prescribing that if A has a right that B does not bring about a certain outcome, then A also has a right that B does not perform any action that has a nonzero risk of bringing about that outcome. Unfortunately, such a strict extension of rights and prohibitions is socially untenable. Your right not to be killed by me certainly implies a prohibition for me to perform certain acts that involve a risk of killing you, but it cannot prohibit all such acts. Such a strict interpretation would make human society impossible. For instance, you would not be allowed to drive a car in the town where I live since this increases my risk of being killed by you.

Hence, rights and prohibitions have to be defeasible so that they can be canceled when probabilities are small. The most obvious way to achieve this is to assign to each right (prohibition) a probability limit. Below that limit, the right (prohibition) is canceled. However, as Nozick observed, such a solution is not credible since probability limits “cannot be utilized by a tradition which holds that stealing a penny or a pin or anything from someone violates his rights. That tradition does *not* select a threshold measure of harm as a lower limit, in the case of harms certain to occur” (Nozick 1974, p. 75).

Clearly, a moral theory need not treat a slight probability of a sizable harm in the same way that it treats a slight harm. The analogy is nevertheless relevant. The same basic property of traditional rights theories, namely the uncompromising way in which they protect against disadvantages for one person inflicted by another, prevents them from drawing a principled line either between harms or between probabilities in terms of their acceptability or negligibility. In particular, since no rights-based method for the determination of such probability limits seems to be available, they would have to be external to the rights-based theory. Exactly the same problem obtains for deontological theories.

Finally, let us consider contract theories. They may perhaps appear somewhat more promising. The criterion that they offer for the deterministic case, namely consent among all those involved, can also be applied to risky options. Can we then solve the causal dilution problem for contract theories by saying that risk impositions should be accepted to the degree that they are supported by a consensus?

Unfortunately, this solution is fraught with problems. Consent, as conceived in contract theories, is either actual or hypothetical. Actual consent does not seem to be a realistic criterion in a complex society in which everyone performs actions with marginal but additive effects on many other people's lives. According to the criterion of actual consent, you have a veto against me or anyone else who wants to drive a car in the town where you live. Similarly, I have a veto against your use of (any type of) fuel to heat your house since the emissions contribute to health risks that affect me. In this way, we can all block each other, creating a society of stalemates. When all options in a decision are associated with risks, and all parties claim their rights to keep clear of the risks that others want to impose on them, the criterion of actual consent does not seem to be of much help.

We are left then with hypothetical consent. However, as the debate following John Rawls's *Theory of Justice* has shown, there is no single decision rule for risk and uncertainty that all participants in a hypothetical initial situation can be supposed to adhere to (Hare 1973; Harsanyi 1975). It remains to show that a viable consensus on risk impositions can be reached among participants who apply different decision rules in situations of risk and uncertainty (If a unanimous decision is reached due to the fact that everybody applies the same decision rule, then the problem has not been solved primarily by contract theory but by the underlying theory for individual decision-making). Apparently, this has not been done and, hence, contract theory does not either have a solution to the causal dilution problem.

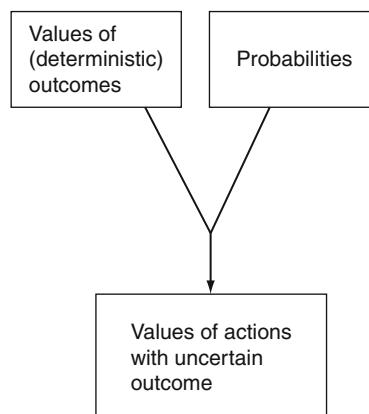

The difficulties that we encounter when trying to solve the causal dilution problem within the frameworks of the common types of moral theories are indications of a deeper problem. The attempted solutions reviewed above are all based on an implicit derivation principle: It is assumed that if the moral appraisals of actions with deterministic outcomes are given, then we can derive from them moral appraisals of actions whose outcomes are probabilistic mixtures of such deterministic outcomes. In utilitarian approaches, it is furthermore assumed that probabilities and (deterministic) utilities are all the information that we need (☞ Fig. 2.3). However, this picture is much too simplified. The morally relevant aspects of situations of risk and uncertainty go far beyond the impersonal, free-floating sets of consequences that decision theory operates on. Risks are inextricably connected with interpersonal relationships. They do not just “exist”; they are taken, run, or imposed (Thomson 1985a). To take just one example, it makes a moral difference if it is one’s own life or that of somebody else that one risks in order to earn a fortune for oneself. Therefore, person-related aspects such as agency, intentionality, consent, etc., will have to be taken seriously in any reasonably accurate account of real-life indeterminism (☞ Fig. 2.4).

Based on this analysis, the causal dilution problem can be replaced by a *defeasance problem* that better reflects the moral issues of risk impositions:

► *The defeasance problem:*

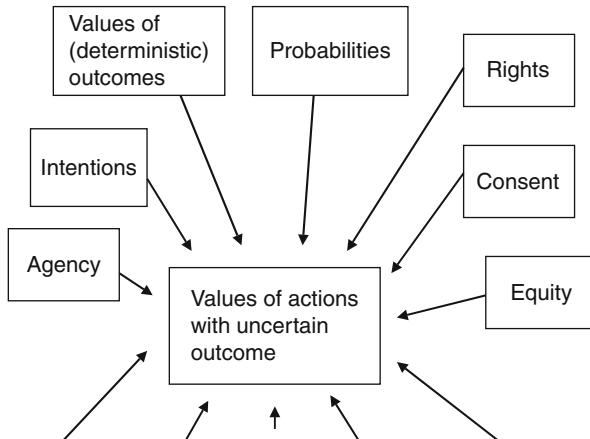

It is a *prima facie* moral right not to be exposed to risk of negative impact, such as damage to one’s health or one’s property, through the actions of others. What are the conditions under which this right is defeated so that someone is allowed to expose other persons to risk?

The defeasance problem is a truly moral problem, not a decision-theoretical one. As far as I can see, it is the central ethical issue that a moral theory of risk has to deal with. Obviously, there are many ways to approach it, only few of which have been developed. It remains to investigate and compare the various solutions that are possible. My own preliminary solution refers to reciprocal exchanges of risks and benefits. Each of us takes risks in order to obtain benefits for ourselves. It is beneficial for all of us to extend this practice to mutual exchanges of risks and benefits. If others are allowed to drive a car, exposing you to certain risks, then in exchange you

■ Fig. 2.3

The traditional account of how values of indeterministic outcomes can be derived

**Fig. 2.4**

A less incomplete picture of the influences on the values of indeterministic options

are allowed to drive a car and expose them to the corresponding risks. This (we may suppose) is to the benefit of all of us. In order to deal with the complexities of modern society, we also need to apply this principle to exchanges of different types of risks and benefits. We can then *regard exposure of a person to a risk as acceptable if it is part of a social system of risk-taking that works to her advantage and gives her a fair share of its advantages*.

This solution is only schematic, and it gives rise to further problems that need to be solved. Perhaps the most difficult of these problems is how to deal with large differences among the members of society in their assessments of risks and benefits. But with the approach presented here, we have, or at least so I wish to argue, a necessary prerequisite in place, namely, the right agenda for the ethics of risk. According to traditional risk analysis, in order to show that it is acceptable to impose a risk on Ms. Smith, the risk-imposer only has to give sufficient reasons for accepting the risk as such, as an impersonal entity. According to the proposal just presented, this is not enough. The risk-imposer has to give sufficient reasons why Ms. Smith – as the particular person that she is – should be exposed to the risk. This can credibly be done only by showing that this risk exposure is part of some arrangement that works to her own advantage. For a more detailed discussion of this approach, see Hansson (2003b).

## Philosophy of Economics

Risks have a central role in economic theory, and there are obvious parallels between the problems of economic risk and the problems concerning other types of risk such as risks to health and the environment. Let us have a look at two interesting issues in the philosophy of economic risk: the aggregation problem and the problem of positive risk-taking.

*The aggregation problem* concerns how we compare risks accruing to different individuals. Standard risk analysis follows the principles of classical utilitarianism. All risks are summed up in one and the same balance irrespectively of whom they accrue to. Thus, all risks are taken to be fully comparable and additively aggregable. In risk-benefit analysis, benefits are added in the

same way and, finally, the sum of benefits is compared to the sum of risks in order to determine whether the total effect is positive or negative. In such a model, just as in classical utilitarianism, individuals have no other role than as carriers of utilities and disutilities, the values of which are independent of whom they are carried by.

An obvious alternative to this utilitarian approach is to treat each individual as a separate moral unit. Then risks and benefits pertaining to one and the same person can be weighed against each other, whereas risks and benefits for different persons are added or otherwise aggregated since they are considered to be incomparable. Such “individualistic” risk weighing is quite different from the total aggregations that are standard in risk analysis. But individualistic risk weighing dominates in medicine. It is applied for instance in ethical evaluations of clinical trials. It is an almost universally accepted principle in research ethics that a patient should not be included in a clinical trial unless there is genuine uncertainty on whether or not participation in the trial is better for her than the standard treatment that she would otherwise receive. That her participation is beneficial for others (such as future patients) cannot outweigh a negative net effect on her own health; in other words, her participation has to be supported by an appraisal that is restricted to risks and benefits for herself (London 2001; Hansson 2004a).

The two traditions in risk assessment differ in the same way as the “old” and “new” schools of welfare economics. In Arthur Pigou’s so-called old welfare economics, the values pertaining to different individuals are added up to one grand total. This is also the approach of mainstream risk analysis. The new school in welfare economics that dominates mainstream economics since the 1930s refrains from adding individual values. Instead, it treats the welfare of different individuals as incomparable. This became the standard approach after Lionel Robbins had shown how economic analysis can dispense with interpersonal comparability (Pareto optimality is the central tool needed to achieve this). The individualist approach that was exemplified above with clinical trials is based on the same basic principles as those applied by the new school in welfare economics (Hansson 2006a).

Mainstream risk analysis and mainstream economics represent two extremes with respect to interindividual comparisons. The aggregations of total risk that are performed routinely in risk analysis stand in stark contrast to the consistent avoidance of interindividual comparisons that is a major guiding principle in modern economics. This difference also has repercussions in the ideological uses of the respective disciplines. It is an implicit message of risk-benefit analysis that a rational person should accept being exposed to a risk if this brings greater benefits for others. The implicit message of modern (new school) welfare economics is much more appreciative of self-interested behavior.

The issue of *positive risk-taking* appears to be more or less specific for economic risks. Risk is by definition undesirable, and we expect a rational person to avoid risk as far as possible. But in economics, risk-taking is often considered to be desirable. The capitalist’s risk taking is acknowledged as essential for the efficiency of a capitalist system, and it is also taken to justify the owner’s prerogative to exert the ultimate control over companies and to reap the profits. As said already by Adam Smith in his *Wealth of Nations*, “something must be given for the profits of the undertaker of the work who hazards his stock in this adventure” (Smith [1776] 1976, p. 1:66).

The risk taking that Smith referred to was a substantial one, namely the risk of bankruptcy. According to Smith, becoming bankrupt is “perhaps the greatest and most humiliating calamity which can befall an innocent man” (Smith [1776] 1976, p. 1:342). This was the risk that the capitalist was supposed to take and to be compensated for. Its seriousness was essential for Smith’s argument as we can see from his negative attitude to arrangements that reduce the

risk from that of bankruptcy to that of losing the invested capital. The most important such arrangement was the joint-stock company (with limited liability) to which Smith was decidedly averse (Smith [1776] 1976, p. 2:741).

But since Smith's time capitalism has been fundamentally transformed, two major reductions in capitalist risk-taking have taken place. The first of these occurred in the latter half of the nineteenth century when corporations with limited liability became the dominant legal form of private companies in the industrialized parts of the world (Handlin and Handlin 1945; Prasch 2004). Due to the massive spread of limited liability, personal risk taking in most major industrial and financial endeavors was brought down from bankruptcy to loss of the original investment, which was exactly what Adam Smith had warned against.

The second reduction in economic risk-taking took place about 100 years later. Beginning in the late twentieth century, private investment in companies has to an increasing extent been mediated by institutions and funds that diversify their securities in a sophisticated way to reduce risk taking. Portfolio theory and modern financial marketplaces have combined to make risk spreading much more efficient than what was previously possible. Today, an owner who has applied prudent risk spreading only runs a risk that approximates the general background risk of the economy. In terms of risk-taking, his situation is arguably less akin to that of businesspeople risking everything they own than to that of the nineteenth century landlords who according to John Stuart Mill "grow richer, as it were in their sleep, without working, risking, or economizing" (Mill [1848] 1965, pp. 3:819–820).

Risk-spread ownership has thoroughly transformed the economic system, but its philosophical implications have not been much discussed. It is for instance not unreasonable to ask what effects this development has on the legitimacy of the owner's prerogative that was previously based at least in part on the risk-taking role of owner.

## Political Philosophy

---

Although risk and uncertainty are ubiquitous in political and social decision-making, there has been very little contact between risk studies and more general studies of social decision processes. Public discussions of risk are dominated by a way of thinking that is markedly different from how democratic decision-making is commonly discussed. We can see this from the frequent references in discussions on risk to three terms that are not much used in general discussions on democratic decision-making.

"Consent" is one of these words. Consent by the public is often taken to be the goal of public communications on risk. The following quotation is not untypical:

- ▶ Community groups have in recent years successfully used zoning and other local regulations, as well as physical opposition (e.g., in the form of sitdowns or sabotage), to stall or defeat locally unacceptable land uses. In the face of such resistance, it is desirable (and sometimes even necessary) to draw forth the consent of such groups to proposed land uses (Simmons 1987, p. 6).

To consent means in this context "voluntarily to accede to or acquiesce in what another proposes or desires" (Oxford English Dictionary). This is very different from the role of the citizen as a decision-maker in a democracy.

The second of these words is "acceptance." The goal of risk communication is often taken to be public acceptance of a presumably rational act of risk-taking. Hence, in discussions on the

siting of potentially dangerous industries, “public acceptance” is usually taken to be the crucial criterion. This usage signals the same limitation in public participation as the word “consent.”

The third word is “trust.” Much of the discussion in the risk-related academic literature on the relationship between decision-makers and the public takes the public’s trust in decision-makers to be the obvious criterion of a well-functioning relationship. This is, again, very different from discussions on democracy in political philosophy. In a democratic constitution, the aim is the public’s democratic control over decision-makers, rather than their trust in them (Hayenjelm 2007).

In contrast to the limited approach to public participation in risk decisions that is indicated by the keywords “consent,” “acceptance,” and “trust,” let us consider the ideal of full democratic participation in decision-making. This ideal was very well expressed by Condorcet in his vindication of the French constitution of 1793. Condorcet divided decision processes into three stages. In the first stage, one “discusses the principles that will serve as the basis for decision in a general issue; one examines the various aspects of this issue and the consequences of different ways to make the decision.” At this stage, the opinions are personal, and no attempts are made to form a majority. After this follows a second discussion in which “the question is clarified, opinions approach and combine with each other to a small number of more general opinions.” In this way, the decision is reduced to a choice between a manageable set of alternatives. The third stage consists of the actual choice between these alternatives (Condorcet [1793] 1847, pp. 342–343).

The discussion on public participation in issues of risk has mostly been restricted to Condorcet’s third stage, and – as we have seen – often also to a merely confirming or consenting role in that stage. This approach is obviously untenable if we wish to see decisions on risk in the full context of public decision-making in a democratic society. Without public participation at all three stages of the decision-making process, risk issues cannot be dealt with democratically. Therefore, the discussion needs to be shifted away from special procedures for dealing with risk. Instead our focus should be on how the special characteristics of risk-related issues can best be dealt with in our general decision-making processes.

## Further Research

Far from being an unusual oddity in philosophy, the topic of risk connects directly to central issues in quite a few subdisciplines of philosophy. In some of these subdisciplines, a significant amount of research on risk has already taken place. In others, only the first steps toward systematic studies of risk have been taken. But in all of them, important philosophical issues related to risk remain unexplored. The following are ten of the most important issues for further research that have been pointed out above:

- When is trust in experts on risks justified, and when is distrust irrational?
- How remote possibilities of disaster should be taken seriously?
- How can we account for probabilistic reasoning that seems rational but is not compatible with the standard theory of probability?
- To what extent, and in what ways, should practical consequences have influence on scientific assessments of risk?
- How can the principles of safety engineering be accounted for, and how do they relate to probabilistic risk analysis?

- How can a risk or safety analysis take into account the possibility that the analysis itself is wrong?
- When is it ethically permissible to expose another person to a risk?
- How can utilitarianism be extended or adjusted so that it provides us with a reasonable account of the ethics of risk-taking?
- Do we have a right not to be exposed to risks and, in that case, when can it be overruled?
- What role should those exposed to a risk have in democratic decisions on that risk?

**Abstract:** The aim of this chapter is to analyze the concepts of risk and safety in the context of societal decision-making. Risk and safety research is a heterogeneous field, and different areas have conceived of the nature of risk in different ways. In the chapter, I categorize risk perspectives in three broad groups: the scientist approach, the psychological approach, and the cultural approach to risk. Between these groups, the nature and status of risk and safety have been the debated subjects. I will attempt to bring some light onto complicated and controversial philosophical topics such as whether risk and safety are natural or normative notions, whether they are social constructions, objective, or even real. This investigation will focus on a range of different questions. I will distinguish between five common definitions of the term “risk,” as well as contrast the notion of *risk* with both the notion of *safety* and the notion of *acceptable risk*. The main part of the chapter will focus on a quantitative or comparative concept of risk, that is, a notion that is in play in statements such as “the risk of flying is lower than the risk of traveling by car” and “the risk of nuclear power is  $10^{-4}$  deaths per reactor year.” The central aspects of such a notion of risk and safety will be discussed, in particular the notions of probability and harm. I will also discuss the common claim that it is the expectation value of the severity of harm that is the correct measure of risk. Furthermore, I investigate additional aspects such as epistemic uncertainty and other, more controversial aspects that have been proposed.

## Introduction

---

Risk research is a discipline in rapid development with contributors from many areas of the natural and social sciences. This reflects a growing concern about risks in society. Both professional and non-professional awareness of risks are increasing, and much effort is put into risk assessment, risk management, and risk communication. As a consequence, there are now well-developed societal practices in place involving risk and safety. Still, the central concepts of risk and safety remain somewhat unclear. When characterized, risk and safety are often treated either as relatively straightforward natural science concepts, or, to the contrary, as fundamentally subjective notions ill fitting for scientific study. However, without an in-depth understanding of its central concepts, the subject matter of risk and safety research remains fuzzy and it is unclear what the objective of reducing risk and achieving safety really amounts to.

The aim of this chapter is to analyze the concepts of risk and safety in the context of societal decision-making. This investigation will focus on a range of different questions. In the first section, I will categorize risk perspectives in three groups: the scientist approach, the psychological approach, and the cultural approach to risk. It aims to give an initial background and show the different points of departure that are characteristic for the heterogeneous field of risk research, and to supply an initial context for us to orient from and relate to in what follows.

In the second section, I distinguish between several meanings of the term “risk,” and discuss the notion of acceptable risk as well as the relation between the notions of risk and safety.

In the third section, I will discuss aspects of the quantitative concept of risk that will be in focus for the remainder of the chapter. I will investigate the fundamental aspects of probability and severity of harm, which are part of most quantitative conceptions of risk and safety. Furthermore, I will investigate additional aspects such as epistemic uncertainty and other, more controversial aspects that have been proposed.

The topic of the fourth section is the nature of risk and safety, by which is meant the status of the concepts: are risk and safety or normative notions, are they objective, or are they social constructions? Are they even real? The aim of the fifth section is to shed some light onto these complicated and controversial philosophical topics.

I suggest some topics for further research in the sixth section, before I end with a short conclusion in the final section.

## Risk Perspectives

---

Several different fields of investigation have been interested in the concept of risk: engineering, economics, political science, sociology, psychology, and philosophy, to name just a few. This heterogeneous research arena has resulted in many different perspectives on risk. Some theorists have grouped these perspectives rather finely. Ortwin Renn, for example, has divided the risk approaches into seven categories: (1) the actuarial approach, (2) the toxicological and epidemiological approach, (3) the engineering approach, (4) the economical approach, (5) the psychological approach, (6) social theories of risk, and (7) cultural theory of risk (Renn 1992, p. 56). (Even a fine-grained categorization such as this is incomplete. As indicated by the present volume, *philosophy of risk* is a growing area of research; cf. e.g., Shrader-Frechette 1993; Lewens 2007; Asveld and Roeser 2009; Hansson 1998, 2009). Often, however, theorists are satisfied with a less fine-grained grouping, depending on the task at hand.

For the purpose of this chapter, let us distinguish between three broad approaches to risk. The first perspective can be called the *scientist approach* to risk. The basic idea is that risk is a phenomenon that may be investigated like most phenomena in science, that is, by employing the scientific method. Risk is something that can, at least in principle, be measured in a systematic way, and the main task of the researcher is to find a sufficiently precise measure of the phenomena and to find ways of reducing the risk as much as possible. On most interpretations, the first four of Renn's perspectives would belong to this category. Statistical and probabilistic tools are important in this perspective as ways of measuring and describing the risks, in addition to investigations into the causal mechanisms of various risk-related phenomena that are at the core of both the toxicological-epidemiological and the engineering approaches (Renn 1992).

The second perspective may be labeled the *psychological approach* to risk. The basic interest in this perspective is to study people's *perceptions* of risk, that is, people's beliefs about risks and their way of relating to them. A dominant psychological method is psychometrical research in which the researcher tries to establish reliable measures of risk perceptions. The aim of the approach is to get a clear and distinct picture of how people estimate risks and how they make choices in relation to them – in particular, what influences whether they deem a risk acceptable or not. Various attitudes toward risk in general – especially risk-aversive and risk-seeking behavior – as well as what types of risk we deem more important than others, are typical topics of interest on this approach (Slovic 2000; cf. also, Hansson 2010 and Summerton and Berner 2003 for this category).

The third approach may be called the *cultural approach* to risk (roughly corresponding to the last two of Renn's categories). Whereas the psychological approach mainly focused on the *individual* and her ways of conceiving of risk-related affairs, the cultural approach takes a broader perspective. On this approach, the main interest is to establish how our conceptions

of risk are culturally mediated, that is, how they are formed by social contexts in our societies (e.g., identity and power). A particular risk statement is always articulated in a cultural context, singled out among many other possible formulations. Moreover, for every risk event we pick out as the interesting one, there are other potentially hazardous events we could have chosen. The cultural approach to risk is interested in, as Clarke and Short put it, “how social agents create and use boundaries to demarcate that which is dangerous” (Clarke and Short 1993, p. 79).

In this chapter, my main aim is analytical in the sense that I will analyze the conceptual aspects or constituent dimensions of risk and safety. What do terms such as “risk” and “safety” mean when we use them in statements such as “It is safe to fly,” “Nuclear power is safer than other means of energy production,” and “The risk of nuclear power is  $10^{-4}$  deaths per reactor year?” In particular, I will investigate the comparable or quantitative notion of risk and safety exemplified in the latter two statements. Here, the scientist conception of risk and safety will form an interesting starting point.

Thus, I will focus on the meaning of the relevant terms, rather than psychological and social aspects such as what individuals think about risks (a topic for risk perception studies) or how these beliefs concerning risk and what we choose as the area of study concerning risk is dependent on our social context (a topic for cultural studies of risk). That does not mean that results from psychological or sociological studies of risk are irrelevant. Since there is a close relationship between our linguistic behavior and the meaning of the term that is used, actual practice matters. In particular, I will in section [Further Aspects of Risk and Safety](#) investigate some suggestions of risk aspects that have been put forward in the literature. Furthermore, I will return to the different perspectives on risk in section [The Nature of Risk and Safety](#), where I will turn to the question about the *nature* of risk and safety, notably whether they are to be seen as objective, scientific concepts or whether they have some other status. Here, researchers belonging to different traditions have tended to take rather different stands.

## Notions of Risk

---

### Five Definitions of “Risk”

---

The terms “risk” and “safety” have been used with many related but distinct meanings. It is helpful to distinguish between at least five different, but clearly related meanings that have been used in the literature (Hansson 2004a; Möller et al. 2006):

1. Risk=an *unwanted event* which may or may not occur (Rosa 1998)
2. Risk=the *cause* of an unwanted event which may or may not occur
3. Risk=the *probability* of an unwanted event which may or may not occur (Graham and Weiner 1995)
4. Risk=the fact that a decision is made under conditions of *known probabilities* (Knight 1921; Douglas 1983)
5. Risk=the statistical *expectation value* of unwanted events which may or may not occur (Willis 2007; Campbell 2005)

The first meaning is displayed in a statement such as “Wildfires constitute the most serious environmental risk in Russia today” or “There is always the risk of an accident when driving in traffic.” “Drunk driving constitutes a major traffic risk” and “Coronary heart disease is the

number one risk of death in America” are two examples of the second meaning of “risk.” A risk in the second sense is sometimes referred to as a *hazard* in an engineering context.

The third meaning is perhaps the most common, for example, in statements of the form “the risk of heavy rainfall this week is more than fifty percent.” Note here that “risk” in this sense is not merely a synonym of “probability,” but is used to mark the undesirability of the outcome, that is, rainfall. Hence a farmer would perhaps say that it is the *chance* of rainfall that is 50% rather than the *risk* of it.

The fourth sense of risk is a technical notion that is often used in decision theory. Here, one typically distinguishes between *decisions under certainty*, which are decisions where all the consequences of the decision alternatives are known; *decisions under risk*, which are decisions where the probabilities of the outcomes are known; and *decisions under uncertainty*, where the probabilities are unknown. In this context, claiming, say, that whether to install a certain warning system is a decision under risk is to claim that the situation can be treated as a decision where the probability of failure of the system is known.

The fifth sense is another technical sense in which the notion of risk is used. While the notion of expected value as such dates from the early development of probability theory in the seventeenth and eighteenth centuries, its application in the risk context is fairly new. It became common after the influential Rasmussen Report of 1975 and is now the standard definition of “risk” in risk analysis (Rechard 1999, p. 776).

The expectation value is the probability-weighted sum of the severity of harm. It measures the *magnitude* of the risk as the combination of two factors, the probability of an unwanted event, and its severity. It supplies an overtly *quantitative* sense of risk that is used both to compare risks, and to give a single magnitude of risk.

In risk analysis, the expectation value is often used for a single quantitative statement of a risk, or as the basis of comparative statements when claims are made that some technology is safer than another. Often in statements such as “the risk of flying is less than the risk of driving a car,” it is the expectation values of both activities that are compared. (Note, however, the potential need for increased precision of such statements, for example, whether the basis for comparison is per traveled kilometer or per traveled hour.)

While all of these five meanings of “risk” are legitimate on their own terms, my main interest in this chapter is the application of the term for comparative or quantitative purposes. The last sense of the term, the notion of expected value, fits this aim. It gives a value of risk for an event that may be compared with other events, and it also gives a unique, freestanding measure of risk. In the next section, I will take a closer look at the quantitative notion, including the expected value conception.

A terminological note before I continue. In the remaining chapter, I will use “harm” instead of “unwanted event,” for several reasons. If a potential unwanted event is small, it may be incorrect to talk about risk or safety. For example, drawing a blank ticket in a lottery would be an unwanted event, but the avoidance of this would not be described as a matter of safety (unless, of course, the lottery was about something severe, such as when a person participates in a game of Russian roulette). Thus, the nature of the unwanted event is relevant here: if its severity is below a certain level it does not count as a risk and safety issue. (The term “unwanted event” also refers to the subject’s desires in an unfortunate way. If you, for some reason, had a desire to hurt yourself, and therefore engaged in a stunt act in which the probability of a severe accident is very high, we might say that you chose a *safe* way to kill yourself, meaning *certain*, but we would never say that you were *safe*.) I will therefore use the term “harm” that – contrary to “unwanted event” – implies a non-trivial level of damage.

## Acceptable Risk

---

The quantitative notion of risk that is our main object of study should be distinguished from the notion of *acceptable risk*. The quantitative notion is in place when we compare risks or ascribe their magnitude. Even if we assume an answer to the magnitude question, whether we should accept a risk of a certain magnitude is yet a further question. In other words, we should distinguish between the *magnitude* of the risk on the one hand, and whether or not a risk of that magnitude should be *accepted*. They correspond to two different notions that must be kept separated in order to avoid conceptual fallacies about risk.

Historically, early studies in risk analysis were aimed at finding a level of risk – interpreted as the expectation value of harm – that should be accepted (Otway 1987). An example of such “low levels of risk” concerns the harmful effects of background radiation, or other risks that we accept in ordinary life. While helpful as comparability tools, the idea of any such fixed levels of acceptable risk have been questioned (Peterson 2002). The general objection to the idea is that if a risk is *additive*, that is, adds to existing risks, there will be an addition to the overall risk even if the risk is small, and hence we need a further justification for adding the risk.

A major reason for accepting or not accepting a risk is naturally due to the benefit of the risk in relation to the harm of imposing it. Cost–benefit analysis of risk is a method of risk analysis that aims to judge the acceptability of a risk by comparing the benefits to the “cost” that the risk corresponds to. While the viability of cost–benefit analysis of risk is heavily questioned (Le Grand 1991; Sen 1987; Hansson 2004b; Fischhoff et al., Kirmsky and Golding, Shrader-Frechette, contributions to Asveld and Roeser 2009), among other things since it predominately relies on the controversial presumption that we may compare risk and benefits on a single (monetary) measure, it is hard to avoid the general idea that the acceptability of a risk has *some* relation to its benefits.

The acceptability of a risk depends also on many moral aspects involving questions such as agency, rights, and volition. Arguably, if a risk is voluntary, such as smoking, it may be acceptable even if the same risk, were it involuntary, would not be. Similarly, a certain risk level may be acceptable if the persons taking the risk are the ones benefiting from them, but not otherwise (Hansson 2004b).

---

## Is Safety the Antonym of Risk?

---

Risk and safety are closely related concepts. Until now, I have followed the tradition and mainly discussed the notion of risk, assuming that the relation between the two is uncontroversial. This, however, cannot always be assumed.

While risk is what we typically quantify and compare, safety is what we want to achieve. In the literature, the notion of safety is predominately used as the sought state-of-affairs. (This is the common usage in regulation and procedural documents, where the focus is on describing rules and procedures to enhance safety, but a direct and precise characterization of the concept of safety is missing; cf. e.g., IAEA 2000). We want the nuclear power plant to be safe, as we do the person walking alone in a city park and the cough medicine we use. Still, both risk and safety are used, as I have done in this chapter, to make comparative claims. The common picture of the relation between the two concepts is that they are antonyms: when the risk is low, safety is high, and conversely, when safety is low, risk is high. We could phrase a statement

“it is safer to be at sea when you are sober than when you have been drinking,” just as well as we could phrase it “it is less risky to be at sea when you are sober than when you are drunk.”

There are, however, at least three potential complications for the antonym picture of risk and safety. The first comes from the fact that the two terms have different connotations. Safety is a positive property, while risk is generally something negative. Therefore, the level of risk may perhaps not be too high for us to claim that X is safer than Y. If there is a high risk for both the plague and cholera, but slightly less for cholera, it may be strange to say that we are safer from the one than the other, even if that would be correct on the antonym view.

Secondly, one should note that the term “risk” is often – explicitly or implicitly – given a technical definition. On such a usage, it is an open question whether safety is its antonym. It has been argued, for example, that, if the expected value of harm is used as a definition of risk, safety is not to be understood as the antonym of risk, since other aspects are relevant for safety (Möller et al. 2006). On a broader notion of risk, including the aspects that will be addressed in the next section, the antonym view is more plausible.

The third complication comes from the monadic use of the safety predicate, most clearly expressible with the term “safe” – such as in “the bridge is safe” rather than the dyadic (or comparative) “the new bridge is safer than the old one used to be.” The application of the safety concept may be given an absolute and a relative interpretation. Consider the question “is my car safe?” One way of answering it is to reply: “No, since there is always a risk of being in a traffic accident – if you want to play it safe, stay home!” That way of interpreting the question would be the absolute sense of safety. According to the absolute interpretation, safety against a particular harm implies that the risk of that harm has been eliminated. Some authors take the absolute sense of safety for granted. For example, in the context of aviation safety it has been claimed that “[s]afety means no harm” (Miller 1988) and that “[s]afety is by definition the absence of accidents” (Tench 1985).

Another way of answering the question would be to reply: “Yes, the car is safe, since the risk of an accident in this car is low, and the latest safety features it comes equipped with also minimize the risk of a severe damage in case of an accident.” That reply would be in line with a relative interpretation of safety, where safety means that the risk has been reduced or controlled to a certain acceptable level. A typical example taken from a safety application states: “[R]isks are defined as the combination of the probability of occurrence of hazardous event and the severity of the consequence. Safety is achieved by reducing a risk to a tolerable level” (Misumi and Sato 1999). The US Supreme Court is explicit about its use of a relative safety concept when they claim that “safe is not the equivalent of ‘risk free’” (Miller 1988, p. 54).

The relative safety concept must not only be distinguished from the absolute interpretation, but also from the above-discussed notion of *acceptable risk*. As we have seen, whether a risk is acceptable may depend on the benefits, and on moral or social aspects. While there is a social element in expressions such as “tolerable level” of risk as well, we do not allow the same leeway to the notion of safety, and it is often reasonable to claim that while something is not safe, the risk is acceptable. Therefore, it seems as if it is actually the notion of acceptable risk that the American Department of Defense is referring to when it states that safety is “the conservation of human life and its effectiveness, and the prevention of damage to items, consistent with mission requirements” (Miller 1988, p. 54).

Both the absolute and the relative concepts of safety are legitimate, but they must be carefully separated in order to avoid misunderstandings. For most practical purposes,

the absolute concept corresponds to an ideal that cannot be realized, and “safe” is used in the relative sense. Hardly anything for which it would be interesting to apply the concepts of risk and safety contains no risk at all, strictly speaking – not even, as the first answer suggested, staying at home.

## Aspects of Risk

---

I will now look at the quantitative notions of risk and safety, that is, the concepts that are in place in statements such as “Flying is safer than going by car” or “Nuclear power has the lowest risk of all energy production methods.”

In the last definition of risk in section [Five Definitions of “Risk”](#), “risk” was defined as the expected value of harm. As noted there, this is the most common definition in risk analysis, and some authors have even taken it as the only rational way of measuring risk. Bernard Cohen, for example, starts off a recent paper with the claim (Cohen 2003, p. 909):

- ▶ The only meaningful way to evaluate the riskiness of a technology is through probabilistic risk analysis (PRA). A PRA gives an estimate of the number of expected health impacts – e.g., the number of induced deaths – of the technology, which then allows comparisons to be made with the health impacts of competing technologies so a rational judgment can be made of their relative acceptability.

In this section, however, I will investigate whether the notion of expected value of harm gives a complete understanding of risk and safety, and I will discuss other aspects that have been suggested in the literature.

Before this, however, let us start with a methodological note. It may very well be held that as long as a definition of a term, for example, “risk,” is internally coherent, it makes no sense to ask whether it is complete. We are *told* what the meaning of the term is, and if this meaning is intelligible, then no complain may be launched.

Indeed, this objection is correct as it stands. Here, however, our aim is to grasp the meaning of “risk” and “safety” in the context relevant to societal decision-making. Hence, whether the technical notion of expected value of unwanted events capture this meaning is another question. Although the expected value may supply a clear and distinct quantitative concept, the important question is whether it fits with the phenomena we are trying to capture.

In other words, our aim is to characterize the notion of risk involved in our natural language usage, not in any internal-to-science-only way. In the end, what decision-makers as well as laypeople want to know when they ask how the *risks* are distributed – or which of the alternatives is the *safest*, etc. – is the answer that is relevant for the intended meaning of the words. If we answer using the same terms but with another meaning, we have not given the adequate answer. Hence, it is important not only that we are clear about how our terms should be interpreted, but also that we are using the *right* interpretation. Risk research is principally an empirical field of study, but if we are dealing with inadequate conceptualizations, our analyses may be inadequate, too. (The approach used here has much in common with *ordinary language philosophy*, in which a core assumption is that knowledge of the meaning of terms is reached not primarily through theories in abstraction, but through a close attention to the details of ordinary language in which it is used (Soames 2005). Cf. also Hare (1952, p. 92) for a similar point against the claim that we may define moral terms as we please.)

## Harm and Probability

---

The notions of harm and probability are central for any quantitative understanding of risk and safety. As soon as we move beyond an absolute conception as discussed in section [Is Safety the Antonym of Risk?](#), where safe means no risk at all, we are dealing with events that *may* take place with different degrees of likelihood, and causing different levels of harm.

Starting with harms, we should note that it is far from trivial to compare their severity. On a commonsense notion of harm, it seems clear that there are many cases in which we may reasonably hold that one harm is more severe than another. In a traffic accident, for example, a death is more severe than a broken leg, and a broken leg is more severe than a bruise. But the relative severities between them are not so certain. How many broken legs, one may reasonably ask, are there on a death? It is not clear what the answer should be.

This is problematic if we think that we can always, in principle, compare risks. In particular, for the expected value of harm to be well defined, the severity of harm must be possible to measure rather extensively. More precisely, we must be able to decide not only that harm A is more severe than B, and that B is more severe than C, but also the relative severity between them. (In technical terms, we must be able to compare harms on an interval scale; cf. Resnik (1987) for a textbook presentation.)

In practice, when arguing for (and applying) the expected value notion of risk one typically limits the measure of the severity of harm to one significant value, typically casualties. So severity of harm in traffic is in the first instance measured in traffic deaths. A perhaps sometimes reasonable assumption behind such a measure is that the less severe harms “follow along,” but that is sometimes a far-fetched idealization.

Even if we assume that death is the primary harm to take into account, it is unclear if the severity of harm is the same in all cases. Is, in all circumstances, the possibility of a 95-year-old person dying from a medical procedure of the same severity as if the patient were 25 years old? This is an area of severe controversy, but we should note that there are ambitious systems of measurement designed to take account of both the quantity and the quality of life generated by healthcare interventions, such as the QALY measure (quality-adjusted life-year).

The second aspect of risk, probability, is a much-investigated concept with a well-established mathematical content, and it is paramount in many important applications. The interpretation in cases of risk and safety is not evident, however. In probability theory there is a well-established distinction between subjective and objective interpretations of the concept. According to the objective interpretation, probability is a property of the external world, for example, the propensity of a coin to land heads up. According to the subjective interpretation, to say that the probability of a certain event is high means that the speaker’s degree of belief that the event in question will occur is strong (Ramsey 1931; Savage 1972). When we are dealing with the repetition of technological procedures with historically known failure frequencies, it may be possible to determine probabilities that can be called objective. However, in most cases such frequency data are not available, unless perhaps for certain parts of the system under investigation. Therefore, frequency data will have to be supplemented or perhaps even replaced by expert judgment. Expert judgments of this nature are not, and should not be confused with, objective fact. Neither are they *subjective* probabilities in the classical sense, since by this is meant a measure of a person’s degree of belief that satisfies the probability axioms but does not have to correlate with objective frequencies or propensities (see section [Uncertainty](#)). The judgments are better described as subjective estimates of objective probabilities. Furthermore, the probability

estimates used in risk and safety analysis are not purely personal judgments even in this sense. Rather, they are based on the best possible judgments that can be obtained. Typically, a probability estimate is interpreted as the best possible judgment from the community of experts.

The theoretical issues of comparing harms and assigning probabilities do not only constitute a problem for proponents of the expected value notion of risk, but for any account that, while objecting to the expected value interpretation *as such*, still takes severity of harm and probability as basic aspects of risk and safety. To the extent that there is a problem in assigning a reasonable probability or severity of harm value for an event, there is a potential problem in assigning a measure of risk. As will be seen in the next two subsections, this problem is present even if we manage to agree about an interpretation of the most reasonable ascription of the probability and severity of harm that can be obtained.

## Risk as the Expected Value of Harm

---

That the severity of harm and its probability are important aspects of risk is well in line with basic intuitions about the notions. Assuming that the measurement problems in the last subsection are solved, it seems reasonable to assume, *all else equal*, that if the likelihood of an accident increases, so does the risk; likewise, if the severity of an outcome increases, so does the magnitude of the risk. So far, it is hard to deny that these two aspects should be part of the quantitative concepts of risk and safety. That, however, falls short of accepting that the expected value of harm supplies the correct measure of risk.

Indeed, some authors, while endorsing the two aspects, have preferred more cautious formulations. Slovic, for example, has defined risk as “a blend of the probability and the severity of the consequences” (Slovic 2000, p. 365). Other authors have likewise expressed themselves in terms of “combinations” rather than explicitly stating how that combination is brought into a measure (Lowrance 1976; ISO 2002; Aven 2007). Still, as previously noted, the expected value is the dominant notion of risk in risk analysis (Hansson 2005).

There is, however, a strong reason for the claim that the expected value of harm is the proper measure of risk. It is, proponents argue, the only measure the use of which will minimize total harm *in the long run*. If we assume the *expected* number of people dying of heart attack in a country is 400,000 per year, that typically means that about 400,000 *will* actually die from heart attack on a given year. Imagine that we had a new revolutionary treatment for coronary heart disease that would decrease the expected number by 100,000. Switching to the first treatment would typically mean that around 300,000 people would die the following year.

This strong correlation between the *expected* value of an outcome and the *actual* value follows from what is called the Law of Large Numbers, which is the theorem in probability theory that states that if independent trials with the same probability of outcomes are repeated, the average value of the trials converges to the expected value. In other words, in the long run, given the above assumptions, actual value converges to the expected value. The classic illustration of this is the tossing of a (non-biased) coin: whereas there is nothing strange in tossing three heads in a row, we would expect the relative frequency after, say, 100 or 1,000 tosses to be very near to 0.5.

There are, however, several objections to defining the risk as the expectation value of harm. In the previous section I discussed some problems with comparing harms in a sufficiently extensive way as to make the notion of expected value well defined. Even if we assume that such a measure is available, however, there are problems with defining risk as expected value.

One main objection takes on the background assumption that is explicit in the very name of “Law of Large numbers.” It is based on noting that as soon as the numbers of events in question are less than “large,” there is no guarantee that the actual outcome is close to the expected one. (Indeed, *given* any number of events, there is no guarantee that the expected value is close to the actual outcome.) Let us imagine a future where we have a much smaller number of people dying from heart attack, say typically 20. In this future society, we are faced with a clear choice (don’t ask me about the mechanisms for this, it is a thought experiment) between medicine A or B. With medicine A there is a 0.00001 probability that 1,000,000 will die, and 0.99999 that no one will die. With medicine B there is a probability of 0.5 that no one will die, and 0.5 that 30 will die. With medicine A, the expected value is 10, whereas the expected value with medicine B is 15. The proponent of the expected value notion of risk would thus claim that using medicine A would mean the least risk, but this, the objectors argue, is not at all clear. The *actual* outcome could in fact be 100,000 deaths in heart attacks the following year, if treatment A is chosen, whereas in case B, it would be, at maximum, 30 persons. Hence, they may conclude, the safest option is B.

The basic idea in this objection is thus that there may be a discrepancy between the expected value and the actual value, depending on the actual distribution of outcomes and their matching probabilities, and that it is thus not irrational to oppose the general identification of risk with the expected value of harm. If we are dealing with “one-shot” events rather than frequent events of the same type and the same independent probabilities, the expected value may be nothing more than *one* aspect of the risk, not the full determinant of its magnitude. In particular, when the potential harmful outcome is extreme, such as the extinction of mankind, the expected value notion is deficient as a measure of the risk.

## Uncertainty

---

While probability and harm are often alluded to as the basic aspects of risk and safety, some authors explicate the terms by focusing on the aspect of *uncertainty*. Hence, risk is sometimes explained with reference to an uncertain consequence of an event (Renn 2005; Aven and Renn 2009). Under some interpretations, however, this notion of uncertainty reduces into probability. Aven (2003: xii), for example, uses probability and probability calculus as “the sole means for expressing uncertainty.” This probabilistic understanding of risk and safety has a substantial justification in the subjectivist *Bayesian framework* (Howson and Urbach 2006). As mentioned above, on a subjectivist interpretation, probability is conceived of as representing all aspects of a decision-maker’s lack of knowledge. On a Bayesian construal, *all* rational decisions are fully representable with precise probabilities, since the rational decision-maker always, at least implicitly, assigns a probability value to each potential outcome. Faced with new information, the agent may change her probability assessment (in accordance with Bayes’ theorem), but she always assigns determinable probabilities to all states of affairs. Thus, in the Bayesian view all uncertainty about what will happen is codified in the probability assessment for the outcome at hand (Ramsey 1931; de Finetti 1937; von Neumann and Morgenstern 1944; Savage 1972).

The reduction of uncertainty to probability is however not the only alternative. On the contrary, as was argued above the probabilities behind risk and safety ascriptions are not typically given a subjective Bayesian interpretation. Rather, it is more in line with what is called

the classical view in decision theory, in which a basic distinction is made between situations with known probabilities and situations where probabilities are unknown or only partially known (Knight 1921). Proponents of the classical view have pointed out that there is a large difference between situations with well-determined probabilities, such as coin-tossing, and less well-determined situations such as assigning probabilities to whether a major accident will happen in a complex plant. In the latter case there is *epistemic uncertainty* that, according to these authors, may not be reducible to a unique probability value in a rational way. This has led many contemporary theorists also of Bayesian bent to argue for the inclusion of (non-probabilistic) epistemic uncertainty into the analysis (Ellsberg 1961; Kyburg 1968; Levi 1974; Gärdenfors and Sahlin 1982).

One way of illustrating the idea of epistemic uncertainty is to imagine two situations in which you are walking alone in the jungle, and are about to cross an old wooden bridge. The bridge looks unsafe, but you have been told by people in the local village that the probability of a breakdown of this type of bridge is less one in ten thousand. Contrast this with a case where you in your jungle walk are accompanied by a team of scientists, come across a bridge, and the scientists carefully investigate the bridge and conclude that the probability that it will break is rather one in five thousand. Even though the probability is now judged as higher, the epistemic uncertainty is far smaller and it is not unreasonable to regard this situation as preferable to the first one in terms of safety.

This kind of example suggests a picture in which the risk increases with the probability of harm, with the severity of harm, and with uncertainty. So two events with the same severity of outcome that are given the same probability for occurring in accordance with the best estimations possible may still warrant different ascriptions of risk, if the uncertainty is considered different in the two cases. Assume, for example, that we are to compare the safety of two different means of energy production that are both given the same probability of severe failure, one utilizing an old and well-tested method, and another utilizing a new method. Naturally, the new method has been well tested as far as possible, but we do not have the same source of performance data for the entire system as in the case of the old method. Here, it may be reasonable to claim that the risk of the new system is higher, due to the greater epistemic uncertainty in question.

Many methods and techniques in safety engineering may, in the first instance, reasonably be interpreted as methods of reducing the uncertainty. Take the method of *inherently safe design*. Here the idea is to switch from controlling potentially dangerous materials and subsystems to using materials and subsystems that are less dangerous in themselves, that is, that do not need to be controlled in the same degree. Hence, a possible hazard is *removed* rather than *contained*. For example, fireproof materials are used instead of inflammable ones, and this is considered superior to using inflammable materials but keeping temperatures low (Möller and Hansson 2008).

While the general notion may be reasonably clear, a fundamental question is how epistemic uncertainty should be characterized in more detail. This is a controversial area in which no consensus has been reached. The most extensive discussions have been in decision theory regarding how to express the uncertainty of probability assessments. Here, two major types of measures have been suggested, binary and multi-valued measures. A binary measure divides the probability values into two groups, possible and impossible values. In typical cases, the set of possible probability values will form an interval, such as: “The probability of an epidemic outbreak in this area within the next 10 years is between 5% and 20%.” Binary measures have been used, for example, by Ellsberg, Kaplan and Levi (Ellsberg 1961; Kaplan 1983; Levi 1986).

Multivalued measures generally take the form of a function that assigns a numerical value to each probability value between 0 and 1. This value represents the degree of reliability or plausibility of each particular probability value. Several interpretations of the measure have been used in the literature, for example, second-order probability (Baron 1987; Skyrms 1980), fuzzy set membership (Unwin 1986; Dubois and Prade 1988), and epistemic reliability (Gärdenfors and Sahlin 1982). See Möller et al. (2006) for an overview.

In summary, while many authors agree that epistemic uncertainty is an important aspect for risk and safety *in addition* to probability, how to include it in more detail is strongly controversial. Perhaps this should not surprise us, however. A general measure of what we do not know may sometimes be too much to ask for, even in theory.

## Further Aspects of Risk and Safety

---

For the quantitative notion of risk, several candidate aspects beyond probability, severity of harm and epistemic uncertainty have been suggested in the literature. In particular, empirical studies of risk – so-called *risk perception studies* – have established many other aspects that are relevant for how people judge risks. For example, in a seminal study Fischhoff et al. (1978/2000) presented eight aspects that determined people's preparedness to accept a risk. In addition to severity of consequence – which I have already discussed – the aspects were: Voluntariness of risk, Immediacy of effect, Knowledge about risk, Control over risk, Newness, Chronic-catastrophic, Common-dread. Results like these have helped shape a demand, directed at risk assessors, to take other aspects than the traditional under consideration.

Now, as I noted in section  [Acceptable Risk](#), there is an important distinction between the *magnitude* of a risk and its *acceptability*. Many of the aspects in the above study seem relevant to the *acceptability* of risk. Still, these aspects return as suggestions for aspects relevant to the very notion of risk as well. May there be any merit to such suggestions?

In evaluating such a claim, we should first distinguish individuals' *conceptualization* from the *concept* in question. While there typically is a deep connection between competence and actual use of a concept, many of our beliefs about a concept can be wrong even if we are competent with it. Moreover, we seldom think that we have full knowledge about how to exactly delimit a certain concept. I take myself as pretty competent with a rather wide range of concepts – such as *table*, *computer*, *book*, and *coffee mug*, just to mention some of the ones I just applied to objects in my proximity – but I am not sure that I would be able to delimit any of these concepts with any certainty. So even if we did show that there is an aspect that many people *take* to be part of the concept of risk, it does not mean that it actually *is*.

Such a skeptical stance has been a common attitude for many traditional risk analysts faced with suggestions beyond their preferred notion of risk, that is, typically the expected value notion (Hansson 2010). In their arsenal, they have used risk studies that seem to have shown the irrationality of people's risk perception. For example, it has been shown that people often take the risk of exposure to chemicals and radiation as something binary – either you are exposed or not – and neglect the dose factor (Kraus et al. 2000/2000). Since actual harm is predominately a factor of dose, it amounts to a misconception of the risk involved.

It certainly is a radical claim that such beliefs about chemical exposure are *irrational*. It is indeed an intelligible position – it just happens to be wrong. But false beliefs are not irrational beliefs. The point to make here, however, is that while there is a *prima facie*

reason to take strongly held beliefs about a notion seriously, if we have sufficient evidence we may show that they are mistaken.

When it comes to many of the suggested candidate aspects of risk and safety, I believe indeed that they are mistaken, when thought of as *conceptual* aspects. Take the aspect of *control* (Möller et al 2006). To say that a certain risk is *more controllable* for an agent than another risk means, in the present context, that there is a more reliable causal relationship between the acts of the agent and the probability and/or the severity of the harm (this is an extension of the psychometrical concept, which only regards the subjective dimension). At first sight one might believe that, everything else being equal, more controllability implies less risk. Arguably, if we only have the option of flying on automatic pilot, we would be less safe than we would if we had the option of turning it off as well. However, this relationship does not seem to hold in general. We have, again, to distinguish between a psychological perception of safety and actual safety, since we may feel safe without actually being safe, and *vice versa*. Consider two nuclear power plants, one of which runs almost automatically without the intervention of humans, whereas the other is dependent on frequent decisions taken by humans. If the staff responsible for the non-automatic plant is poorly trained, it seems reasonable to maintain that the automatic plant is *safer* than the non-automatic one *because* the degree of controllability is lower in the automatic plant. Arguably, even if they are excellently trained, a high degree of control may lower the safety. Consider a third nuclear plant that is much less automated than the ones we have today. Due to cognitive and mechanical shortcomings, a human being could never make the fast adjustments that an automatic system does, but this plant has excellent staff that perform as well as any human being can be expected to do under the circumstances. In spite of this increased control this too would be a less safe plant. The reason is that the probability of accidents due to human mistakes would be much greater than in a properly designed, more automatic system.

The effects of control on safety in our nuclear plant example can be accounted for in terms of the effects of control on probability. If increased human control decreases the probability of an accident, then it leads to higher safety. If, on the other hand, it increases the probability of accidents, then it decreases safety.

Denying that control is part of the *concepts* of risk and safety is not denying that it may have other relations to the phenomena. For example, it may be a *heuristic device* in many situations: it might be that having the option to causally control our systems often would increase their safety. This correlation, however, is an *empirical* possibility rather than a conceptual one.

For other aspects, it seems rather clear that what is at stake is not the quantitative notion of risk and safety at all, but that they are reasons for the acceptability of a risk. Voluntariness of risk, for example, seems to be about the acceptability of imposing involuntary risk and not a claim that the degree of voluntariness changes the magnitude of risk in any sense.

There are, however, aspects of a potential risk event beyond probability, severity of harm and epistemic uncertainty that have been argued to belong to the concept of risk and safety (Möller 2009a, 2010). Although admittedly controversial, they are instructive in order to further demonstrate the complexity of inferring ascriptions of risk and safety.

*Distributive aspects* illustrate a further complication with harms and risk: even if we assume a measure, such as a reasonable way of comparing a broken leg with a casualty (as discussed above), how to infer the risk from different *distributions* of potential harms may not always be clear (Hansson 2005; Möller et al. 2006).

Imagine that a revolutionary method of building encapsulated nuclear power plants has made the population safe from even the unlikely event of a meltdown and thus decreased

the total expected value of harm. The only drawback is that service staff must make some internal maintenance and this is very risky, having a high expected value of harm, several magnitudes above current levels for any staff. Let us further assume that the level of epistemic uncertainty is deemed to be negligibly low in both the current and the new and revolutionary method.

The question we can ask ourselves is whether, in cases like these, safety is merely a matter of receiving as low an expected value of harm as possible in a population, or if the distribution of potential harms also should count? Maybe we should not hold that a situation is safer than another if there are some people carrying significantly higher risks than others? In most societal activities carrying risks, there is an uneven distribution of potential harm. Persons living close to risky artifacts such as energy production plants or heavy chemical plants take a higher risk load than persons living further away. Likewise, for road traffic safety there is a debate about using cables for protecting the vehicle from driving off the road. The cables are successful in avoiding many potentially lethal car accidents; however, they may also be very dangerous for motorcyclists; much more so, in general, than if the motorcyclists merely went off the road. Since there are many more cars than motorcycles on the roads, the expectation value of harm is smaller when using the wires than not, yet for the motorcyclists the risk is much higher. It may be asked whether it is then reasonable to claim that the method is safe as long as the total expected value is kept low, regardless of the particular risks for motorcyclists.

*Delimitation issues.* The second aspect I will mention highlights the complicated nature of selecting the base events for ascriptions of risk and safety – in this case the harmful potential outcomes (Möller 2010). Let us imagine a situation where we are to judge whether automobile traffic between two particular cities is safer than airplane traffic. Extensive frequency data tells us that the probability of serious harm when traveling by airplane is lower than traveling by car. We have reason to believe, however, that to a significant extent, the one-car accidents are intentional, that is, acts of suicide. For air traffic, however, there are almost no accidents that may reasonably be labeled as suicide. If we were to exclude the suicide cases from the frequency data, the expected value of harm for car travel would be lower.

In this thought example, we face the question of how to delimit the risk and safety concepts: what events should count as risk events, and hence be included in frequency data and other means of evaluating the risk and safety at hand? If we were to include all harmful events, air travel would be safest. But it seems wrong to include also suicides in the statistics of road traffic safety. It is one thing to allow mistakes from the driver – and a main part of accidents certainly derive from the human factor – but in judging what means of transportation is the safest, it seems irrelevant that it is possible to use the car also as a tool of committing suicide. Note that this is not a question of epistemic uncertainty (although in practice there certainly is such a question as well). The question is rather that given that we know that an event is a traffic suicide event, should we include it in the basis for the frequency data? It is evident that only some harms count, not others, and we may reasonably doubt the answer, in the thought experiment, to which means of transportation is the safest.

Admittedly, in these two cases of distribution and delimitation, our intuitions may vary. But it seems at least plausible to doubt here that what has the lowest expectation value of harm in these cases are actually safest. Note that for this to be plausible, we do not need to claim that the actual risk of one event is greater or even equal to the other when the expected value of harm of it is less. The weaker claim that the risks are incommensurable, that we cannot reasonably compare them in such a case, is sufficient.

As mentioned above, there are many aspects of risk and safety proposed in the literature; distribution and delimitation aspects such as mentioned here are mere examples of the questions involved in inferring the risk from a given, complex situation. Still, they exemplify the possibility of further reasonable inferential aspects for the quantitative notion of risk, even beyond the general question of how the dimensions of probability and severity of harm should be combined into one measure. In the next section, we will investigate whether these aspects, among others, represent a problem for a scientific notion of risk.

## The Nature of Risk and Safety

---

The nature of risk and safety has been understood in widely different ways in the literature. Some authors have taken risk to be a scientific, objective, or natural notion, picking out real properties in the world, while others have taken it to be something far more normative or subjective, or even denied its existence. Generally, these commitments can be mapped to a high degree with the three risk perspectives that were mentioned in section [Risk Perspectives](#): the *scientist notion* of risk, the *psychological approach*, and the *cultural approach*. On the scientist approach, risk is typically seen as a scientific notion and, correspondingly, a phenomenon that may be investigated and measured in a systematic way, at least in principle. With that often comes the idea that risks are natural, objective, and real features of the world. On the *psychological approach*, the focus is on how individual people conceive of risks and their acceptability. But many psychological researchers are interested in how this relates to how the risks actually *are*, and often seem to assume that there is an objective fact of the matter to compare with (Summerton and Berner [2003](#), p. 6; Hansson [2010](#), p. 232).

The strongest opposition to conceiving risk and safety as objective concepts comes from proponents of the *cultural approach* to risk. As mentioned in section [Risk Perspectives](#), on the cultural approach, risk is typically seen as a subjective and social phenomenon. Often this is expressed in terms of a social construction: risk is a social construction, since the content and delimitation of risks are socially articulated and treated. People from different cultures as well as within one culture have very different views on what constitutes a risk and how severe a risk may be. Sometimes proponents of this view express that there is no fact of the matter over and above these individual or cultural views, committing them to a denial of risk as objective and perhaps even real. (These are merely initial characterizations: as will become clear, all of the three risk perspectives are *compatible* with objectivist, subjectivist, or constructivist conceptions of risk as described below.)

Even if we assume that there is a lot to say in favor of the initial characterization just given, it should be unpacked a little more carefully. Taking risk to be *natural*, *objective*, or *real* are distinct thoughts that I will investigate further in the following section. First, in section [Risk and Normativity](#), I will distinguish between taking risk and safety as *natural* concepts on the one hand, and as *normative* concepts on the other, and discuss some allegedly normative aspects of risk and safety. In section [Thick Concepts and Reductionism](#), I will present an interpretation of risk and safety as what in philosophy has been called *thick concepts*, and discuss the idea that risk can be reduced to a natural concept. Lastly, in section [Risk, Objectivity, and Social Constructions](#), I will discuss the idea that risk and safety are social constructions, and the related question whether that means that risks are not objective or real.

## Risk and Normativity

In the traditional use, a natural concept is a concept that is invoked in scientific explanations or, more narrowly, used to express the laws of nature (Little 1994; Vallentyne 1998; the latter characterization is in line with traditional understanding of natural kinds: the close relation between natural kinds and law-like regularities is emphasized by most natural kind theorists, cf. Lange 2007; Boyd 1991; Hacking 1991; Wolf 2002). The philosopher G.E Moore has offered a number of influential characterizations to this effect, suggesting that a natural property is a property that is the subject matter of natural science and psychology, and that it is a property that can be known by means of empirical observation and induction (Moore 1903, pp. 25–27). Paradigmatic natural concepts are *water*, *gold*, *mass*, and *redness*.

Normative concepts are typically characterized as opposed to natural concepts. An often-used image is that the natural and the normative have opposite “directions of fit”: to be true, natural claims should fit what the world is like, whereas it is what the world is like that should fit the true normative claim (Williams 1985, Blackburn 1998). Normative concepts such as *good*, *right*, and *fair* are thus action-guiding; that an action is good, right, or fair entails that we have a reason to perform it. (I am in this chapter using “normative” broadly in a sense that refers both to deontic concepts such as *right*, *ought*, and *permitted*, and to value concepts such as *good*, *bad*, and *better*. Sometimes “normative” is used to refer only to the former category, while “evaluative” is used only for the latter. While the relation between deontic and value concepts is an interesting topic in its own right, for the purpose of the present chapter, it is the distinction between the cluster of these broadly normative/evaluative concepts on the one hand, and the natural concepts on the other, that is of interest.) In contrast, natural concepts have no such *prima facie* action-guiding feature: that something contains water may be a reason to drink it if you are thirsty, but not otherwise.

Is risk a natural or a normative concept? As we have seen, many proponents of the scientist approach to risk view it as a perfectly natural, descriptive concept. This goes in particular for proponents of the expectation value of harm conception of risk, where risk is understood as a function of probability and severity of harm, where both harm and probability are taken as natural concepts.

However, the picture of risk and safety as natural, scientific concepts has been criticized. The criticism is grounded on either *external* or *internal normativity*.

*External normativity* is the normativity involved in answering questions about whether or not a risk should be imposed, is acceptable, or small enough to be safe. I label it “external” since it is external to the quantitative notions of risk and safety that have been the main subjects of investigation in the current chapter.

Many sources of external normativity have already been mentioned in section [● Acceptable Risk](#) on acceptable risk. As soon as we leave the realm of absolute safety as discussed in section [● Is Safety the Antonym of Risk?](#), where safety is interpreted as a level of no risk, the question whether a certain level of risk should be accepted, or deemed safe, is relevant. In the early studies of acceptable risk, much work centered on what level of risk people thought was acceptable. Reasonably, what people *take* to be an acceptable level of risk is relevant for what level we *should* accept. Indeed, this is a basis for democratic decision-making. But generally they are different questions. The latter question about what level we should accept is a paradigmatic normative question. Hence, even if we take a certain level of safety as a given,

whether that level is *sufficiently* small to be acceptable or safe is a further normative question about what we have reason to do.

This normative status is most obvious when the reasons for accepting or not accepting a risk do not have to do only with the levels of risk as such – e.g., whether they are larger than other risk levels that we have accepted (see section 2 [Acceptable Risk](#)) – but with moral considerations, such as rights, agency, and autonomy. It is particularly evident when the acceptability of a risk depends on moral reasons that go in different directions. For example, that the direct risk of smoking is voluntary may be seen as a reason for allowing it in public areas. On the other hand, there may be a statistical connection between allowing people to smoke in public areas and the number of people that actually take up smoking. That could be considered as a reason against allowing it. The outcome of such a question of whether or not to allow public smoking, however based on scientific results on its harmful effects, is clearly a normative statement.

*Internal normativity.* That questions of acceptable risk and safety are normative, however, is hardly controversial today, especially after the evidently normative problems involved in trying to set a general limit for acceptable risk mentioned above. To the contrary, in modern risk analysis one is careful to distinguish between the quantitative assessment of risks with the assessment of the viability or acceptability of the risk. This corresponds to the typical division of risk analysis into two stages: *risk assessment* and *risk management* (NRC 1983; EC 2003; sometimes, as in the NRC model, risk assessment is divided into two stages as well, the research stage and the assessment stage). Risk assessment is traditionally considered the scientific stage where the estimations of the risks at hand are produced. Risk management then uses the output of the risk assessment as input for making a decision about the risk, ultimately whether to accept or reject it.

Thus, theorists that claim that risk is a natural concept – who we will refer to as *naturalists* – should typically be seen as referring to the *quantitative notion* of risk. Compare with paradigmatic measures such as *length*. Here, we may claim that someone's length may be a natural, scientific property and still agree that whether that length is acceptable for a certain task, such as being a basketball player, is a normative affair.

Proponents of a naturalist view on risk have several reasons in their arsenal. While the nature of probability is arguably a debated subject, as previously mentioned what is normally of interest in risk and safety contexts is not a subjective Bayesian notion but rather an objective notion such as relative frequencies (Resnik 1987). In addition, it is often claimed that severity of consequences may in many cases be measured to a sufficient degree. A basic measure is the number of lives at stake, so that higher severity means more potential deaths.

Critics, on the other hand, point to the very complications concerning the aspects of risk that I have discussed in this chapter. Probability, for example, may seem as an untouchably scientific notion due to its profound mathematical basis, but while a relative frequency is indeed a statistical fact, its role in deciding the actual probability of an event may be questioned, since it records historical data and the question is always how that applies to the situation at hand. Moreover, for many complex systems, we have sufficient frequency data for only parts, and have to estimate the overall probability, and there may be no value-free way of making that estimate.

This dependence on values is even clearer when we move beyond probability to epistemic uncertainty. There is no established measure of uncertainty. The many alternative suggestions put different aspects of uncertainty to the forefront, and it is unclear that there can be a general measure of such an elusive entity.

Naturalists can reply that these objections merely point to the fact that there are *epistemic values* involved when making risk and safety ascriptions. However, they may continue, this is not anything specific to the risk and safety area – in fact, philosophers of science have argued that epistemic values such as reliability, testability, generality, simplicity, etc., are integral to the entire process of assessment in science (McMullin 1982; Kuhn 1962; Lakatos and Musgrave 1970). Hence, they are the kind of values that the scientific experts are competent to apply in their scientific enterprise. Naturalists conclude that showing that risk ascriptions are normative in this sense merely puts it on the same level as our most paradigmatic natural notions such as *water* and *mass*.

In other words, on the naturalist defense, we have to be skeptics about *all* scientific notions in order to be skeptical about the notion of risk. Some theorists bite the bullet and draw that skeptical conclusion (Mayo 1991, pp. 254–255; Wynne 1982, p. 139). But even if we accept that all scientific claims are conditioned by epistemic values, and that this does not make them normative notions in the sought sense (merely an internal-to-science-only sense), it may be doubted that the values involved in risk ascriptions are limited to these values. The values involved in criteria for accepting a theory or an empirical result into the scientific corpus are typically biased toward avoiding false-positives, that is, taking something as a scientific fact when it is not. For risk and safety analysis, however, we may have a broader scope in order to avoid underestimating the risks (Möller 2009b; Wandall 2004).

Probability and epistemic uncertainty are only two dimensions of risk and safety, however, and the problem for the risk naturalist may be even larger when we turn to harm, and to the further problem of inferring risk and safety from all of these aspects. Even if we grant that a certain harm may be a perfectly natural notion, it is less clear that severity of harm may be ascribed in any value-free way. As I mentioned in section [Further Aspects of Risk and Safety](#), neither comparing different harms nor ascribing a level of severity to an event such as a death seems to be possible to do in a value-free way. Indeed, it seems normative if anything is.

Furthermore, there is the added complication of inferring risk and safety from its “base aspects.” As we have seen, the traditional risk assessment measure of expected value of harm has been heavily criticized. If we do not accept the expected value as a measure of risk, how then are we to infer the risk? Is there a scientific way of making this inference, one using – at the most – only values internal to science? The skeptic to risk as a natural concept doubts this.

If we include also the more controversial inferential *distribution* and *delimitation* aspects discussed in section [Further Aspects of Risk and Safety](#), the risk naturalist faces even further obstacles. To argue – as in the case of the nuclear power plant where staff were to be exposed to a significantly larger potential harm than the population at large – that there are cases where the uneven distribution of potential harm is relevant for the very level of risk (and not only for the acceptability of a certain level) is to argue that distributive aspects are *part* of the very concept of risk and safety. And it seems doubtful, even if we grant that natural science may give us a probability and a severity of harm for an event, that there is anything for natural science to say about such distributive questions as these.

The delimitation aspect also seems to be a normative aspect of risk and safety, that is, a normativity due to which events should count as safety events, relevant for assessing the question of the risk and safety in the case at hand. The traffic suicide case indicates that not *all* potential harms are relevant for risk and safety. What is qualitatively identical on the level of physical harm is not necessarily identical for evaluating the risk and safety because one event is a suicide and the other an unintentional accident. It has been argued (Möller 2009a, 2010) that

there are several potential properties of a harmful event that may motivate an exclusion of it as a risk-relevant event in certain circumstances, e.g., that it constitutes harm-seeking behavior or harms that are too small in the relevant circumstance (even if they are frequent), etc.

## Thick Concepts and Reductionism

---

As we could see in the subsection above there are several arguments for the normative nature not only of notions such as *acceptable risk* and *safe*, but also for the normativity of the quantitative notion of risk itself. Is risk as a normative notion a threatening idea for the proponent of the naturalist notion of risk? Perhaps the naturalist may acknowledge that risk and safety are normative notions and yet argue that they may be reduced to natural ones? After all, it should be clear that the notion of risk has a substantial amount of non-normative content. In this section, I will place this idea in a broader philosophical context, namely, the philosophical debate of thick evaluative concepts.

When I introduced the notion of normative concepts above, I mentioned such normative concepts as *good* and *right*. Even if the arguments for risk and safety as normative concepts are sound, they seem to differ from these paradigmatic ones. That an action is good or right tells you that it is the thing to do, at least *prima facie*, but it does not tell you anything about what type of action it is. It does not have any (or at least not much) descriptive content, only normative content. To be kind to a stranger may be morally right, but so can, many believe, starting a war (that is the assumption behind the “*just war*” concept). And these actions seem to have very little in common, except for the – assumed – normative status of being right.

Certainly, there is also a normative dimension of risk. That something constitutes a risk is typically a reason against (allowing, using, performing) it, and the larger the risk, the stronger is that reason. Risk has a negative evaluative “direction,” just as safety has a positive one. But risk is also importantly different from the paradigmatic normative notions of right and good, in that it is a notion with substantial descriptive content. Indeed, the richness of descriptive content is the main argument for the scientist approach to risk and safety. There are many descriptive characterizations of risk and safety that render them quite different from the paradigmatic normative notions of good and right: the central role of severity of harm; that a harm is not certain but may obtain; that a risk is greater the more likely it is that the harm may occur and the greater the harm, etc. Perhaps, proponents of the scientist approach to risk may argue, there is a possibility to acknowledge that risk has a normative aspect to it, but that we may, for scientific purposes, *reduce* the notion to its natural part.

In moral philosophy, there is an analogous debate among the kind of concepts that are called *thick normative concepts* – or thick concepts for short. In philosophy, John McDowell and Bernard Williams introduced the notion of thick concepts in the 1970s and 1980s (McDowell 1978, 1979, 1981; Williams 1985). Thick concepts are concepts such as *cruel*, *brave*, and *selfish*, concepts that have *both* descriptive and normative content. As such, thick concepts seem to differ from both paradigmatic natural concepts such as *water* and *length*, which have no such normative quality, as well as from paradigmatic normative concepts such as *good* and *right*, which are said to be solely or primarily normative. On the traditional analysis, a thick concept fills a double function: it describes a feature (world-guided function), and it evaluates it (world-guiding function).

On our characterization of risk and safety, it seems as if these notions fit right into this category: that something is safe is a positive feature of the entity, and that something carries a risk is a negative feature of it. But it is not simply positive or negative, it is positive or negative *in a certain way*; it has a certain descriptive “shape,” as I noted above. Grasping these aspects of the concepts is part of what one has to do in order to understand their meaning. Hence, it has been argued, risk and safety are to be understood as thick evaluative concepts (Möller 2009a, 2010).

When theorists first started to investigate (what would later be called) thick concepts, they believed that these could be analyzed as a *conjunction* of a descriptive part and an evaluative part, by which is meant that the descriptive content and the evaluative content can be independently given (Stevenson 1944; Hare 1952). “X is courageous” could therefore be analyzed as something along the lines of “X intended to act in the face of danger to promote a valued end” and “this is (*prima facie*) good-making.” Furthermore, it was commonly assumed that the descriptive part determined the reference of the thick term. A thick concept, on this analysis, is a concept with a descriptive shape that decides the extension, and an evaluation that commends or condemns an entity for having these descriptive features. If this were correct, a descriptive reduction of a thick concept would, at least in principle, be possible. While something may still be said to be lacking in the understanding of the concept of courage in a person who grasped the descriptive part but took a neutral evaluative stance toward it (did not believe that courage was either good or bad), this person would be fully able to identify courage. For the concepts of risk and safety, this would mean that there indeed was a descriptive part that one could – in principle – isolate and operationalize. Perhaps an agent that understood only the natural part of risk and safety would not have a full understanding of the concept and all of what it signifies, but she would still be able to get the extension of the concept right. If this is possible, risk and safety would be normative concepts, but they would still be able to be *reduced* to natural concepts in the following important sense: natural concepts would still suffice as the descriptive kernel of the concept that would allow us to compare risk in a scientific, non-normative way. The normativity of risk and safety, on this understanding, could then be acknowledged without any threat for the scientific status of risk ascriptions.

To make this reductive idea clearer, it may be helpful to compare with the notion of body mass index (BMI), which is an individual’s body weight divided by the square of his or her height). Having a BMI higher than 25 (based on the standard unit values kilogram and meter) is typically evaluated negatively, as it is considered bad for the health. Conversely at the other end of the spectrum, a BMI below 18.5 is considered a too low relative weight. In this sense, BMI may be seen as a concept that is a compound of both descriptive and evaluative parts. Here, however, the descriptive part is sufficient for picking out the extension of the term.

BMI is an example of a term with fully technical primacy: it is developed and applied using only natural notions. Hence, it is not at all surprising that these natural aspects are sufficient – it is a definitional fact of the term. What may be – and is – questioned is when a certain BMI is indeed unhealthy. That is, the evaluative aspects seem to have a secondary status as projections on the fundamentally descriptive or natural concept of BMI. The descriptive part, however, is rock solid.

The normative aspects argued for in the previous subsection, however, are hard to picture as secondary projections on the descriptive aspects. The point of the critique of a natural, non-normal conception of risk has been that normative aspects are prevalent in the very *ascription* of the quantitative risk, and not only in the evaluation of a previously already given

quantification. Hence, in order to *establish* the magnitude of the harm, or the way in which the probability and severity are to be combined into a risk measure, we make evaluations that are over-and-above the natural basis of these notions.

For such notions where there is no clear primacy of a technical definition, philosophers in the thick concept debate have been increasingly skeptical of the reductive idea. Philosophers such as John McDowell, Bernard Williams, and Jonathan Dancy have argued that no such separation of a descriptive, autonomous part on the one side and an evaluation on the other can be given (McDowell 1978, 1979, 1981; Williams 1985; Dancy 1995, 2004). The only way to understand a thick concept is to understand the descriptive and evaluative aspects *as a whole*. The idea is that for a thick concept, the evaluative aspect is profoundly involved in the practice of using it, and therefore one cannot understand a thick concept without understanding also its evaluative point. (I here use the epistemological framing of the claim used by McDowell. Dancy (1995) goes even further, making the metaphysical claim that the descriptive and evaluative content is an indissoluble amalgam.)

On the analysis of risk and safety given in this chapter, it is hard to see the normativity of the aspects of risk and safety as a secondary, projective aspect of a notion that is otherwise essentially descriptive. The main reason for this is that the normative aspects of risk figured not only as an evaluation of the “finished product,” as in the BMI example and in the question of the acceptability of the risk, but on the very ascription of the core aspects of risk, such as harm and epistemic uncertainty, and the delimitation and distributive aspects.

For risk and safety, thus, there is an essential interdependence between the natural-descriptive aspects and the normative-evaluative aspects. That an event has a higher expected value of death than another event – treated as a natural input – is typically a reason to ascribe the former a higher risk than the latter. But this is not the case if there are other harms than death that should count as well, or a questionable distribution of the harmful outcomes for the latter case (as in the staff in the novel nuclear plant), or if the epistemic security is much higher in the latter case, etc. – all arguably normative aspects. In this respect, risk and safety are unlike paradigmatic natural concepts such as gold. Even if people treated gold as something positive, as many do, this does not change the fact that only substances of a certain atomic number counts as gold: descriptive notions are all that matters. And it is unlike concepts such as BMI, or arguably even concepts as *fat* – on its quantitative notion at least – where descriptive aspects are all that counts for identifying something as having a higher BMI, or as being fatter.

On this reading, risk and safety seem to be of the same essential thick kind that philosophers such as John McDowell, Bernard Williams, and Jonathan Dancy argue cannot be separated into a natural part and a normative part, but must be treated as concepts that are *both* natural and normative, and for which no natural reduction can be given that suffices to pick out the extension of the terms. Currently, this anti-reductive camp is the dominant one in the debate about thick concepts, and also theorists such as Simon Blackburn who initially defended the reductive view (Blackburn 1984) have later abandoned it (Blackburn 1998). Even if Hare defended a reductivist strategy as late as in his 1997: 61, contemporary separatists argue instead for a weaker claim, namely, that a thick concept can be separated into a thin normative concept and a description, but that for the extension of a thick concept, the normative part is needed as well (Elstein and Hurka 2009). In other words, the output of recent moral philosophy is skepticism of the reductive claim for thick concepts such as risk and safety.

## Risk, Objectivity, and Social Constructions

Let us now assume, in line with the arguments in the previous subsection, that risk and safety are thick normative concepts that cannot be reduced to natural ones. Is this bad news for proponents of the scientist or psychological approach to risk? Many theorists in the risk debate seem to make a close connection, if not equivalence, between a notion's status as natural or descriptive, and its being an objective concept. If a concept is not a natural concept, they seem to assume it is subjective rather than objective. It is important to note, however, that this fails to appreciate the large debate in philosophy concerning the status of the field of the normative, in particular the moral domain. In fact, many of the main proponents of the irreducible normativity of thick concepts mentioned above, for example, McDowell and Dancy, are moral realists who believe that there are objective truths in moral discourse. Hence, it is important to notice that claiming that risk is normative is not the same thing as claiming that it is non-objective.

In this subsection, I will investigate a common critique of the notions of risk and safety that seem to claim something stronger than mere normativity, namely, that these notions are essentially subjective or socially constructed. Objectivity and reality are philosophical questions that run deep very fast, and it would take us too far to argue for any particular position in this chapter. The current aim is rather to clarify the extent to which claims of subjectivity of risk, or even the non-reality of risk, are strong and radical claims.

Many theorists from the social sciences that approach risk on what I have called the *cultural perspective* argue that risk is a social construct, which is often labeled as a subjective, social feature rather than a feature of objective reality. People from different cultures as well as within one culture have very different views on what constitutes a risk and how severe a risk may be, they point out, and they go on to claim that there is no fact of the matter over and above these individual or cultural views (Douglas and Wildavsky 1982; Wynne 2000; Slovic 2000). Judith Bradbury, for example, describes the cultural view as the view that risk is conceived as "a socially constructed attribute, rather than as a physical entity that exists independently of the humans who assess and experience its effects" (Bradbury 1989, p. 381).

It should be noted that subjectivity in Bradbury's sense is a rather radical view. It means that the risk of climbing the ascent of K2, or driving 150 km/h in New York City, depends on humans assessing these activities rather than on physical facts that exist independently of such activities. In order to see the radicalism in such a position, and question whether the basic insights of the social constructivist idea motivate such radicalism, let us distinguish between three senses in which something can be socially constructed.

Let us call the first sense of social construct (essential) *reference-dependence*. A social system is needed in order for such an entity to exist. The paradigmatic example here is money (Searle 1995): in order for a piece of paper, metal object, or other physical entity to be money, it has to play a certain role in a social system. Before humans invented the concept of money and established the system in which it had a place, there was no such thing as money. If we take away the system, if we moved away from that sort of economy, or if intelligent life ceased to exist, there would be no money anymore.

The second sense of social construct is weaker: *interactive-dependence* (Hacking 1999). An entity that is interactive-dependent is not essentially dependent on any social system in which it is conceptualized. Still, its conceptualization in a social context affects the entity thus categorized. *Woman*, for example, is such an interactive category. By effectively categorizing someone

as a woman – or stop doing so – one is affecting the way in which the person is viewed by others and herself, which behavior is typical and expected, right and wrong. Before we had a *concept* of woman, there existed women, in the sense that the kind of entities existed that (sufficiently) fit the concept. Its introduction, however, has changed the very category: a basic insight of feminism is that categorizing someone as a woman affects how she conceives of herself, which is one of the important problems for societal change. It is why merely *formally* allowing women entrance to societal positions and roles that used to be restricted to men does not by itself establish a substantial shift in the social structure, even if there are no essential biological restrictions that prohibit such a shift.

The third sense of social construct is the weakest: *sense-dependence*. (The distinction between reference-dependence and sense-dependence is taken from Brandom (2002, pp. 194–195), although it is here used in a slightly different way.) The idea here is that the entity in question is neither interactive-dependent nor essentially reference-dependent on its conceptualization and the social system in which it figures. However, our being able to *grasp* the concept and thus classify objects and properties in the world in accordance with it is dependent on a social context in which it has evolved. An example is the concept of a quark. The concept of a quark is dependent on the modern development of physics. While the concept of a quark was developed independently by Murray Gell-Mann and George Zweig in 1964, their being able to develop it was of course the fruit of social arrangements – ideas and institutions – throughout centuries. Indeed, all complex concepts such as those of theoretical entities in natural science theories are the fruit of social construction in this sense.

This third sense of the socially constructed is by far the weakest. Most philosophers of language would admit that *any* concept is socially constructed in the sense of having been developed in a social environment, for the simple reason that language *in total* is a social construct. Now, the extent of that sociality, and how necessary – as opposed to merely historically contingent – it is for language to be thus developed, may be disputed, but it seems to be an undeniable fact that the ability to express claimable content to other beings, to categorize objects and events in order to refer to them by language, is a social affair. How can it not be? Still, there is certainly a difference between the level of social exchange that is needed for different concepts. The concept of quarks need a bit more social lever – the development of advanced physics – in order to be constructed than, for example, the concept of food, which is closely connected to basic human needs.

Equipped with these three senses of social constructs, the one that most clearly fits Bradbury's description of risk as a "socially constructed attribute, rather than as a physical entity that exists independently of the humans who assess and experience its effects" is the first one, the essential reference-dependence. In the two other senses it seems (and I have assumed in the explanation of them) that while the *concept* is a social construct, the *entity* may exist independent of the humans that assess and experience its effects. It does make sense to state that women – and men, and children, and humans in general – existed prior to the construction of a concept to sort them out as such. Or, at the very least, further argument is needed in order to show why this is not so. For reference-dependent concepts such as money, it is the other way around: it makes little sense to claim that money existed before the conceptual practice involving it was in place.

In the debate, the range of claims sorted under the banner of social constructivism is very broad. Often in practice the core claim seems to be something closest to the third sense of social construct, which primarily focuses not on the entity as such but on the *concept* we have

developed. For example, take Summerton and Berner's description of the main premise of the cultural approach:

- What is identified as a risk is not based on an *a priori* "fact" as identified by technical or medical experts; neither are risks merely rule-of-thumb assessments made by isolated individuals. The ways in which individuals – including experts – interpret risk can instead be seen as an expression of socially located beliefs and world views that to a large extent stems from the individual's situated position and experiences within social hierarchies, institutions and groups (Summerton and Berner 2003, pp. 6–7).

Their claim is much less radical than Bradbury's, since they explicitly limit themselves to what is *identified* as a risk by individuals, claiming first that it is not the same as what experts take it to be, and second that it is, for all individuals including experts, to a large extent a consequence of her social environment. None of this is a denial of the possibility of risks *existing* independently of individuals experiencing them.

Indeed, some theorists make clear that they are not arguing against objectivity per se. Clarke and Short point out that "objects might be dangerous in some objective sense" (Clarke and Short 1993, p. 79). The basic task on the cultural view, however, "is to explain how social agents create and use boundaries to demarcate that which is dangerous" (Clarke and Short 1993). In other words, the motive for making a claim of social construction in a domain can be to underline an explanatory focus: that of investigating how social circumstances, such as organizational environments, social hierarchies or other aspects of our socio-cultural context, play a part in how we conceptualize our world as well as what we take to be the extension of those concepts.

This explanatory task may of course be of paramount importance for how we should arrange our investigations into risks, and how to make decisions about them. Furthermore, it may convincingly show how our conceptions feed back into the phenomenon itself, that is, give detailed insights into the interactive-dependence of risk and safety. (Note that risk and safety are only indirectly interactive-dependent, since *we* are the ones affected by something's being categorized as risky – thus possibly changing the risk at hand – not the risk-entity itself.)

Importantly, however, neither sense-dependence nor interactive-dependence entails subjectivity. There may still perfectly well be an objective fact of the matter whether it is safe to climb K2, even if the actual safety depends on how we have perceived of it, as mediated, for example, by its manifestations in our training and preparation before attempting it, or in how we react to things that happen while climbing. Hence, even if risk and safety are both sense-dependent and interactive-dependent concepts, they can still be objective concepts corresponding to real properties in the world.

There are, however, claims that are made under the heading of social constructivism that deny the reality of risk (e.g., Ewald 1991, p. 199; Dean 1999, p. 177). Also a risk psychologist such as Paul Slovic makes this inference from constructivism to non-realism in a rather recent paper when he contrasts danger with risk, claiming that "danger is real, but risk is socially constructed." (Slovic 1999, p. 689) It is hard, though, to see the motivation for this denial of reality status for risk. Slovic's justification is representative: "Risk assessment is inherently subjective and represents a blending of science and judgment with important psychological, social, cultural, and political factors" (Slovic 1999). But even if we grant that risk *assessment* is subjective – for example, that it has uncorrected biases from cultural and political factors that result in faulty norms – this does not mean that risks cannot be real. Note that even if the *assessment* of our oil

reserves are biased by wishful thinking as well as political and economic agendas, in addition to pure scientific uncertainty in the current models of estimation, it does not follow that oil is not real (or that Eve can have less oil in the tank of her car than Jones has in his).

If no further arguments are presented, it seems that the claims of subjectivity and anti-realism are unjustified inferences from sound insights into the societal nature of concept grasping and assessments of phenomena. In Slovic's claim in particular, this impression is enhanced from the seemingly arbitrary demarcation line between risk and danger. What constitutes a danger (or hazard) seems to be just as connected to human affairs as risk. So if danger is real, why not risk?

Lastly, we should note that even the strongest version of dependence I have mentioned, essential reference-dependence, in itself entails neither subjectivity nor anti-realism. Take the concept of money. The common wisdom is that money is indeed real, and claims concerning them may be objectively true or false, even if it is also true that the existence of potential money facts such as "My mobile phone is now worth roughly \$200 less than when I bought it" or "I sold my car for \$2,000" is dependent on a complex mix of social arrangements.

Naturally, none of the distinctions made in this subsection are by themselves an *argument* for the objectivity or reality of risk. Rather, the aim has been to distinguish between some of the different types of claims that the overall label of social construction may amount to, and to make plausible that denial of objectivity of risk and – even more – the reality of risk lies at the far end of this spectrum.

## Further Research

---

As emphasized at the outset, risk and safety research is a heterogeneous field, and there are many interesting areas for research.

## Analysis of Key Concepts

---

*Mapping different risk and safety conceptions.* In this chapter, several common interpretations of risk and safety have been discussed. Although it is well known that different people use the key concepts of risk research differently, a better mapping of the differences in usage of "risk" and "safety" in various fields is much needed. In particular, this is important for the psychological research where people's attitudes toward risks are the target, and where the terms are generally less clearly defined than in technical areas.

*Risk versus safety.* As indicated in this chapter, risk and safety are frequently treated as antonyms. While this may often be harmless, this treatment is not always viable. For example, it hides a difference in focus between risk research and safety research that should be more clearly explored.

*Uncertainty.* Uncertainty is an aspect of (lack of) safety that is sometimes hidden by the focus on handling the risk. Epistemic uncertainty is an important aspect of safety ascriptions, but, as emphasized in this chapter, there is large controversy as to how this notion is to be measured. Moreover, in many areas of risk and safety, the traditional method of coping with uncertainty is by an increased emphasis on probabilistic safety analysis (PSA). Sometimes, as in for example the nuclear industry, this has amounted to a very high level of descriptive sophistication. Even on this sophisticated level of PSA description, however, there are residual

uncertainties, uncertainties that cannot be captured by PSA alone. Finding ways of handling these remaining uncertainties is an important task.

*Safety versus security.* While the concept of security is strongly interrelated with the concept of safety, there are important differences in the actual *practices* of the two fields. For example, security measures are more focused on protection against intentional threats, whereas safety measures have been directed against non-intentional harmful events as well as utilizing, to a greater extent, probabilistic methods. Investigating the differences and similarities in how safety and security are understood can be an important way to develop our understanding of both notions, and, consequently, develop our methods of ensuring safety and security.

*Safety culture.* The notion of a safety culture is studied by the social and behavioral sciences and employed by safety professionals. But it is rather unclear what a safety culture consists in. Is it an evaluative concept, and what counts as a good or bad safety culture? Can an organization lack a safety culture, or is that equal to a bad one? And what does “culture” signify in the context? Since it is considered an important “tacit” aspect in reaching safety, more conceptual clarity about the notion is called for.

*The status of risk and safety.* In this chapter, we touched on the complicated issues about the status of risk and safety. In addition to the overarching questions of naturalness, normativity, and constructivism, there are also interesting questions of subjectivity and objectivity when it comes to certain aspects of risk and safety. For harm and probability in particular, there are both subjective and objective interpretations. How these interpretations are best understood, and how this matters for risk and safety research, are pressing interdisciplinary concerns.

## Further Issues

---

Related to these conceptual investigations, there are methodological, epistemic, and ethical issues for future research. Examples of such topics include:

*Knowledge: implicit and explicit.* Although effort is made in articulating explicit, propositional accounts of risk and safety, a significant amount of knowledge of risk and safety remains tacit in an organization. In connection with concepts such as uncertainty and safety culture, the relation between tacit and explicit knowledge of risk and safety should be investigated.

*The sequential process approach.* The viability of the common sequential process in safety analysis of starting with a scientific assessment of the risk, followed by an evaluative step in which the overall safety decision is made, depends on the viability of suitably isolating the descriptive, scientific aspects of the risk at hand. Any limitations to this approach have methodological consequences, not only for how we should go about gaining acceptance for a certain risk, or how we should compare risks to the advantages of the technology causing the potential risk, but for the actual enterprise of gaining *knowledge* of the risks involved. A common assumption in risk analysis is that ethical aspects come as merely an *addition* to the risk assessment, something to be considered in risk management only – an assumption that may be questioned, as in the arguments in this chapter that evaluative aspects surfaces already “inside” the very assessment of the risk. An important area of future research involves investigating the consequences of the internal as well as external presence of ethical aspects in risk assessment and management.

*New versus old.* Trying out new methods and techniques is paramount for technological progress. Yet, this means by definition less tested in actual circumstances, which often implies

a large epistemic uncertainty. The circumstances when it is ethically correct to use new designs in potentially dangerous facilities is an interesting question in need of further research, both in general and in the many applied areas of risk and safety research.

*Control versus integrity.* Another trade-off of interest is the one between on the one hand surveillance and detailed supervision or control, and on the other, integrity and autonomy at the workplace. Here, what is deemed most safe and what is deemed as respecting the right to integrity and autonomy may not go hand in hand, and what to do with cases when these ideals clash is a central moral question in risk and safety ethics.

*Disagreement.* As indicated throughout this chapter, there are many different conceptions of safety, as well as many different ways of assessing the very same conception (such as the expected value conception). How should we best treat disagreement about risk and safety? Some disagreements are about scientific issues proper, and these seem reasonable to solve within the scientific community. Also scientists disagree, however, and sometimes on a level that is significantly relevant for the risk assessment. What should we do in such circumstances? But even when there is no disagreement of the underlying natural properties, we may disagree about the normative aspects of risk and safety, as well as about further ethical considerations. How we best treat such different cases of disagreement is a pressing topic for future study.

## Conclusion

---

In this chapter, I have analyzed several aspects of the concepts of risk and safety. As I started by pointing out, there are many different – if overlapping – perspectives from which the questions of risk and safety are treated, as well as several interpretations of the terms “risk” and “safety” that are relevant in the context of societal decision-making. An evident, but still often neglected consequence of this heterogeneous set of interpretations is that we should always keep in mind the possibility of talking past each other in matters involving risk and safety. There are many viable ways of using the terms, and ascertaining that we are on the same track is a minimal condition for risk and safety communication.

The main focus in the chapter has then been on the quantitative notions of risk and safety. Central aspects such as probability, harm, and uncertainty have been treated. In particular, the controversial question of how risk and safety should be inferred from these aspects – and possibly even additional ones – should be kept in mind. Moreover, whether risk and safety are natural concepts or contain normative aspects that cannot be reduced to natural ones are important questions for how we should understand these concepts. Finally, I pointed out that even if risk and safety are normative concepts – as I indeed believe they are – this is not equal to the claim that risk and safety cannot be objective or that they are constructed in any deep sense. Still, risk and safety are central concepts in societal decision-making, and both scientific and extra-scientific concerns are vital if we are to make the best decisions when risks are involved.

**Abstract:** There exist a variety of different understandings, definitions, and classifications of risk, which can make the resulting landscape of academic literature on the topic seem somewhat disjointed and often confusing. In this chapter, I will introduce a map on how to think about risks, and in particular uncertainty, which is arranged along the different questions of what the different academic disciplines find interesting about risk. This aims to give a more integrated idea of where the different literatures intersect and thus provide some order in our understanding of what risk is and what is interesting about it. One particular dimension will be presented in more detail, answering the question of what exactly we are uncertain about and distinguishing between five different levels of uncertainty. I will argue, through some concrete examples, that concentrating on the objects of uncertainty can give us an appreciation on how different perspectives on a given risk scenario are formed and will use the more general map to show how this perspective intersects with other classifications and analyses of risk.

- ▶ I beseech you, in the bowels of Christ, think it possible you may be mistaken (Oliver Cromwell, addressing the Church of Scotland, 1650) (From Carlyle 1871).

## Introduction

---

What we mean by risk is not a clear issue because many writers use the word with slightly different meanings and definitions, even beyond the more vague everyday usage of the term. Aven and Renn (2009), for example, have found 10 different definitions they gathered from the wider risk literature. The problem of clear terminology continues if we go into the various classifications and clarifications of risk and uncertainty, with scholars distinguishing between risks, uncertainties, indeterminacies, ambiguities, and levels, objects or locations of risk and/or uncertainty. With this in mind, I feel slightly apologetic about writing about another scheme devised by myself and David Spiegelhalter (Spiegelhalter 2010; Spiegelhalter and Riesch *in press*), where we use, again, our own terminology, this time in trying to distinguish between different things we can be uncertain about. In this chapter, I will try to explain our distinctions and where they correlate and/or fit in with other classifications of risk and uncertainty, as well as provide an argument on why we feel this particular classification adds to the literature on risk theory by going through a couple of real-world examples.

As Norton et al. (2006) note in their reply to the paper by Walker et al. (2003) discussed below, “an important barrier to achieving a common understanding or interdisciplinary framework is the diversity of meanings associated with terms such as ‘uncertainty’ and ‘ignorance,’ both within and between disciplines” (Norton et al. 2006, p. 84). The proliferation of what we mean by risk and how we categorize it within the literature is partly due to the different agendas the different disciplines have with regard to the topic. The question “what do we want to know about risk?” will be answered differently by scholars, for example, interested in risk perception and those interested in the “risk society.” Asking this question explicitly may help us in finding out where the different disciplinary approaches to risk intersect. Our classification is partly intended to do just that, mostly because I (as a sociologist) and David

Spiegelhalter (as a statistician) have always had slightly different conceptions of what is academically interesting about risk, and our collaboration was partly an attempt to build a conception of risk which is useful for both social and scientific/technical disciplines and will be useful for communicating across this divide by giving a clear account of how and why, in Funtowicz and Ravetz's phrase, there is "a plurality of legitimate perspectives" on risk (Funtowicz and Ravetz 1993 p. 739). At the same time, I hope it will provide a useful and relatively simple map through which the different academic disciplines' interests in risk can be compared and connections seen more easily.

In this chapter, I want to advance the idea that one can confront the different meanings which risk is given and offer an idea of how they are related. There exist many other schemes that try to categorize risks such as Renn and Klinke (2004), Stirling (2007), or van Asselt and Rotmans (2002), and I will try to show how they fit in to our overall picture in the following section. As a departing point, I take risk to mean roughly a function of the uncertainty of an outcome and its impact. This definition leaves room for plenty of uncertainties itself, especially since there is no agreement on how to measure impact, or how to compare impacts of completely different categorization, and there is plenty of literature in risk studies devoted to this problem.

The uncertainty part of risk however is itself very problematic. There are some uncertainties we can put a number on, some where we can only evaluate qualitatively and some we have absolutely no idea on how to even start evaluating them. The classification I will propose here is meant to bring some order into the way we think about uncertainty and provide a way in which different types of uncertainty and its classifications can be, if not directly compared, at least brought under the same scheme. Comprehensive surveys of what uncertainties and risks really are and how they should be classified can easily lead to a rather complicated structure that becomes less useful as a heuristic tool for people working within risk. This is more so on the social, policy, and communication aspects than in the technical risk assessment areas, for whom such schemes will be more useful, and I will concentrate on the former in this chapter. Out of the many different dimensions in which uncertainty can be categorized, we chose one in particular which we believe is most helpful when we seek to understand how different people and groups conceptualize and react toward risks. It is meant to analyze risks according to the following question: What kind of thing exactly are we uncertain about?

## Background

---

Philosophical classifications of probability have traditionally focused on questioning where our uncertainty derives from, with the two main choices being uncertainty inherent in the system, and uncertainty arising from our incomplete knowledge. These two interpretations of probability are named by philosophers (Hacking 1975, see also Gillies 2000) *epistemic* probability and *aleatoric* (also often called *ontological* or *ontic*) probability. This basic distinction still underlies modern philosophical theories of probability and can be seen, for example, in the philosophical split between Bayesian (subjective) and frequentist (objective) interpretations of probability in statistics (see also Gillies 2000).

Uncertainty in a larger sense, as opposed to the mathematically defined concept of probability, has also seen attempts at classification. An early and very influential distinction

came from Frank Knight, who distinguished uncertainties which are quantifiable which he called risks, and those that are not quantifiable, which he called uncertainties:

- The essential fact is that 'risk' means in some cases a quantity susceptible of measurement, while at other times it is something distinctly not of this character; and there are far-reaching and crucial differences in the bearings of the phenomena depending on which of the two is really present and operating. [ . . . ] It will appear that a measurable uncertainty, or 'risk' proper, as we shall use the term, is so far different from an unmeasurable one that it is not in effect an uncertainty at all (Knight 1971 [1921]).

This classification has proved to be very influential especially among sociologists, but is in my opinion slightly unfortunate as it propagates confusion with the traditionally defined concept of risk equaling probability times outcome (or, in the more modern sense focusing on negative outcomes, probability times harm). Although I recognize the usefulness of Knight's distinction for this work, to avoid confusion I prefer to work with the conception that risk refers to a measure of uncertainty combined with the potential outcome.

Combining these two perspectives in a sense, Stirling (2007) recently proposed to divide both the uncertainty as well as the outcome aspects of risk into "problematic" versus "unproblematic" in a similar way to which Knight distinguished between quantifiable and unquantifiable uncertainty. This results in a two by two matrix: at the corner where the probabilities as well as (our knowledge of) the outcomes are unproblematic there are risks associated with the typical statistical risk analyses such as Monte Carlo simulations or cost-benefit analyses – these scenarios he terms "risks" in the traditional sense used by most scientists and risk analysts. Scenarios where the probability is knowable, but we are more unsure about the outcomes, he terms "ambiguities"; risks where conversely the outcomes are unproblematic but the probabilities are, he calls "uncertainties." When neither are unproblematic, he talks about conditions of "ignorance." It is worth also pointing out that the term "ambiguity" is used in other disciplines, for example, behavioral economics, to mean unknown probabilities, which is almost precisely the opposite to Stirling's sense – this demonstrates, again, the problems of terminology within the wider risk literature. Technology assessment on the other hand traditionally uses similar terminology but without taking Stirling's ambiguity into account.

Stirling argues that dividing risks into these categories can give us guidance on the circumstances when the precautionary principle could be a valid rule: by dividing risks into qualitatively distinct groups, he argues that the principle can be an important rule for helping with decision making in those circumstances where the outcomes or probabilities are not well understood, and no other type of decision rule would otherwise be helpful.

Another influential attempt at classifying risk elaborated to inform risk assessment policy eventually evolved to inform Funtowicz and Ravetz's very influential concept of postnormal science (Funtowicz and Ravetz 1990, 1993). Funtowicz and Ravetz proposed to map risks as a measure of uncertainty and impact ("decision stakes") and claimed that risks with low uncertainty and impact are the ones familiar from applied science for which traditional mathematical tools of risk analysis are most appropriate. Risks with medium but not high uncertainty and/or impact are in the domain of "professional consultancy," which "uses science; but its problems and hence its solutions and methods, are radically different" (Ravetz 2006, p. 276). The label "postnormal science" applies to situations characterized by high uncertainties and/or high stakes.

Renn and Klinke (2004) similarly use this map with axes denoting uncertainty and impact and identify several areas on that map that delineate qualitatively different risk situations, though these depart from Funtowicz and Ravetz's three areas on the map by being more fine-grained: For example, the points in the map where the probability is low but the potential harm is great, they call "Damocles" risks, named after the Greek king who according to the legend had a sword suspended above him by a thin piece of string (the analogy being that the probability of the string breaking at any one point in time is low, but when it happens, the outcome is rather dramatic, at least for Damocles). Points with high probability and high harm they call "Cassandra" risks, after the Trojan prophet who knew about the fate of the city but whose warnings were ignored. Hovering more in the background is a larger area of the map, where we are not very knowledgeable about the event's probabilities or its outcomes ("Pandora" risks).

Brian Wynne introduced his classification of risks as an improvement on the Funtowicz and Ravetz (Wynne 1992) classification which defines postnormal science. Like Stirling, Wynne sees "risks" as situations where the outcomes and the probabilities are well known and quantifiable. Uncertainties are present when "we know the important system parameters, but not the probability distributions" (p. 114). By contrast, the next level, "ignorance," is more difficult to define: "This is not so much a characteristic of knowledge itself as of the linkages between knowledge and commitments based on it" (p. 114). It is "endemic to scientific knowledge" (p. 115), because science has to simplify what it knows in order to work within its own methods. Finally, "indeterminacy" is seen as largely perpendicular to risks and uncertainties, because it questions the assumption on the causal chains and networks themselves. Thus, indeterminacy can be a huge factor in a particular situation even when the risks and uncertainties are judged to be small.

I am sympathetic to Wynne's classification because it recognizes that both quantifiable types of uncertainties as well as the less tangible deeper uncertainties are present at the same time in some situations and thus not mutually independent, which is a necessary realization away from other schemes such as Funtowicz and Ravetz's map. According to Wynne,

- ▶ Ravetz et al. imply that uncertainty exists on an objective scale from small (risk) to large (ignorance), whereas I would see risk, uncertainty, ignorance and indeterminacy as overlaid one on the other, being expressed depending on the scale of the social commitments ('decision stakes') which are bet on the knowledge being correct (Wynne 1992, p. 116).

However, there are for me still some problems with it. First, and more trivially, is the question of terminology. Like almost every other theorist of risk that comes from the social science side, Wynne and Stirling take "risk" itself to be one of their categories, and then proceed to label the other categories somewhat arbitrarily – this results in a mess of technical definitions that leave no special terminology for the overall thing they intend to classify. We cannot call them classifications of risks (or uncertainties) because risk and uncertainty are already part of the classification system. Moreover, this use of the term risk clashes somewhat with the common definition of risk as a measure that combines uncertainty and outcome. This has not helped that another influential tradition of risk theory embodied by Beck (1992) and Giddens' (1999) work takes risk to mean something altogether more nebulous.

Another concern over Wynne's classification, though, is that the categories seem somewhat hard to pin down, in the sense that indeterminacy, for example, includes the various social contingencies that are not usually captured in conventional risk assessments, but what these

social contingencies are, and how they relate to the other types of uncertainties is not categorically stated. It is not entirely clear, at least to me, where the boundaries lie, or even if there are supposed to be any precise boundaries. Ignorance, he writes, is “conceptually more elusive” and best explained through a lengthy example. All this in effect makes Wynne’s conceptualization hard to explain and therefore possibly ineffective as a tool for bridging the divide between the social and the technical aspects of risks. The inclusion of broad concepts such as social contingencies as well as quantifiability leaves the feeling that Wynne’s categories slice through several useful other distinctions on risk (such as those introduced below, in particular that of Walker et al. 2003). While Wynne’s categories are helpful as a conceptual tool to analyze reactions to risk and identifying shortcomings in conventional scientific approaches to risk that need to be addressed, it remains unclear exactly how they intersect and relate to each other. In a way, our own classification presented below is an attempt to reformulate Wynne’s insights in a way that makes more intuitive sense and which hopefully helps in addressing the question of how Wynne’s categories relate to each other.

Van Asselt and Rotmans (2002) classify risks according to the source of our uncertainty, distinguishing primarily between the two major sources introduced above of epistemic and aleatoric uncertainties (or, in their terminology, uncertainties due to lack of knowledge and uncertainties due to the variability of nature). Uncertainties due to lack of knowledge include, for example, lack of observations/measurements, inexactness or conflicting evidence, while uncertainty due to the variability of nature includes variability in human behavior, value diversity, and the inherent randomness of nature. Aiming to go further than this, Walker et al. (2003) include more dimensions in the classification than merely the source of uncertainty. Thus, they distinguish between location, level, and nature of uncertainty: the location uncertainty can be subdivided between context, model, input and parameter uncertainties, and the final outcome uncertainty. Location uncertainty therefore roughly describes what we are uncertain about, i.e., “where uncertainty manifests itself within the whole model complex” (p. 9). The levels of uncertainty describe the “progression between determinism and total ignorance” and include, in order, statistical uncertainty, scenario uncertainty, recognized uncertainty, and total ignorance. Finally, the nature of uncertainty is, like in van Asselt and Rotman’s classification, mainly about the source of uncertainty, and can roughly be divided into epistemic and ontological uncertainties and subclassified as done by van Asselt and Rotmans.

In this chapter, I hope to be able to add a more inclusive categorization that stays within the spirit of Wynne’s as well as Walker et al.’s (2003) ideas but revolves more centrally around the question of what exactly it is that we are uncertain about, which roughly translates to the “location of uncertainty” dimension in Walker et al. This I will try to use to find interconnections between different literatures on risk. I will argue also that it is useful to apply the scheme to a selection of real-life uncertainties and use it to delineate and make sense of different groups’ varying assessments of a situation because they place different importance on the different objects of uncertainty that are all present to various degrees in all of the cases. I will start by making some preliminary distinctions about risk and uncertainty which will enable us to see where this fits into the various other definitions and classifications of risk. I will borrow Walker et al.’s (2003) idea of different dimensions here, but add that, in our context, these dimensions can best be thought of as different answers to the question on what we want to know about risk.

Firstly, we conceptualize risk as a measure of uncertainty of an event happening times the severity of the outcome. As argued above, this is the usual definition of risk, though it is not

used like this by all commentators, some of whom depart more from Knight's (1971) famous distinction between risks as quantifiable uncertainties versus uncertainties that are not quantifiable, which explains Wynne and Stirling's decisions to put "risk" as one of the categories within their overall schemes. Other writers such as those from the "risk society" tradition (Beck 1992 and Giddens 1999) use risk in a much more vague way which is not so much interested in quantifiable or nonquantifiable or even in the separation of uncertainty and severity of the outcome, but sees it more as the vague possibility that things can go wrong. This is again due to the fact that risk sociologists are interested in different aspects of risk (for example, how increasing awareness and preoccupation of risk affects late modern society). There is therefore not much point in criticizing some work for using vague definitions of risk because, from their point of view, there is simply not that much value added to having a precise working definition of what risk is. However, I hope to be able to show how our distinctions can contribute nevertheless to a better understanding of how the conception of risk that is seen as interesting to sociological and cultural approaches can be compared to other conceptions of risk.

Starting from the definition of risk being a measure of uncertainty and severity of outcome, it is secondly to be noted that neither uncertainty nor severity of outcome are in most cases easily measurable or even definable. Our scheme will leave the very interesting problem of severity of outcome for others to work out and concentrate specifically on the uncertainty aspect of risk.

Starting from the question of "what do we want to know about risk?" we can produce a table of different classifications of risk which are designed to answer that question in different ways. We may, for example, be interested in why we are uncertain, we may be interested in who is uncertain, how it affects individuals or society at large, how is risk represented and how should it be represented, and what is it exactly that we are uncertain about? These are the categories I use below, though there will possibly be more dimensions than those, and other authors may want to divide them differently (Walker et al. (2003), for example, distinguish between levels of uncertainty (whether we take a deterministic position or not) and nature of uncertainty (i.e., uncertainty seen as either aleatoric or epistemological), which I would both see as different sources of uncertainty (we can be uncertain *because* we take an epistemological stance and *because* we have an idealized deterministic situation)).

*Why are we uncertain?* Here we can list classifications that have been made regarding the sources of uncertainty, such as in the scheme of van Asselt and Rotmans, which also relies on the philosophical distinction between epistemological and aleatoric (or ontological) uncertainty described above: we can be uncertain either because of our lack of knowledge or because there is an inherent variability in nature. These two fundamental positions are often seen within the more sociological literature on risk as aspects that different situations of uncertainty can take on, so that, depending on the context, an uncertainty can be either epistemological or aleatoric: "it often remains a matter of convenience and judgment linked up to features of the problem under study as well as to the current state of knowledge or ignorance" (Walker et al. 2003 p. 13). In the philosophical literature, by contrast, it is more often assumed that the distinction is a result of different worldviews: we can, for example, be determinists in our general philosophical outlook, in which case, strictly speaking, all uncertainties are epistemic. In most everyday examples, the boundaries of whether an uncertainty should be considered epistemic or aleatoric seems to be a result of the setup, but the precise boundaries or even existence of the boundary to a large extent also depends on our philosophical stances and background assumptions and knowledge. We can, for example, see the probability of winning

the lottery jackpot with a given set of numbers as purely aleatoric, because even with the most sophisticated current scientific methods, we are some way away from predicting the numbers drawn even if, philosophically, we are strictly speaking determinists who believe that an all-knowing demon could calculate the final result from the initial state. In this example, the existence of probability that is for practical purposes aleatoric even for strict determinists is fairly obvious, though this is not necessarily the case in others. As I will argue below, there are other, epistemic, considerations to be made when we assess the likelihood of winning the lottery.

*Who is uncertain?* The question of the subject of the uncertainty is interesting from the point of view of psychologists or sociologists, who want to know what effect uncertainty has on people or on society at large. Different people respond to uncertainty differently, as shown, for example, in the well-known “white male effect” and similar phenomena discovered by risk psychology research (Slovic 2000). The subject of the uncertainty is also important for policy making since we would need to know how different groups and individuals respond to risks and representations of risk. For example, my current project investigates local opinions on energy infrastructure: to understand the dynamics of risk opinions within the area the infrastructure is being planned, we need to have a more detailed understanding of who the local actors and groups of actors are and how they interact with respect to interpretations of risk. Whether “the public” consents to the infrastructure being built in their back-yard ultimately depends on a complex interplay between local and national politicians, civil servants, the project developers, media representations, local and national NGOs and residents’ interest groups, as well as the individual resident’s understanding which is strongly influenced by, and in turn influences, the other stakeholders. Putting “the public” in scare quotes above is meant to signal that there is no monolithic public, with similar agendas, identities, or worldviews. Understanding who the relevant actors are and how they arrive at their conceptions of risks and how they influence and are influenced by other groups of actors is vital for the analysis of what role risk plays in planning decisions.

*How is uncertainty represented?* Representations of uncertainty can take on different forms, which is again related to where the risk stands and is perceived along the other dimensions. We can, for example, simply deny that there is any uncertainty or risk at all or just concede that there is some, but more or less, undefined uncertainty. If we want (and know more about the situation), we can give a list of possible outcomes, either on their own or with some indication, qualitative or quantitative, on how likely each outcome would be. Should we have chosen a model we think is appropriate, we can give the result of the risk assessment as say a probability, with or without error bars or other representations of uncertainty on that final number.

How we represent risks depends very much on our knowledge of the situation, denying risk is a valid action when we do not know of any, and a simple list of possible outcomes is useful when we lack knowledge of how likely each outcome would be. However, which representation people chose in practice often depends also on what message they want to get across, or even reflects philosophical stances or implicit assumptions made. For example, if we want to make the risk of taking a particular medication look high, we can choose to represent it in relative rather than absolute terms. Similarly, we can give a positive or negative frame: for example, there is technically no difference between saying that “your chance of experiencing a heart attack or stroke in 10 years without statins is 10%, which is reduced to 8% with statins” and “your chance of avoiding a heart attack or stroke in 10 years without statins is 90%, which is increased to 92% with statins” – yet these two formulations have different connotations for

the reader (example taken from Spiegelhalter and Pearson 2008). We can express probabilities in percentages or “natural frequencies,” where research has shown that people are intuitively better able to understand natural frequencies (Gigerenzer 2002). We can produce bar charts, pie charts, “smiley charts” on top of the verbal expressions, and these again convey different impressions of how risky something is. Finally, we can express uncertainties according to our philosophical understanding – if we say that I have a 10% chance of having a heart attack within the next 10 years, that can either mean “10% of people with test results like me will have a heart attack,” or “10% of alternative future worlds will include me having a heart attack.” Again these scenarios while both expressions of the same amount of uncertainty will qualitatively feel different to people, with the second usually seen as the more persuasive way to get people taking their medicines, because it is more personalized (see also Edwards et al. 2001 on the effects of framing risk to patients)

*Responses to uncertainty:* How do people react to uncertainty? Do we, or should we, respond rationally to risk, for example, by doing a cost-benefit analysis to evaluate risks (Sunstein 2005)? Slovic et al. (2004) argue that while analytical and affective are two distinctive ways of reacting to risk, they interplay to produce rational behavior. But maybe even this distinction between affective and analytical needs to be challenged (Roeser 2009, 2010).

On a larger societal level, the risk society literature concerns itself, among of course other things, with how a society responds to risks (specifically our own, late modern – i.e., contemporary Western – society). Here, the issue is not so much about the nature of the risk as such (though it plays a role as I will outline below), or even whether the risks are real or not, but with the role that an increasing awareness of risk plays within late modern society. In particular, they describe the intuitive pessimistic induction through which people have come to realize (or at least believe) that there are always unexpected uncertainties and the possibility of things going horribly wrong with any possible new technological invention (the “unintended consequences of modernity”). Thus, as society has become more reflexive about its own technological achievements, the awareness of risk has become a more powerful driver of social forces than it was previously when risks were more perceived as due to intangible forces of nature rather than consequences of our own society, and therefore modern Western society’s response to risk has become qualitatively different to what it was before.

*Understanding uncertainty:* How people understand uncertainty is a related but somewhat orthogonal issue to the above – this may relate, for example, to the literature of social representations of risk (Joffe 1999; Washer 2004), which uses the social psychological literature of social representations (Moscovici 2000) to characterize how risk issues are perceived and made sense of through associated reasoning – new abstract and intangible concepts as are usually found in topics surrounding risk are conceptually anchored to concepts that are already understood, and thus new concepts are better assimilated into a group’s already held worldviews. Washer, for example, describes through the analysis of newspaper reports of recent new infectious disease outbreaks like SARS or avian flu and how these unfamiliar diseases (and the risks they represent) are being commonly anchored to already understood and familiar diseases (erg. the Spanish influenza outbreak of 1918), or to other aspects, such as vaguely xenophobic expectations of lax health and hygiene practices of the countries of origin; these mechanisms thus place the new disease into different categories of risk than they might otherwise have been perceived if anchored differently.

Hogg (2007) similarly uses a social psychological perspective, social identity theory (Tajfel 1981) to describe issues of intergroup and in group trust, arguing that our social

identities about which groups we belong to effect how we trust the risk statements of others – in-group members are trusted more than out-group members, and even within groups, individuals who are more prototypical in that their characteristics conform well to group norms and values, are trusted more than more marginal members.

Here, we can also list other approaches that are interested in the social construction of risk. Cultural theories of risk such as the influential approach of Mary Douglas (1992) and the risk society argument are relevant here as well, because it is concerned with how societies construct (and thus understand) risks.

*What exactly are we uncertain about?* I left this category until last because this will be my focus in the following section. The object of our uncertainty has been the concern of several classification systems described above when, for example, Wynne talks about uncertainty over causal chains or networks. Similarly, Walker et al. (2003) talk about “locations” of uncertainty, defining that as “where uncertainty manifests itself within the whole model complex” (p. 9), and distinguishing between uncertainty about the context (uncertainties outside of the model), models, inputs, parameters, and the final model outcome. In the following section, I will propose our slightly similar scheme which aims more at a rather general classification of the main types of objects we can be uncertain about which translates somewhat into Walker et al.’s locations of uncertainty, but is aimed at dispensing a too fine-grained classification in favor of one that we feel makes intuitive sense and can help explain different groups’ reactions toward the same risk scenarios.

In slicing the risk literature into these different categories of what they find interesting about risk, I recognize that a lot of work on risk looks at interactions between these different categories: for example, we can be interested in how different representations of risk and different aspects of risk can affect different people or groups of people. But I hope that this way of presenting the risk literature helps make sense of these interactions, and can therefore provide an interesting look into how different aspects of research on risk interlock. Our specific distinction between different objects of risk is itself designed in part to explain different outlooks on risk. In the following sections, I will present the different objects of uncertainty and, following that, explain through a few examples of how objects of uncertainty interconnect with some of the other dimensions of risk in a way which will hopefully give us a fuller description of the different risk scenarios.

## Objects of Uncertainty

---

Our classification (Spiegelhalter and Riesch [in press](#)), somewhat unwise in retrospect, divides the objects of uncertainty into different “levels.” I am calling our decision unwise because this suggests a particular linear hierarchy which may be misleading, but also because other commentators have attached the label “level of uncertainty” to some of the other dimensions of uncertainty outlined above. Specifically, Walker et al. use the term “levels of uncertainty” to describe the spectrum from determinism to “total ignorance.”

We distinguish between three types of uncertainty within the modeling process, and two without. Our use of the term model here is meant to be rather generic. Philosophical and social studies of scientists have shown that the term “model” can be used in varying ways in science (Bailer-Jones [2003](#)), and, thus, generally it does not have the precise definition that it would have in mathematics or statistics. For example, the everyday constructions through which we as

laypeople make sense of risk situations is taken here to be a kind of model as well, since we take our own incomplete information of the world and how we understand things to work and thus gain an understanding of what might happen. The difference between the nonexpert modeling we do in our everyday life and the expert risk assessments is at the end merely a matter of background technical knowledge and competence and levels of commitment, rather than a huge qualitative difference. There is of course much more to be said about lay understanding and construction of risk perspectives, but, for my purposes, it should be enough to use the term “modeling” in an inclusive way that encompasses both expert and lay processing of risk.

By using the term model in this broad sense, I can apply it to different and varying real-life uncertainties and can include the formal mathematical application of the term as well as the more vague, everyday usage of model, in order to achieve applicability of our scheme across a wide variety of real-life risk situations, where precise mathematical or statistical modeling is impossible, impractical, or simply overlooked.

The categories I will present here are not meant to be mutually inclusive, and they will overlap. On the contrary, as I will argue with a couple of examples, in most risk situations, various levels of uncertainty are present at the same time, and our differences of opinion about risks may be due to us giving different importance to different levels.

*Level 1:* Uncertainty about the outcome. The model is known, the parameters are known, and it predicts a certain outcome with a probability  $p$ . An example here is the throw of a pair of dice: Our model is in this case the fundamental laws of classical probability, the parameters are the assumption that the dice are fair and unloaded, and the predicted outcome of, say, two sixes is  $(1/6) \cdot (1/6) = 1/36$ .

This is comparable to the “final model outcome” in Walker et al. On its own, this level of uncertainty exists only in rather idealized situations, as in arguably the example above of the dice. However, this is the level at which we as members of the public are most likely to encounter risk, for example, when we read in a newspaper that “the chances of developing bowel cancer is heightened by 20% if we eat a bacon sandwich every day” (which is a real example taken from the case study further elaborated below). Such clear numbers, in the vast majority of cases, hide the fact that there are additional uncertainties related to the process in which experts arrived at it.

*Level 2:* Uncertainty about the parameters: The model is known, but its parameters are not known (Once the parameters are fixed, then the model predicts an outcome with probability  $p$ ).

This may simply be a lack of empirical information: If only we knew more, we could fix the parameters.

Our concept of uncertainty about the parameters itself hides a variety of different ways in which we can be uncertain about them: We can have fairly good, quantified probabilities about what the parameters should be as they might simply be a matter of getting better information about the system that is being modeled, but, more problematically, we could also be uncertain about how better measurements themselves are achieved, and/or our uncertainty about the parameters can itself only be expressible as a probability distribution, or even only a qualitative list of possibilities, or lastly we might simply have no idea of what the possibilities could be in the first place. Thus, here some of the different dimensions as outlined above intersect with the object of uncertainty: our uncertainty about the parameters can be due to epistemic or aleatoric sources, and it can be represented in different ways.

Unlike Walker et al. we make no distinction between parameter and input uncertainty here, firstly for reasons of simplicity, but also because this more fine-grained distinction is not all that useful when we try to apply our scheme to real-life examples. Similarly, we would also class uncertainties over boundary conditions and initial values into this category as well, all of which may strain the term parameter uncertainty into categories not strictly speaking considered parameters as such – at the end, however, we decided to balance usefulness and simplicity with detail.

*Level 3:* Uncertainty about the model: There are several models to choose from, and we have an idea of how likely each competing model is to reflect reality. Models are usually simplifications about how the world works, and there are often several ways of modeling any given situation.

This is analogous with Walker's model uncertainty, and again, this uncertainty itself can be presented in different ways and may be due to different sources. The way we should represent the uncertainties over model choice is more of a contentious issue and, of course, depends on the precise source of that uncertainty itself. In Spiegelhalter and Riesch ([in press](#)), we advocate a Bayesian approach to compare competing models (after Hoeting et al. [1999](#)). This though will not be everyone's favored approach, which means that, in most situations, we will encounter varying approaches to representations of model uncertainty.

Here, there can be, and frequently are, disagreements between the experts themselves, which means that to the nonexpert public or other consumers of a risk assessment, the uncertainty over the model choice is often related to other factors, such as how much trust they place in the experts to evaluate their model choices honestly or competently, and involves furthermore making a judgment between different experts' assessment when faced with disagreement – however competence and honesty are assumptions that are made only implicitly (only rarely will experts be honest enough to consider their own competence as part of the overall risk assessment – building in an estimation of your own honesty into a risk assessment poses even more problems) and not strictly speaking part of the modeling process. There is therefore is a qualitatively different uncertainty for consumers and for producers of risk assessment, which will be the next level.

*Level 4:* Uncertainty about acknowledged inadequacies and our implicitly made assumptions. Every model is only a model of the real world and never completely represents the real world as such. There are therefore inevitable limitations to even the best models. These limitations could arise because some aspects that we know of have been omitted, or because of extrapolations from data or limitations in the computations, or a host of other possible reasons. Similar in a way to Wynne's concept of "indeterminacy," this is about questioning the assumptions we make, for example, about the validity of the science itself, and thus goes slightly perpendicular to the problems of choosing the models and parameters. These include the "imaginable surprises" (Schneider et al. [1998](#)), that is, things we suspect could occur but about which we do not know enough to be able to include them in the model.

As outlined above, this is where the question of trust comes into force as these are factors that are implicitly not assumed to matter in the risk assessments but not (or rarely) part of it. Similarly, there are always many assumptions about the world that have to be made and that are not part of the modeling process because they are assumed for one reason or another. For example, the risk referred to above of eating too many bacon sandwiches relies not only on the empirical and theoretical studies performed in the analysis, but also on the accumulated medical knowledge about cancer that was taken as given within the risk analysis. Any error

within the fundamental scientific background assumed in a model that is supposed to reflect the real world albeit simplified will make that model less reliable. Therefore, uncertainties in our assumptions and scientific background knowledge are also inadequacies that are acknowledged but not usually part of the modeling process itself. At the same time, these are inadequacies in the process that are at least acknowledged in some way even if not particularly acted upon.

Dealing with acknowledged inadequacies can be done through informal, qualitatively formulated acknowledgment or listing the factors that have been left out of the model, or of course simple denial that there are any in the first place.

*Level 5: Uncertainty about unknown inadequacies:* We do not even know what we don't know. This particular type of uncertainty was made notorious through Donald Rumsfeld's famous speech on "unknown unknowns":

- ▶ There are known knowns. These are things we know that we know. There are known unknowns. That is to say, there are things that we now know we don't know. But there are also unknown unknowns. These are things we do not know we don't know (Rumsfeld 2002).

There are as yet not very many formal approaches to unknown unknowns in the risk literature, though the concept has been well known for a while – for example, Keynes wrote that about some uncertainties, "there is no scientific basis on which to form any calculable probability whatever. We simply do not know" (Keynes 1937). Long before Keynes and Rumsfeld, however, a concept similar to unknown unknowns was introduced by Plato through the famous "Meno's paradox": How can we get to know about something when we are ignorant of what it is in the first place? (Sorensen 2009). It is also related to Taleb's concept of "black swan events" in economics (Taleb 2007) which are events that were not even considered but which, due to their high impact, have a tendency to completely change the playing field, and which is one of the concepts he used to warn about (what turned out to be) the 2008 world financial crisis.

These inadequacies are difficult to deal with formally or informally because we don't really know what they may be, and we are constrained in a way by the limits of our imagination of what could possibly go wrong – Jasanoff (2003), for example, identifies lack of imagination as one of the factors limiting our knowledge for proper risk assessments in postnormal science (p. 234).

Responding to unknown unknowns is naturally very difficult because by definition we do not know what they are. We can however acknowledge them through simple humility that it is always possible that we are mistaken, as demonstrated by Cromwell's quote in the epigraph. Another way is to brainstorm every possibility we can think of and letting our imaginations go wild. This approach is of course never going to be able to cover everything that could go wrong and will therefore not eliminate unknown unknowns.

A slightly more formal way of responding to unforeseen events is the introduction of "fudge factors," for example, in bridge or airplane design, where we design the structure to be a bit stronger than even the worst case scenarios that we could think of require – though even then there is always the conceivable possibility that something worse may happen.

These levels in a way relate to different concerns of different disciplines – who are after all interested in different aspects of risk. For example, the traditional mathematical and philosophical problems of probability theory are mostly concerned with level 1 uncertainty. Statisticians are mostly concerned about level 2 and 3 uncertainty, that is, finding the right model

and, within that model, adjusting the parameters appropriately. It seems unfortunately that uncertainties on which we cannot have a particular mathematical handle on are so often ignored by statisticians and risk modelers – often probably for the pragmatic reason that there simply is not much they can say about the higher levels with the mathematical tools of their trade. Shackley and Wynne (1996), for example, write that in their study of policy discourse on climate change, policy makers were concerned about the validity of the models, while the scientists themselves never even considered that to be an issue, but were instead more concerned about measurement errors within their models. This is to an extent an unfair generalization. An informal survey of technical abstracts from a recent Carbon Capture and Storage conference (Riesch and Reiner submitted) has shown that while model uncertainty is not generally discussed, it does occasionally get mentioned, alongside even an occasional awareness that there are uncertainties associated with unmodeled or unmodelable inadequacies. Nevertheless, worries about model inadequacies were certainly not a prevalent concern among the scientists and risk modelers.

This expert discourse unfortunately distorts the way we perceive particular risks because higher level uncertainties still exist. This may lead to situations like the ones described by Taleb (2007) when he writes about economists having forgotten that unforeseen out-of-the-blue events can occasionally happen and completely mess up our predictions – the sort of events he calls “black swans” if they also have a high potential impact.

The risk society approach of Beck and Giddens is talking mostly about levels 4 and 5, where it is hypothesized that late modern society is living with the increased realization that unmodeled and unmodelable risks are pervasive, and that even if we had some kind of handle on them, there is always the possibility of completely unforeseen events, what Beck calls the “unintended consequences” that he mostly associates with new technology, but which need not necessarily be tied in with it. In Beck’s characterization of late modern society, we have now become accustomed to the realization that despite the best risk modeling of science and engineering experts, technological innovations and advances always have unforeseen consequences, completely left-field occurrences that the original evaluations failed to take into account – in other words, we now know that we live with level 4 and 5 uncertainties all around us. In a way, it matters less to the sociological literatures whether these risks are real or not, but the mere realization that they do happen affects the way late modern society evaluates technological progress and ultimately, itself. Beck’s work has been criticized for ostensibly being about risk, but not quite understanding the concepts of risk analysis and probability (Campbell and Currie 2006), though this slightly misses the point because, within this scheme, it is not really the nature of risk that is important, but responses to it.

As I have tried to argue above, the different disciplinary approaches to risk intersect in different ways – not only do they find different objects of uncertainty important, but they are also interested in different topics among the other dimensions. However, I have not yet found a comprehensive way of translating between the different approaches, and my categorization between different dimensions of risk is meant to solve this. In particular, I feel that the objects of uncertainty dimension which I presented here in more detail can be an important perspective with which to analyze different risk situations in a way that makes sense to the different disciplinary approaches. In the following section, I will go through several examples to illustrate what this perspective can show how all levels of uncertainty are present in most situations involving risks or uncertainties. In particular, I am interested (as a sociologist) to explain how different groups’ perceptions of essentially the same scenario can differ

so dramatically: because through their background experience, assumptions, and worldviews, they will attach different importance to the different levels described above. One important departing point therefore is my assertion that all the levels are present in every risk situation, and that the relative importance that is attached to them depends on who is mulling over it, and I will argue for that below. This seems to be more important on the objects of uncertainty dimensions more than on some of the others, and therefore I feel concentrating on these will help us bring about a more comprehensive way of translating between the various risk literatures, as these will be interested in different objects of uncertainty within each situation.

## Examples

---

In this section, I will explore how these five levels of uncertainty can help explain what happens in various real-life cases in which risk, perceived or real, is a factor, and how our concept of the levels explain different perceptions and how this can lead to the communication difficulties between groups with different perspectives (say between proponents and opponents of carbon capture in the third example). In each of these cases, all five levels of uncertainty are present, though they are differently important and relevant depending on the example.

### The Lottery

I will start with a situation which traditionally is seen as less problematic because it seems to rely only on outcome uncertainty. In a typical national lottery, such as in the UK, there are 49 balls, and each week, 6 balls are drawn; people who have chosen all six correctly win the jackpot. While the exact rules of how much you win are more complicated (depending on the lottery), the case is at least on the surface clearly of level 1: The model is known, the parameters are known, there are no known inadequacies in the model; all the uncertainty that remains is the probability predicted by the model.

This however does not mean that there are no uncertainties present of the other levels, they are simply more hidden and seem less relevant. Level 2 uncertainty concerns the uncertainty of the parameters. In this case, one of the parameters that we have assumed were fixed concerned the individual probability for each ball to come up, thus the question essentially revolves around whether the lottery machine is fair. This is of course a question that we *should* be asking ourselves when we play the lottery, though we rarely do because we trust the authorities that set up the game. As soon as that trust is lost however, level 2 uncertainty comes to the foreground in our evaluations of how likely a jackpot win is. But this is also an empirical question – for the regulator to make sure that the parameters are what we assume them to be, the equipment is regularly checked, and therefore even if we trust the operators to run a fair game, there is still residual empirical uncertainty over the measurements performed during the equipment checks.

Level 3 and 4 uncertainties, in this case, are less likely to bother us because the situation is relatively simple. We, thus, do not really have competing models with which to describe the lottery: unlike in the examples below, where we have situations for which we need a model to describe it, in this case, we start with the model and set up the reality to fit it – that is, after all how the game was constructed. Therefore, in this case, we have a lot of confidence that

the mathematical model we use to describe the game is accurate and not likely to be replaced by one that reflects the situation better.

This however does not necessarily reflect the situation from the point of view of the *consumer* of the lottery – given that the rules of the game are published but the precise probabilities for a given type of win are not necessarily, we have to make our own calculations, and, for the mathematically less able among us (such as myself), there remains the very real possibility that I have made a mistake in estimating my chances of winning. Again the lottery is a pretty simple situation where even I will not have many difficulties; however, the same cannot be said about other games of chance such as blackjack where there is no real model uncertainty from the point of view of an able calculator, but where for the average player, the probabilities are very much subject to uncertainties over mathematical ability. The trust that we have in the operator mentioned above to demonstrate why our parameter assumptions may be wrong is itself a frequently *unacknowledged* inadequacy: The probability that the operator is cheating is, even if somehow quantifiable, rarely part of the model (which in turn makes out the parameter uncertainty to be only dependent on empirical questions) used to estimate the probabilities of winning or the expected pay-out. Yet again, for the consumer who may have a different estimation of the trustworthiness of the operator, level 4 introduces an unmodeled uncertainty, and their estimations of this uncertainty will be different according to background knowledge and assumptions.

Considering completely unexpected scenarios now, maybe the machine could blow up during the draw, invoking maybe the need to refund punters – again this would affect the probability of winning overall in a slight way. Or the operator could be declared bankrupt, in which case, it is not clear whether there would be refunds at all, and the issue would probably only be solved on a case by case basis depending on the whims or political pressure of put upon the government as is the case when other companies fold (even though customers will usually not get refunds if a company goes bankrupt, there are often cases, such as tour operators, where political intervention may make an exception). The possibilities here are of course only restrained by my imagination and as soon as I formulate them they are not strictly speaking unknown unknowns. However, the relative ease with which we can conjure up scenarios which are not foreseen at all points toward a large background level 5 uncertainty which cannot be eliminated completely or even adequately estimated through better modeling.

These considerations I hope demonstrate that even in seemingly very clear situations that are not usually assumed to be subject to other than level 1 uncertainties, our estimation of the uncertainties rely to a large extent on our trust in the operator, our background assumptions and mathematical abilities, and these differ from person to person.

## Saving Our Bacon

What exactly does it mean when we are informed that we are facing an increased risk (by 20%) of bowel cancer if we eat more than 500 g of processed meat a day (WCRF 2007a)? Again, I will hope to demonstrate here that in this claim, there are several levels of uncertainty interwoven because, depending on which perspective we take, we can evaluate the uncertainties of different objects in varying ways. Therefore, making sense of that claim will involve untangling them. (Incidentally, the lifetime risk of bowel cancer is estimated in the report as 5%, which raises to 6% when we eat a lot of red meat a day. In relative terms, the increase of risk is 20%, while in

absolute terms it is 1%. The fact that the WCRF chose to present the more scary relative increase in their press strategy, rather than the more informative absolute increase, tells us a lot about their communication priorities, see also Riesch and Spiegelhalter 2011).

The claim above is based on a meta-analysis performed by the World Cancer Research Foundation of various published trials that investigated the incidence of bowel cancer among people who consume a lot of red meat versus those that do not (WCRF 2007a). One level of uncertainty therefore involves what the studies, as aggregated by the accepted rules of how researchers should do meta-analyses, tell us about eating processed meat: the model is known (in this case, the rules involved of doing the analysis, as well as the rules of the individual studies aggregated in the meta-analysis), the parameters are fixed (in this case the empirical evidence), and together they predict the outcome, bowel cancer, as 20% higher than without the consumption of processed meat. This is the level of uncertainty at which the WCRF communication strategy operated: Our science has found that the risk is p, and that is what the public should know about red meat (as suggested by the WCRF press strategy; WCRF 2007b; WCRF 2007c).

However, especially when looked at from the perspective of the reader of the report, the other levels of uncertainty are there in the background as well and have been emphasized by some of the other actors in the debate: Level 2 uncertainty is, to a certain extent found in the report itself, as this represents the empirical uncertainties surrounding each individual study in the meta-analysis (i.e., fixing the parameters through empirical data): These empirical errors have been aggregated, and since the meta-analysis involved lots of different studies, the overall error has been reduced, and this level of uncertainty is represented through the use of error bars in their charts. Error bars of course did not make it into the verbal communication that accompanies the study's conclusion; instead, the information about uncertainty here is formulated qualitatively: The report distinguishes between the evidence being “convincing,” “probable,” and “limited.” In the final communication of the report, the inherent experimental error, the level 2 uncertainty, was not quantitatively included and could possibly be said to be relatively low. There were though a small qualitative indicators in the wording of the press release:

- ▶ There is *strong evidence* that red and processed meats are causes of bowel cancer, and that there is no amount of processed meat that can be confidently shown not to increase risk (WCRF 2007c, my emphasis).

While level 2 uncertainty has been addressed in the report, if only qualitatively as a way of showing some caution in interpreting the results, level 3 uncertainty posed more problems and was the sort of uncertainty that the expert critics of the report have focused on: This is uncertainty surrounding choosing the model itself. In this case, that translates to the controversy of how the meta-analysis was done, and specifically which studies were included in the analysis. Critics of the report have pointed out that the meta-analysis has left out many individual studies that, if included, would have given the whole analysis a different result. Whether or not there was much merit in these criticisms, they at least demonstrated that no amount of certainty in the analysis itself can remove the uncertainty inherent in choosing the model. The methodology of meta-analysis in general, while an established tool within medical research, is nonetheless not without its critics, and again, though I will not comment on whether these criticisms have much merit, they demonstrate that even within the expert community there are differences of opinion, and therefore, especially for nonexpert bystanders

like me, there is an additional uncertainty over whether the whole methodology used by the report is sound in the first place.

This is compounded by level 4 uncertainty because even if we did have certainty over which studies should have been included, and whether meta-analysis in general is the best way to pool the results from these studies, there is still residual uncertainty about the scientific background assumptions underlying the study, which relies to a large part on previous medical knowledge on for example cancer which is seen as well-established and therefore not considered a factor to be included in the model at all. This is to an extent not too much of an inadequacy because the study being an empirical evaluation of several selected trials and observational studies does not rely much on previous medical knowledge; however, it *does* rely on previously established medical and scientific knowledge and assumptions that these methodologies are a valid way of establishing knowledge. Again though it is not my place to comment on whether there is any merit to these criticisms, that is a criticism that certainly has been made, not so much by medical experts, but by alternative health practitioners who reject a large amount of otherwise established medical knowledge and methods. For the nonexpert bystander, again, the situation is that of competing groups who both claim to have expert status and who have different opinions about what the study shows and can even in principal be expected to show. This is then a different level of uncertainty altogether for the consumer of the report.

Added to that, there are other implicitly made assumptions in the report which relate to the honesty and competence of the researchers themselves. Of course, we can't expect them to take these concerns seriously as an additional uncertainty in their own science, but these are not assumptions that can automatically be assumed by the reader. Both of these two levels of uncertainty (3 and 4) were emphatically not voiced in the official communication by the WCRF, which is understandable because they would have cast doubt on their own experts' judgment. However, they were certainly voiced by the critics: Level 3 uncertainty, as shown above, was the expert critic's response, of fellow medical researchers who accept the general methodology but object to the way it was performed in this instance, while level 4 uncertainty is more usually the response of critics who disagree with meta-analyses generally or who distrust or disbelieve some of the assumptions that medical research takes as established (these are not very influential among medical researchers, but have some influence among alternative medicine campaigners).

Finally, there is level 5 uncertainty: We may be completely wrong footed about the risks of processed meat – maybe the results of all the studies were a systematic error in the design of contemporary medical studies that we do not know about? Maybe something even more exotic has gone wrong? Admittedly, in this particular case, it is quite hard to imagine possible level 5 uncertainties, but this is of course the nature of this level of uncertainty as I have defined it by us not having any handle on it, and not even ever having thought of the possibility. Accordingly, giving a numerical estimation of this level of uncertainty is impossible. Beyond gut instincts, we cannot even tell if it is likely or not likely that something is fundamentally wrong with our conceptions of the problem. In the next examples, I will show that while in this case level 5 uncertainty is not much incorporated in the current thinking about the subject, in many other situations involving risk, level 5 uncertainty can be central.

The complications and disputes involved in this case are connected with the protagonists talking about different levels of uncertainty: The WCRF experts talked about level 1 uncertainties in their take-home message to the general public, while at least acknowledging level 2 uncertainties when talking among themselves and in communication with other experts.

Level 3 uncertainty is the level at which the expert critics attack the report, while the less listened to nonmedical critics attacked it at level 4. Meanwhile, level 5 uncertainty looms menacingly in the background. Some of the media interpretation and discourse about the WCRF study and its press releases can be found in Riesch and Spiegelhalter (2011).

## **Carbon Capture and Storage**

Carbon Capture and Storage (also referred to as Carbon Capture and Sequestration), or CCS, is a technology designed to reduce carbon emissions from fossil fuel burning power plants by capturing the CO<sub>2</sub> through various processes and storing it underground in depleted natural gas reservoirs or other suitable storage sites. The technology is seen by its proponents as an important and technically feasible way to lower carbon emissions because it relies on already fairly well-known mechanisms. While it is admittedly only planned as a relatively short-term solution to be deployed while renewable energy sources are being developed further, it solves some of the problems of “technology lock-in” that could happen if we concentrated only on a few favored energy sources such as solar- and wind-power which we have no guarantee yet that they will be deployable at a large enough scale to reduce carbon emissions in time to avert catastrophic climate change. Therefore, it is seen as part of a necessary portfolio of energy technologies that needs to be included if we want to avoid putting all our eggs in one basket (as argued for example by the influential Stern report, Stern 2007). Further benefits of the technology include more security in the energy supply because it would make burning coal an environmentally sound energy option again and, therefore, reduce the dependency some countries with large coal resources like the UK have on foreign gas imports. A more environmentally appealing further benefit of CCS is that when the technology is developed far enough, it can be used in conjunction with biomass burning power plants and therefore represents one of the few currently technically feasible ways of *removing* carbon from the atmosphere.

Despite these advantages, CCS has many opponents principally among the environmental community, who argue that it merely propagates our dependency on fossil fuels and drives funds away from developing more promising energy technologies which need to be developed anyway because even proponents of CCS see it only as a short term solution (Greenpeace 2008). Finally, one objection to CCS which threatens to be a show-stopper is the safety risks to local people and the local environment that are posed by possible CO<sub>2</sub> leakage from the storage reservoirs and the pipelines that transport the CO<sub>2</sub> from the power plants to these sites. It is these safety risks of CCS that I will concentrate on here; however, the other arguments for and against CCS are relevant here because it is our background worldviews, knowledge, and assumptions which color the way we perceive specific risks. One immediately obvious example of how our background knowledge may color our perception of the risks of the technology concerns our knowledge (and uncertainties within that knowledge) of the toxicity of CO<sub>2</sub>. While CO<sub>2</sub> is not, in fact, neither toxic nor flammable (it does, however, act as an asphyxiant, and therefore still represents a potential though somewhat lessened danger to people living near leakage sites), public opinion surveys on perceptions of CCS have shown that worries over CO<sub>2</sub> are very much in the forefront of public safety concerns (Itaoka et al. 2004; Mander et al. 2010).

Level 1 uncertainty in this case is the final number of the risk assessment, which is usually the basis on which politicians or energy companies would claim that experts find the technology to be very low risk. These numbers are arrived at through models which make of course

several assumptions. A general model of how carbon storage works depends very much on local conditions if we want to arrive at numbers for any particular reservoir and the surrounding area. The local conditions vary in great detail, and therefore experts who perform risk assessments of prospective sites need to investigate them very closely – what are the exact geological formations the CO<sub>2</sub> would be stored in, what are the properties of the cap-rock formations that are needed to keep the CO<sub>2</sub> from traveling up, are there seismic fault lines and if so how would they affect the storage, how many man-made injection wells are there, and how exactly are they going to be sealed once the CO<sub>2</sub> is injected, what is the general three-dimensional shape of the landscape above the possible leakage sites (since CO<sub>2</sub> is heavier than air, there is a chance that it might stay if it leaks into a valley and thus cause greater potential health risks). All these are in a sense parameters that need to be put into the general models if we want to arrive at a final number of expected deaths per year. All of these are subject to their own uncertainties, either because of potential measurement error, or even a more general lack of understanding of the local conditions which in practical terms can only be estimated.

At level 3, there is the choice of general model. In the case of CCS, there is still some argument over whether models developed by the gas and oil industries are really applicable to the storage of CO<sub>2</sub> (Raza 2009). There are also potential debates to be had over precisely what statistical methods should be used and their applicability. Writing in a Dutch popular science magazine article about the proposed (now canceled) CCS storage site under the town of Barendrecht near Rotterdam, Arnoud Jaspers felt that there is some additional uncertainty over model choice when he interviewed modeling experts, for example, some of the models simply did not take into account the three-dimensional structure of Barendrecht and therefore arrived at unreliable scenarios of what would happen should CO<sub>2</sub> leak (Jaspers 2009, 2010). As this shows, not every relevant bit of information makes it into all the models, and there is therefore some uncertainty about which model would be the best to use.

Furthermore, there are other things that are not considered in any model because we simply do not know enough about them or their relevance to be able to model them, these then are the acknowledged inadequacies we term level 4 uncertainties. A recent draft guidance document by the European Union on the implementation of Directive 2009/31/EC concerning geological storage of CO<sub>2</sub> (EU 2010), for example, divides the types of risk expected from reservoir leakage to be “Geological leakage pathways,” “leakage pathways associated with man-made systems and features (i.e., wells and mining activities),” and “other risks such as the mobilization of other gases and fluids by CO<sub>2</sub>” (p. 31). While the first two are routinely part of the models, the “other” category provides more of a problem because, other than listing some possible scenarios that can only to be considered on a “case by case” basis, there is not that much additional analysis that can be introduced. Therefore (as a brief glance through the technical papers on CO<sub>2</sub> storage at the GHGT10 conference has shown – discussed in more detail in Riesch and Reiner submitted), most risk models of CO<sub>2</sub> storage consider leakage pathways along geological fractures or man-made boreholes but do not as such feature other possible leakage pathways either because they are judged to be not very important or, more worryingly, not enough is known about them to include them in the models.

Lastly, there are level 5 unknown unknowns which are not part of the modeling process, not because we do not know enough about them, but because we do not know about them at all. Giving a concrete example is, again, impossible since simply by thinking about them they become known unknowns. However, there are scenarios that can be imagined by the public

that are never even considered in the expert literature. For example, the cover illustration to Jaspers' (2010) popular science article on CCS features a huge "blow-out" scenario with a vast amount of CO<sub>2</sub> escaping explosively and destroying large parts of Barendrecht's neighborhood with rescue helicopters hovering around the scene like tiny flies in relation to the explosion; painting the picture of carbon storage as a huge shaken soda bottle bubbling menacingly underneath the town which will explode spectacularly as soon as there is any kind of leak. This scenario was emphatically not considered in any risk assessment partly because such an explosion would be contrary to anything we know about the behavior of stored CO<sub>2</sub>, and it is probably fair to say that therefore it is not included in risk assessments nor even considered as a known inadequacy of the models. Nevertheless, this scenario of *something* going horribly wrong somehow is a valid concern especially for those who do not possess the expert background knowledge to adequately judge it as so unlikely as to not even be worth including in the model.

This rough overview on the risk debates on CO<sub>2</sub> storage is meant to show that there are very much different perspectives we can take on the risk of CCS, and which ones we put most stock in depend on our background knowledges and ideologies. As in the red meat and cancer example above, different actors in the debate have emphasized different types of uncertainties in this case. Energy companies like Shell or BP who are developing CCS projects, as well as those politicians who are keen on promoting it take comfort from the fact that final risk assessments put the safety risks of the technology as very low, and in much of the industry communication literature on CCS, it is these figures that get mentioned rather than any more technical discussion surrounding how they were acquired. Literature from environmental groups on the other hand see the uncertainties in a different context by highlighting the potential of measurement errors in local evaluations, casting doubt on the modeling processes involved (for example, Greenpeace 2008).

## Climate Change

This leads us to a final very brief example because the one thing that complicates debates about CCS is its relation to the mitigation of climate change. Man-made climate change presents a particular problem, not because there are by now any doubts left that it is happening, but because the forecasting of how bad it will be under various scenarios is a very imprecise business. Scientists who try to predict possible climate futures almost always start by admitting that they are working from one particular model, and that there are several that we know we could use instead that give different estimates, and we rarely have any good handle of working out how likely each model is to reflect reality. In fact, it is often acknowledged that we know so little and climate and weather patterns are so complex that there are always possible factors that we do not even know that we do not know about which can take us by complete surprise.

Uncertainties in climate change modeling are thus dominated by levels 4 and even 5: We have several models to choose from, but not much knowledge on how well they are doing their jobs, and even then we are well aware that our forecasting is hostage to completely unforeseen things as well. Social science research on climate modelers themselves has shown that there is a wide range of expert opinions on the best modeling process and that, moreover, experts themselves will have an unreliable estimation as to the possible shortcomings of their own models (Lahsen 2005). Even then, if they have an adequate estimation of the reliability of their

models, experts find it hard to communicate them, especially when these estimations cannot be quantified (Hillerbrand 2009). Therefore, yet again, for the nonexpert observer of these debates, the most important uncertainty is not over which model is best, but over which expert to trust most, and because there is so much disagreement and unreliability of the experts' own assessments of their models, this uncertainty weighs more for the nonexpert than for the experts.

## Further Research

---

By conceptualizing uncertainty along the various dimensions introduced above we can gain an appreciation of what the different disciplines find interesting about risk and, hopefully, find how they interconnect. The risk society literature, for example, as I outlined above is interested in different aspects of risk than the risk management literature. Considering the particular dimension that I think is most important in my map, the objects of uncertainty, gives us an idea of how and why different people estimate uncertainties differently even when presented with the same information and furthermore shows how different disciplines can themselves study risk from different perspectives.

This is therefore more useful for sociological research than the otherwise admirable combined system of van Asselt and Rotmans (2002) and Walker et al. (2003), whose scheme was designed primarily for use by experts in integrated assessments. Unlike Wynne's and Stirling's systems, which were designed for sociologists to understand and analyze different reactions to uncertainty, my map and classification tries to be more inclusive and meticulous in teasing apart different aspects of uncertainty, while hopefully still being simple enough to be useful for gaining an immediate and intuitive understanding of why and how opinions on risk so often differ. This can then become a useful tool when social scientists communicate the problems of the social contexts of risk to technical experts – this is after all a role performed very often by social scientists who have been funded by scientific research institutions and funding agencies “to look at the social side of things,” but who often struggle to make the social insights relevant and intuitive to the technical experts they work with. This is a main reason why we (Riesch and Reiner submitted; Upham et al. 2011) use this framework in the study of risk opinions on energy infrastructure (CCS and biofuels, respectively), to so far very positive reactions from the technical communities. This approach therefore tries to marry the socio-logical usefulness of Wynne with the technical relevance of Walker and van Asselt and their colleagues.

Though the scheme presented here is meant to be illustrative rather than prescriptive, it shows some clear lessons for risk communication strategies. Since, as I have argued here, different people are worried about different aspects of the risks and, in particular, attach the uncertainty to different objects, risk communication strategies often fail to convey the information that people actually find important. While there is no silver bullet with which to persuade people who simply do not trust the experts, or who's understanding of technological risks gives a higher importance to unforeseen events, taking these different perspectives into account will ensure that the conversation at least does not disintegrate into different actors failing to understand each other. In designing a communication tool about the risks of CCS, for example, we may want to pay particular attention not just to the risks as calculated by the risk assessment, but also how it was arrived at, what the uncertainties with the parameters are, what

was the choice of models available, and why was this particular one chosen, what possible inadequacies were not modeled and finally what are the plans for action should unforeseen consequences occur.

Future research will hopefully develop some of the other dimensions along the more detailed level as I have tried with the objects of uncertainty dimension (and as van Asselt and Rotmans have already done with the sources of uncertainty). This would then allow us to construct a more detailed table through which we can map, at a glance, where the different academic literatures on risk lie and intersect and which may help researchers in finding connections and future ideas for more integrated interdisciplinary research on risk.

Work is also underway to develop case studies which apply the objects classification to different risk scenarios. I have summarized here the application to CCS (Riesch and Reiner submitted); furthermore, we are applying it to the problem of indirect land use change for the biomass energy industry (Upham et al. 2011). Furthermore, detailed studies on more diverse risk situations will hopefully be able to tease out more of the potential but also limitations of our scheme.

**Abstract:** This survey provides a brief overview of the treatment of risk in economics, starting from early principles in the 1940s and 1950s and extending until the most recent developments. It shows how original ideas about economic behavior under conditions of risk and earlier definitions of risk aversion were progressively refined to include prudent behavior in risky situations and precise concepts of risk measurement. The survey is partial because it focuses on the mainstream model of economic behavior under risk. It ignores, among other topics, issues raised by the contractual relationships between imperfectly informed agents in markets for risk transfers, as well as behavioral traits (such as loss aversion) often observed among market participants. Besides, it does not cover models of risk management that have become popular in financial mathematics. Some applications of the economics of risk in the insurance domain are however briefly reviewed.

## Introduction

---

Between Daniel Bernoulli's seminal contribution ([1738](#)) and the mid 1940s the economic theory of risk made little progress. An entertaining account of this slow development can be found in Borch ([1990](#)) (see also Bernstein ([1996](#))). Since then, however, the field has been continuously and rapidly expanded and it is now very difficult – if not impossible – to summarize the state of the art in a limited amount of space.

In this survey, we describe some very specific aspects of this wide expansion process. They will be limited to developments made in the mainstream model – the expected utility model (EU) – even though alternative models will be briefly mentioned in section [From the Origins to the End of the 1960s: A Broad Overview](#). We will also limit our presentation to the analysis of individual economic behavior under conditions of risk, leaving aside issues raised by the risk management of corporations and financial institutions and by economic equilibrium in the markets for risk transfer when agents have differential information. These issues are more specifically addressed in domains like corporate finance, financial economics, and the theory of contracts – all domains that draw on lessons from the economics of risk. Notice also that, for lack of space, many other aspects of modern risk theory will not be discussed here. For instance, the notions of “risk measure” and “value-at-risk” (VaR), initially developed in the mathematical finance and actuarial literature (see Artzner et al. [1999](#); Crouhy et al. [2001](#); Föllmer and Schied [2002](#)) and that led to so many theoretical, empirical, and practical developments over the past years, will be left aside in this survey. Similarly, the numerous implications of the economics of risk in more applied fields such as health economics, financial economics, public economics, and environmental economics will not be covered here. We will restrict ourselves to a very brief account of some developments in insurance economics.

Our survey is organized as follows. In the first section we provide a broad overview of developments until the end of the 1960s. These include the principle of optimal behavior under conditions of risk – the maximization of expected utility – the definition and measurement of risk aversion and the fundamental results about the optimal allocation of risks among individuals. While we concentrate in the second section on personal attitudes toward risk, we adopt in the third section a more “statistical” approach and present the fundamental concept of a “mean-preserving increase in risk.” Combining results from the second and the third sections, we discuss in the fourth section the impacts of risk on preferences on one hand

and on choices on the other hand. The fifth section reviews more recent literature focusing on risk attitudes beyond risk aversion, namely, prudence and temperance. The results reviewed in the fifth section lead us to cast a new look in the sixth section on the coefficient of relative risk aversion initially presented in the first section. Our survey ends in section [Further Research: Applications – Insurance as an Example](#) with some comments about applications and a brief account of results obtained in the theory of insurance demand, followed by the [Conclusion](#).

## From the Origins to the End of the 1960s: A Broad Overview

---

Although he never used any of the expressions we are so familiar with today (“declining marginal utility,” “concavity,” “risk premium,” etc.), Daniel Bernoulli set up in 1738 the foundations of the modern economic theory of risk. Using either abstract examples (e.g., the St. Petersburg game) or more real-world examples (the Amsterdam merchant who wants to insure goods to be shipped), he convincingly argued that decision makers (DMs) could attach to a lottery a value below its mathematical expectation contrarily to Pascal and Fermat who had argued that the value of a lottery was given by the mathematical expectation of its consequences. His argument relied on the idea that the utility of gains – not the gains themselves – matters and that utility increases with gains at a declining rate. Quite surprisingly, his so fundamental and deep ideas remained unnoticed by economists for a very long time. It is fair to say that these ideas were not formulated in precise modern economic terms until the works of von Neumann and Morgenstern (1947), Friedman and Savage (1948), Arrow (1965, 1971) and Pratt (1964).

## Expected Utility

---

Thanks to the work of von Neumann and Morgenstern (1947), later extended by Savage (1954), we know under which assumptions of rational behavior a risky situation can be evaluated by the expected utility of consequences. More formally, if a lottery  $\tilde{w}$  – i.e., a probability distribution of outcomes – leads to mutually exclusive outcomes ( $w_1, w_2, \dots, w_s, \dots, w_S$ ) with probabilities of occurrence ( $p_1, p_2, \dots, p_s, \dots, p_S$ ), where  $s = 1, 2, \dots, S$  denotes the state of nature with probability of occurrence  $p_s$  leading to outcome  $w_s$ , its value is given by its expected utility (EU):

$$E[u(\tilde{w})] = \sum_{s=1}^S p_s u(w_s)$$

where  $u$  is a cardinal increasing function of  $w$ .

For a continuous density of outcomes  $f(w)$  defined on  $[a, b]$ , one has:

$$E[u(\tilde{w})] = \int_a^b u(w)f(w)dw.$$

The *expected utility theorem*, as expressed by von Neumann and Morgenstern (1947), states that an individual makes decisions under risk as if he or she maximized the expected value of a *cardinal* utility function of outcomes. For each individual, the utility function is unique up to a positive linear transformation. The theorem is based on a few axioms defining consistent behavior in choices among lotteries:

- (A1) *Preordering*: Considering a set of lotteries  $A, B, C, \dots$ , each pair of lotteries is characterized by a preference or indifference relationship ( $\succsim$ ): either  $A \succsim B$ , or  $B \succsim A$ . Besides, the relationship is reflexive ( $A \succsim A$ ) and transitive: if  $A \succsim B$  and  $B \succsim C$ , then  $A \succsim C$ .
- (A2) *Continuity*: If  $A \succsim B \succsim C$ , then  $\exists q \in [0, 1]$  such that  $B \sim \{(q, A); (1 - q, C)\}$ , where the symbol  $\sim$  means “is indifferent to” and where  $B$  is a “compound lottery.”
- (A3) *Boundedness*: For any lottery  $L$ , there exist bounds  $y$  and  $z$  such that  $L \succ y$  and  $z \succ L$ ,  $\forall L$  where the symbol  $\succ$  means “is preferred to.”
- (A4) *Independence or substitution*: Consider three lotteries  $A, B$ , and  $C$ . Then, for any  $C$

$$A \succ B \Rightarrow \{(p, A); (1 - p, C)\} \succ \{(p, B); (1 - p, C)\} \quad \forall p \in (0, 1]$$

$$A \sim B \Rightarrow \{(p, A); (1 - p, C)\} \sim \{(p, B); (1 - p, C)\} \quad \forall p \in [0, 1]$$

Compared with the axioms needed to represent choices under certainty using an *ordinal* utility function, it turns out that only the fourth axiom is new. This axiom is however necessary to yield the EU theorem. For this reason, it has been the target of criticisms, starting with Maurice Allais (1953) arguing that this axiom goes beyond requirements of rational (i.e., consistent) behavior. In a famous experiment, he showed that a significant proportion of individuals violate expected utility theory when faced with choices where one of the lotteries is the certainty of receiving a large amount (Allais' paradox). His observation has been repeatedly confirmed in numerous experiments since then. Axiom A4 is at stake in observed violations of expected utility theory. The Allais paradox has thus led some scholars to develop competing theories of decisions under risk, not relying on the independence axiom and commonly referred to as “nonexpected utility theory.” The most well known is *prospect theory* (Kahneman and Tversky 1979; Tversky and Kahneman 1992). However, these theories have met with criticism too. None of them has received widespread acceptance so far and none has proved as fruitful and flexible as EU theory in the development of models explaining various features of economic life.

In von Neumann and Morgenstern (1947), the probabilities of outcomes are given and the measurable utility underlying choices may be easily derived, for each decision maker, observing his or her choices. The utility function reflects his or her subjectivity, his or her behavior toward risk. Savage (1954) goes one step further: introducing concepts of states of nature, events, and conditional preferences, and using a different set of axioms he shows that rational choices in risky situations are driven by the maximization of subjective expected utility. The choices reflect the existence of a measurable utility function over outcomes *and* of a subjective probability measure over events. For a clear presentation of the axioms used by Savage, see Dumas and Allaz (1996). The two approaches to expected utility mirror the two concepts of probability: in von Neumann and Morgenstern, probabilities are provided by experience (frequency interpretation), whereas in Savage probabilities reflect a subjective degree of belief. See also Fishburn (1989).

## Attitudes Toward Risk

---

In an early contribution, Friedman and Savage (1948) showed that the shape of the von Neumann–Morgenstern utility function defines behavior toward risk. If the outcome brings utility, the function is increasing: marginal utility  $u'(w)$  is positive for all individuals, whatever their attitude toward risk. The latter is reflected in the second derivative.

- An increasing linear function denotes indifference toward risk: the individual behaves as if he or she maximized the expected outcome,  $\max E[u(w)] \equiv \max u[E(w)]$ . In this case, marginal utility is constant and the second derivative equals zero.
- A concave function denotes risk aversion: the individual prefers the certainty of obtaining outcome  $E(w)$  to the uncertain prospect  $\tilde{w}$  with expected value  $E(w)$ :  $E[u(w)] < u[E(w)]$ . This inequality, known as Jensen's inequality, characterizes a concave function: marginal utility is decreasing,  $u''(w) < 0$ .
- Finally, a convex function denotes a risk-loving individual: risk yields more utility than the certainty of the expected outcome,  $E[u(w)] > u[E(w)]$ . In this case, marginal utility is increasing,  $u''(w) > 0$ .

Besides this definition of risk aversion, Friedman–Savage observed that many individuals purchase insurance contracts, for all sorts of risk, and also buy lottery tickets. In the first case, they behave as risk averters: they pay more than the expected value of loss to avoid a loss; in the second case they behave as risk lovers, paying more than the expected value of gain to participate in the lottery. To solve the paradox, Friedman and Savage proposed a utility function with an inflection point at the level of current wealth, a convex segment following a concave segment. This ad hoc solution has not been retained in the subsequent literature. It is commonly accepted today that risk aversion prevails in society, which leads to justify the use of concave von Neumann–Morgenstern utility functions. Marginal utility is decreasing, an assumption familiar to economists for a very long time. Participation to lotteries by fundamentally risk-averse individuals is rationalized by other considerations such as overestimation of probabilities of gains, pleasure from gambling, and desire to change for a “better life” with more enjoyment, i.e., to switch to a different utility function.

## Risk Aversion

---

In two almost simultaneous, yet independent, papers, Arrow (1965) and Pratt (1964) defined the risk premium, denoted  $\pi$ , as an amount of money a risk-averse decision maker (DM) would accept to pay to replace a random prospect  $\tilde{w}$  by its expectation  $E(\tilde{w})$  received with certainty.

Formally,  $\pi$  is solution to:

$$E[u(\tilde{w})] = u(E(\tilde{w}) - \pi) \quad (1)$$

Using a Taylor series approximation, more particularly appropriate for relatively small risks, it can be shown that

$$\pi \approx \frac{\sigma_{\tilde{w}}^2}{2} \left( -\frac{u''(E(\tilde{w}))}{u'(E(\tilde{w}))} \right) \quad (2)$$

where  $\sigma_{\tilde{w}}^2$  is the variance of  $\tilde{w}$ .

The ratio  $\left(-\frac{u''(E(\tilde{w}))}{u'(E(\tilde{w}))}\right)$  is positive for a risk-averse DM. It is called the coefficient (or index) of *absolute risk aversion*. This index, that we denote  $A$ , has played a central role in the economics of risk, as well as in other fields like finance, operations research, and psychology, to name a few. It turned out to be more particularly important through assumptions made about its behavior when the expected outcome changes. The term “absolute” reflects the fact that  $A$  plays a role in optimal decisions under risk when absolute outcomes are considered, e.g., the chance of a gain or of a loss of a certain amount. Defining the outcomes  $w$  as amounts of wealth, Arrow’s original assumption was that  $A$  decreases in wealth: a wealthy individual is less concerned by the risk to gain or lose \$100 than a poor individual. This assumption of *decreasing absolute risk aversion* (DARA) has been repeatedly supported by empirical evidence and experimental studies (see, for instance, Levy 1994). In financial economics, e.g., it implies that risky assets, like common stocks, are normal goods: the demand for these assets increases when wealth increases.

Arrow and Pratt also developed the concept of *relative risk aversion* linked to a *proportional* risk premium. The coefficient of relative risk aversion is defined as  $R = wA$ , where  $w$  represents the DM’s initial wealth. It turns out that  $R$  is useful when the amount at risk is a proportion  $\alpha$  of the initial endowment, with final random outcome  $\tilde{w} = w(1 + \alpha\tilde{\varepsilon})$ . Arrow hypothesized that  $R$  is increasing with wealth, meaning that a risk-averse DM will invest a smaller proportion of his or her wealth in risky ventures as his or her wealth increases. However, this hypothesis of increasing relative risk aversion (IRRA) has not been supported unambiguously by empirical observations and experimental surveys. Indeed, none of the hypotheses of increasing, decreasing, or constant relative risk aversion could be rejected with high confidence until now (see Meyer and Meyer 2005).

## The Allocation of Risks Among Individuals

A very important concept in economics is general equilibrium. Walras (1874) demonstrated mathematically that, whatever the number of products and markets in the economy, a system of free competitive markets governed by the forces of demand and supply tends to a situation where all markets are simultaneously in equilibrium – the effective demand being equal to the effective supply at the clearing price. Pareto (1896) later showed that this general equilibrium situation is characterized by a remarkable welfare property: it is impossible to increase the utility of one individual without simultaneously decreasing the utility of at least one other individual (Pareto optimality).

The Walras model of general equilibrium is a static model: it has one period and no uncertainty. In the wake of debates about risk and uncertainty during the 1950s, Debreu (1953, 1959) and Arrow (1953, 1964) used the state of nature concept to extend Walras’ model to multiple periods and uncertainty about the future. Debreu (1953, 1959) introduced the concept of state-contingent goods. Goods and services are characterized not only by their intrinsic characteristics, but also by the specific date and state of nature for their delivery. For example, with  $m$  goods and services, two periods, 0 and 1, and  $S$  states of nature at period 1, there are  $m + mS$  markets:  $m$  spot markets and  $mS$  state-contingent forward markets. An umbrella delivered on November 1 if it rains is not the same state-contingent good as an umbrella delivered on the same date if the sun shines. Essentially, the analysis remains the same but it applies to a much larger number of markets, with the same general equilibrium and

optimality properties. The crux of Arrow's (1953) contribution was to show that finance allows to economize on markets. In a monetary economy, the introduction of contingent securities (or conditional claims) leads to the same general equilibrium as the Debreu model with contingent goods. At each period, only  $m + S$  markets are necessary, instead of  $m + mS$ :  $m$  markets for the spot exchange of goods against the numeraire and  $S$  markets for the spot exchange of numeraire against conditional claims on the future numeraire. Instead of purchasing an umbrella delivered on November 1 if it rains, the forward-looking individual purchases a financial contract promising to pay a certain amount at that date if it rains. This amount may then be used to purchase a spot umbrella (or a raincoat). The same result is obtained by economizing on markets: finance favors efficiency. Note also that the two models, Arrow and Debreu, work if there exist complete markets for future delivery:  $mS$  markets for contingent goods in the Debreu version,  $S$  markets for contingent claims in the Arrow version.

A characteristic property of Pareto-optimal general equilibrium is that the ratios of marginal utilities are equalized among individuals. For example, considering two individuals  $i$  and  $k$  in the economy, two future states of nature  $s$  and  $\theta$ , and assuming identical subjective probabilities among individuals, the optimal allocation is characterized by:

$$\frac{u_i'(w_{i\theta})}{u_i'(w_{is})} = \frac{u_k'(w_{k\theta})}{u_k'(w_{ks})} \quad (3)$$

This optimal allocation is obtained either by having a complete system of free competitive markets with each individual maximizing his or her utility under a budget constraint, or by letting a benevolent and omniscient dictator allocate resources by maximizing a weighted sum of individual utilities under constraints of available resources.

Expression (3) is known as *Borch's condition* (Borch 1960, 1962). It has important societal implications. By inspection, it may be seen that if individual  $i$  has an optimal allocation with more wealth in state  $\theta$  than in state  $s$ , the ratio on the LHS of (3) is less than one, by diminishing marginal utility. The expression implies that this must also hold for individual  $k$  on the RHS. As  $i$  and  $k$  are arbitrary, this implies further that aggregate wealth is larger in state  $\theta$  than in state  $s$ :  $W_\theta > W_s$ , where  $W_s = \sum_i w_{is}$ . As a result it must be that

$$w_i = f_i(W) \quad (4)$$

all  $i$ , with  $f_i$  an increasing function.

Expression (4) reflects the *mutuality principle*: at the Pareto-optimal equilibrium, whatever the way to obtain it (free-markets economy or mandatory allocations by the State), it must be that idiosyncratic (individual) risks do not play a role. The allocation of each individual is an increasing function of aggregate resources. If aggregate wealth is higher, everybody is better off; if aggregate wealth is lower, everyone suffers. The individual risks have been canceled by diversification, for instance, using social insurance or a system of complete markets for private insurance. Only the macroeconomic (systematic) risk is left.

This risk cannot be eliminated by diversification. It must be shared among individuals, one way or the other. One possibility is a mandatory distribution of resources, using for instance an egalitarian system. But in a market economy, this allocation is performed by the financial market. Every security in this market is actually a portfolio of Arrow–Debreu conditional claims. By exchanging securities on financial markets individuals and institutions perform changes in the allocation of risks related to future wealth. A simple mathematical derivation

starting from the optimality conditions yields that each individual participates in this process according to his or her absolute risk tolerance (the inverse of absolute risk aversion). It turns out that function  $f_i$  in (❸ 4) has positive first derivative given by

$$f'_i = \frac{\partial w_i}{\partial W} = \frac{T_i^a}{\sum_k T_k^a}$$

where  $T^a = 1/A$ .

Thus, participation in aggregate risk is driven by risk tolerance. Individuals with a relatively higher degree of risk tolerance purchase more risky financial assets. Doing this, they take a larger share of aggregate risk. Compared to more risk-averse individuals, they will lose more if aggregate wealth decreases and gain more if the economy performs well and aggregate wealth increases. To sum up, in the economy, insurance markets perform the diversification of individual risks and financial markets allow the sharing of aggregate risks. Notice, finally, that a particular class of von Neumann–Morgenstern utility functions – the HARA class where HARA means “hyperbolic absolute risk aversion” – yields linear absolute risk tolerance coefficients and therefore linear sharing of systematic risks among individuals.

## Mean-Preserving Changes in Risk

In the early seventies Rothschild and Stiglitz (RS) (1970, 1971) published two papers that nicely complemented those of Arrow and Pratt (AP) discussed above under section ❸ Risk Aversion. While AP had looked at preferences, i.e., properties of a DM’s utility function, RS paid essential attention to the statistical properties of the risk faced by the DM and then established a link between these statistical properties and the utility function.

To start, they raised the following question: when can we say that a random variable  $\tilde{Y}$  is riskier than another one  $\tilde{X}$ ? To make the comparison feasible and independent from other considerations, they assumed that the two variables have the same mean, i.e.,  $E(\tilde{X}) = E(\tilde{Y})$ , hence the term “mean-preserving.” While Pratt had given different plausible definitions of risk aversion and then shown their equivalence, RS did the same for the notion of mean-preserving changes in risk. Here are two possible and apparently different definitions of a mean-preserving increase in risk:

- $\tilde{Y}$  is obtained from  $\tilde{X}$  by adding zero-mean independent risks  $\tilde{z}$  to  $\tilde{X}$ ;
- $\tilde{Y}$  is obtained from  $\tilde{X}$  by taking some weight away from the center of the density of  $\tilde{X}$  and transferring it to its tails without changing the mean (*mean-preserving spread*, or MPS).

Each of these two different definitions makes sense and RS showed that both are equivalent. Besides, they established an important link with preferences that is stated as follows:

- If  $\tilde{Y}$  is an MPS of  $\tilde{X}$ , then every risk-averse DM will prefer  $\tilde{X}$  to  $\tilde{Y}$ .

This result is really important. First, it suggests a very general definition of risk aversion that is based on attitudes toward changes in risk instead of being based on the concavity of the utility function, something specific to the EU model. Further, as will be shown in section ❸ Preferences Versus Choices, this result leads to an interesting distinction between preferences on the one hand and optimal choices on the other. Finally, as will be shown in section ❸ Higher-Order Risk Attitudes: Prudence and Temperance, the RS paper led much later to

the introduction of new concepts such as prudence and temperance which characterize attitudes toward risk beyond risk aversion – hence the term “higher-order risk attitudes.” These new concepts are themselves related to statistical notions such as “downside risk increase” (Menezes et al. 1980) or “outer risk increase” (Menezes and Wang 2005) which are described by Ekern (1980) under the more general term of “ $n$ th degree increases in risk” (see section [Further Research: Applications – Insurance as an Example](#)).

To be fair toward a large body of statistical and economic literature, it is worth mentioning that the notion of MPS represents a special case of *second-order stochastic dominance*, in which the comparison between random variables is made without the restriction of equal means. The notion of stochastic dominance was introduced into economics by Hadar and Russell (1969) and Hanoch and Levy (1969). For a detailed survey, see Levy (1992).

## Preferences Versus Choices

---

Among many other important results, Pratt (1964) indicated in the last section of his paper that, in accordance with intuition, as a DM becomes more risk averse, he or she would engage less in risky activities. This result was confirmed later on in the analysis of many specific situations, e.g., in Mossin (1968) for insurance decisions, or in Sandmo (1971) for production decisions.

Because this result was so natural, a widespread belief developed about the answer to an apparently similar question: given the DM’s degree of risk aversion, will he or she take a less risky position when the return on a risky investment vehicle becomes riskier? Because an increase in risk aversion (for a given risk) or an increase in risk (for a given risk aversion) are both welfare reducing for risk-averse DMs, it was thought they would also have a similar impact on optimal choices. But in fact, it was realized in the mid 1980s that a riskier investment return did not necessarily imply less risk taking by a risk-averse DM. In a sense, the MPS concept as developed by Rothschild and Stiglitz (see section [Mean-Preserving Changes in Risk](#) above) proved to be too general to produce the desired intuitive result.

From this observation emerged a literature that tried to narrow down the MPS concept to a less general concept that would yield the meaningful comparative statics result. The reader is referred to a succession of papers – Eeckhoudt and Hansen (1980); Meyer and Ormiston (1985); Black and Bulkley (1989); Dionne et al. (1993) – in which sequentially less restrictive assumptions are imposed upon the MPS to generate the required result about the observed choices of a risk-averse DM. This literature culminated (and came to an end) with a paper by Gollier (1995) who derived the necessary and sufficient condition that must be imposed on the MPS to induce less risk taking by a risk-averse DM. Since this condition is technical, the reader is referred to the original article or to a survey of this question by Eeckhoudt and Gollier (2000).

While the economics literature on these topics has been developed around the notion of an MPS, a very interesting contribution on a related question in the financial management literature is worth mentioning. Fishburn and Porter (1976) looked at the optimal choice for an investor when the risky investment return benefits from an improvement in the sense of first-order stochastic dominance (FSD), i.e., a “good news” since a random variable  $\tilde{X}$  first-order dominates another one  $\tilde{Y}$  if for any value  $m$ ,  $P_r(\tilde{X} \leq m) \leq P_r(\tilde{Y} \leq m)$ .

Of course, such a good news improves the DM’s welfare (as soon as  $u' > 0$ ), but will it imply more risk taking? As in the case of the MPS, Fishburn and Porter showed that the answer is not straightforward. They then gave sufficient conditions either on the DM’s utility function or on

the nature of the FSD improvement to obtain the desired result. Quite interestingly, the desired result on the utility function is that the coefficient of relative risk aversion  $R$  defined in section [\(6\) Risk Aversion](#) should not exceed unity. We return to this condition in section [\(6\) Relative Risk Attitudes](#).

## Higher-Order Risk Attitudes: Prudence and Temperance

While the assumptions made about the behavior of the absolute risk aversion coefficient  $A$  turned out to be appropriate to discuss insurance or portfolio choice problems, they turned out to be insufficient for the analysis of savings choices. In this field, early papers by Leland (1968); Sandmo (1970); Drèze and Modigliani (1972), and later on Kimball's (1990) contribution stressed the role of the sign of the third derivative of the utility function in the unveiling of a precautionary motive for saving. Since Kimball coined the term "prudence" for a positive value of  $u'''$  and since  $u''' > 0$  generates precautionary saving – as we will show below – it was admitted for a long time that prudence and precautionary saving were "the same thing."

To see this link, let us consider two very simple saving problems with a two-period horizon. In the first problem, current and future incomes ( $y_1$  and  $y_2$ ) are known with certainty. The individual's problem is to choose a current consumption level,  $c_1$ , maximizing intertemporal utility, i.e.,

$$\underset{c_1}{\text{Max}} \ u(c_1) + u\{(y_1 - c_1) + y_2\} \quad (5)$$

To simplify the notation, we assume – without loss of content – that utility is time additive and that the interest rate and discount factor on utility are zero. The optimum is obtained for a value of  $c_1$ , denoted  $c_1^*$ , such that:

$$u'(c_1^*) - u'\{(y_1 - c_1^*) + y_2\} = 0 \quad (6)$$

so that  $c_1^*$  satisfies  $c_1^* = \frac{y_1 + y_2}{2}$ .

This well-known result illustrates "consumption smoothing": thanks to his or her choice of  $c_1^*$  the DM can obtain the same consumption level in each period.

Now, let us introduce risk in the savings problem. This can be done by considering that future income becomes random so that  $y_2$  is replaced by  $\tilde{y}_2 = y_2 + \tilde{\varepsilon}$ , where  $\tilde{\varepsilon}$  is a zero-mean risk.

The optimization problem is now:

$$\underset{c_1}{\text{Max}} \ u(c_1) + E\{u\{(y_1 - c_1) + y_2 + \tilde{\varepsilon}\}\} \quad (7)$$

with a first derivative evaluated at  $c_1^*$ :

$$u'(c_1^*) - E\{u'\{(y_1 - c_1^*) + y_2 + \tilde{\varepsilon}\}\} \quad (8)$$

Comparing [\(6\)](#) and [\(8\)](#) one notices that, by Jensen's inequality:

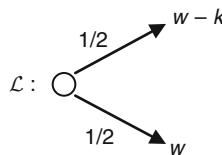

$$E\{u'\{(y_1 - c_1^*) + y_2 + \tilde{\varepsilon}\}\} \geq u'\{(y_1 - c_1^*) + y_2\} \Leftrightarrow u''' \geq 0.$$

If  $u'''$  is positive, it can then be shown that the solution to problem [\(7\)](#), denoted  $\hat{c}_1$ , falls below  $c_1^*$ . Indeed, in this case, we can see from the above relationships that [\(8\)](#) is negative. To obtain the first-order condition – [\(8\)](#) equals zero – and given that the second-order condition

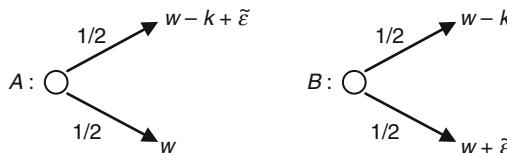

(negativity) is fulfilled by concavity of  $u - c_1$  must decrease, which yields  $\hat{c}_1 < c_1^*$ . Faced with future income risk, the DM reduces current consumption in order to build up precautionary savings.

While the link between prudence ( $u''' > 0$ ) and precautionary saving is instructive and elegant, one should nevertheless notice a discrepancy between the motivations for risk aversion ( $u'' < 0$ ) and for prudence ( $u''' > 0$ ). Risk aversion was defined as a general attitude toward risk, independently of a specific decision context in which this risk may arise, whereas prudence was developed in a specific context, the precautionary motive for saving. For this reason, prudence could appear as a concept which lacks generality.

Fortunately, more recent work, e.g., Eeckhoudt and Schlesinger (2006), has shown that prudence – like risk aversion – reflects a general attitude toward risk. To see this, consider the following simple binary lottery  $\mathcal{L}$ :

where  $w$  and  $k$  are positive amounts and  $\frac{1}{2}$  represents the probability of obtaining the stated amount of wealth. Assume now that a DM facing lottery  $\mathcal{L}$  must also face, with probability  $\frac{1}{2}$ , the prospect of a subsequent zero-mean risk  $\tilde{\varepsilon}$  that he or she does not like (because he or she is risk averse). If this DM adopts the principle that it is worthwhile “combining good with bad” (instead of ending with either “good-good” or “bad-bad”), then he or she will prefer to face the  $\tilde{\varepsilon}$  risk when his or her wealth is  $w$  instead of  $w - k$ . In other words, he or she will prefer  $B$  to  $A$  when faced with the choice between the two following lotteries:

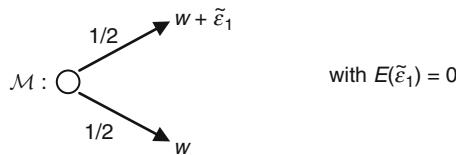

Put differently, he or she prefers “disaggregating pains.” Quite obviously, pains are disaggregated in  $B$ , not in  $A$ , and if  $B \succ A$  it is easily shown (see Eeckhoudt and Schlesinger 2006) that in the EU framework

$$B \succ A \Leftrightarrow u''' > 0$$

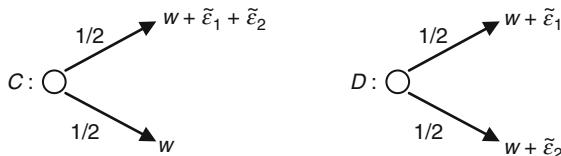

As a result, prudence has now a status equivalent to that of risk aversion: it reflects a very general attitude according to which risk-averse DMs prefer to avoid the concentration of pains. When faced with a prospect of a future risk (which they dislike), they feel less concerned by this prospect if it arises in a “good” state of nature – a state where the marginal utility of wealth is lower. Notice that this explanation of “prudence” provides the fundamental rationale for precautionary saving. In this case, the DM knows that he or she faces a future risk on his or her income. She prepares for this risk by saving more – which decreases his or her future marginal utility of wealth.

It is shown by Eeckhoudt and Schlesinger (2006) and by Eeckhoudt et al. (2009b) that this principle can be extended to higher orders of successive derivatives of  $u$ . Consider for instance the notion of *temperance* ( $u''' < 0$ ). Originally, temperance was linked to the following idea expressed by Kimball (1993): “It is reasonable to think that an unavoidable risk might lead an agent to reduce exposure to another risk even if the two risks are statistically independent.” Again, this definition is more related to a decision (“reduce exposure”) than to a fundamental preference. However, it can also be interpreted as a preference for disaggregating pains.

To see this, start from lottery  $\mathcal{M}$  where:

For a risk-averse DM,  $w + \tilde{\varepsilon}_1$  is the bad component of  $\mathcal{M}$  (it is dominated by  $w$ ). Now, suppose that with probability  $1/2$  this individual has to face another independent zero-mean risk  $\tilde{\varepsilon}_2$  (i.e., an additional pain) that he or she prefers to allocate to the good state. He or she prefers  $D$  to  $C$  where:

Eeckhoudt and Schlesinger (2006) show that in the EU framework

$$D \succ C \Leftrightarrow u'''' < 0, \text{ i.e., temperance.}$$

As a result, the sign of the fourth derivative of the utility function can be interpreted, like the sign of the second and third derivatives, as reflecting an attitude toward risk.

The reasoning can easily be extended to higher orders so as to give an interpretation to the alternating signs of successive derivatives of the utility function. When  $u$  exhibits such a property, shared by many (if not all) commonly used utility functions, the individual is said to be “mixed risk averse” (Caballé and Pomansky 1996).

Let us close this section with some general observations:

- While our discussion here concentrated on one-dimensional utility functions, the preference for “combining good with bad” also gives interesting insights about bi- or multidimensional utility: see Richard (1975), Eeckhoudt et al. (2007), and Tsetlin and Winkler (2009);
- Because the principle of “combining good with bad” is easily understood, it lends itself easily to experimentation: see Deck and Schlesinger (2010) and Ebert and Wiesen (2009);
- There is a natural link between the preferences discussed in this section and attitudes toward successive moments of a probability distribution of outcomes (a topic often

discussed in the finance literature): see Menezes et al. (1980), Chiu (2005), Roger (2010) or Ebert (2010);

- The principle of “combining good with bad” is also at the heart of the theory of asset prices. Prices of risky assets are obtained by discounting future payoffs. A fundamental principle arising from theoretical analyses, such as Arrow–Debreu pricing, stochastic discount factor analysis, or martingale pricing, is that prices of assets that pay in bad states of nature are “inflated,” compared to prices of assets that pay in good states. The individuals are prepared to pay more to “combine good with bad” (payoffs in a bad state), than to “combine good with good” (payoffs in a good state). The analysis shows that pricing occurs as if the market participants were adjusting the probability of states of nature, according to their overall market status (good or bad states). Given the above considerations, it is not surprising to find that prudence plays a role in defining a dividing line between good states and bad states for the pricing process (see Danthine and Donaldson 2005).

## Relative Risk Attitudes

---

So far, we have mostly paid attention either to the signs of the derivatives of the utility function, which indicate directions of preferences, or to the coefficient of absolute risk aversion  $A$  and its properties. This coefficient turns out to play a central role in the economics of risk when risks are additive.

In this section, we consider in more detail multiplicative risks from which one obtains inter alias the coefficient of relative risk aversion  $R$  defined in section [❸ Risk Aversion](#). Very early, three observations were made about this coefficient. First, from its definition (see section [❸ Risk Aversion](#)), this coefficient is equal to the elasticity of marginal utility of wealth with respect to current wealth. Secondly, many comparative statics results depend on the impact of wealth on the value of  $R$  and this impact is not unambiguously positive, negative, or null. Thirdly, it turns out also that many comparative results depend on a comparison between the value of  $R$  and unity. Notice indeed that because  $R$  is an elasticity, it has no dimension (in contrast to the risk premium  $\pi$  or to the coefficient of absolute risk aversion  $A$ ). For this reason, it can be compared to a pure number.

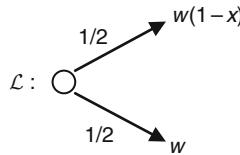

Note also that attention was paid more recently to the coefficients of absolute and relative prudence. Following the lead of Pratt (1964) in defining  $A$ , the coefficient of absolute prudence  $P_a$  was defined in Kimball (1990) as:

$$P_a = - \frac{u'''(E(\tilde{w}))}{u''(E(\tilde{w}))}$$

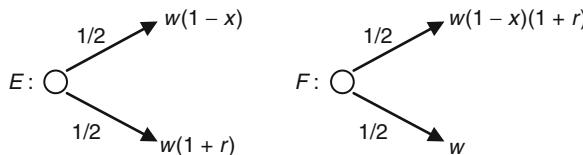

This coefficient is positive for a prudent, risk-averse DM. From there, the coefficient of relative prudence is defined as  $P_r = wP_a$ . While unity appears to be a sort of benchmark value for  $R$ , it is shown in Eeckhoudt and Schlesinger (2008) and in Danthine and Donaldson (2005) that the benchmark value for  $P_r$  is two.

In this section, we try to provide an intuitive interpretation for the benchmark value of unity applied to  $R$ . The reader can then refer to more technical papers that extend the reasoning to  $P_r$ , e.g., Eeckhoudt et al. (2009a).

Let a DM face a risk that, with probability  $\frac{1}{2}$ , reduces his or her wealth  $w$  to  $w(1 - x)$  where  $x$  is a positive number strictly smaller than unity. Hence, the DM faces a lottery  $\mathcal{L}$  represented as follows:

Now, this decision maker has the opportunity to benefit from a contingent increase in wealth in proportion  $r$ , where  $r$  is a strictly positive number. Depending on where he or she chooses to apportion this contingent increase, he or she faces one of the two lotteries  $E$  and  $F$ :

Which lottery will he or she choose? From section [Higher-Order Risk Attitudes: Prudence and Temperance](#), and the preference for combining good with bad, one tends to consider that  $F$  is preferred. However here, because of the multiplicative nature of the loss and gain, a new feature appears: lottery  $E$  has a higher mathematical expectation than lottery  $F$ , so that not all risk averters will prefer  $F$  to  $E$ . Only those who are “sufficiently” risk averse will prefer  $F$ .

What does it mean to be “sufficiently” risk averse? It can be shown that this is determined by whether or not  $R$  exceeds unity. To gain intuition about this result, consider a DM with a logarithmic utility function  $u(w) = \ln w$ . For this function, as is well known,  $R$  is constant and equal to 1. Besides, in this particular case,

$$E[\ln(\tilde{w})]_E = \ln w + \frac{1}{2} \ln(1 - x) + \frac{1}{2} \ln(1 + r) = E[\ln(\tilde{w})]_F$$

Consequently, with logarithmic utility, hence  $R$  constant and equal to unity, the DM is indifferent between  $E$  and  $F$ . To prefer  $F$ , the DM must be more risk averse than an individual with logarithmic utility. Using simple properties of the concave transformation of a utility function, it can be shown that this corresponds to  $R > 1$ . Conversely, a DM with  $R < 1$  will put relatively more emphasis on the fact that  $E$  has a larger mathematical expectation of final wealth than  $F$ , and he or she will prefer  $E$ .

To go to higher orders, beginning with relative prudence, one replaces  $(1 - x)$ , which corresponds to a known multiplicative loss, by  $(1 + \tilde{\varepsilon})$ , where  $\tilde{\varepsilon}$  is a zero-mean random variable (also a pain for a risk averter). Following basically the same argument as above, it can be shown that, to yield a preference for “combining good with bad,”  $P$ , must exceed 2. Details about this result are provided in Eeckhoudt et al. (2009a).

## Further Research: Applications – Insurance as an Example

The economics of risk has found numerous applications. All areas of economic life are concerned by questions of risk and uncertainty, but some of them more directly and more fundamentally than others. Health economics is one of them. This is due to the fact that, for any individual, the health status may change stochastically in time. However, health economics raises specific difficulties. The health status enters the utility function, besides wealth. Hence, the appropriate utility function is multidimensional and for this reason cross-derivatives of the utility function play a role in the analysis. For example, it is important for analytical purposes to have information on whether the marginal utility of wealth increases or decreases when the health status deteriorates. Concepts such as prudence and temperance become more complex to use when utility is multidimensional (see Eeckhoudt et al. 2007). Issues raised by health economics go much beyond the domain of the present survey. They have been addressed in numerous studies. Culyer and Newhouse (2000) edited a two-volume handbook of research on this topic.

Finance is another topic where the economics of risk has proved highly fruitful. Because finance deals with the transfer of purchasing power in time – from the present to the future and from the future to the present – and because the future is uncertain, finance is directly and fundamentally concerned by risk. In this case, the application of the economics of risk is straightforward. Wealth is appropriately considered as the one and only argument in the utility function and concepts such as risk aversion and prudence have direct applications in the study of financial behavior. Financial securities are easily conceived as lottery tickets providing specific payoffs in different states of nature. Indeed, as indicated before (see section ➤ [The Allocation of Risks Among Individuals](#)) any financial asset may be conceived as a portfolio of Arrow–Debreu contingent securities and its trading serves to transfer risks among individuals and institutions, reducing or eliminating the risks for some of them, and not necessarily increasing the risks for the others if a diversification process takes place through the transfer. The finance literature is huge and has witnessed a tremendous development since the 1960s with the applications of the economics of risk to financial economics issues. It is not appropriate to try to give even a brief account of this literature in this survey. The reader is rather referred to a textbook, such as by Danthine and Donaldson (2005). But within the broad area of finance, a specific aspect of risk transfer deserves a few paragraphs. This is insurance.

Insurance contracts are financial assets: they promise payments in the future, in specific states of nature, against the payment of a sure amount today (the insurance premium). As any other financial security, but still more obviously, they also represent bundles of Arrow–Debreu securities. They do not pay anything if a specific risk (the insured event) does not materialize. But they pay an indemnity in the states of nature where this event occurs. If the event represents a risk that is diversifiable in society (at least to some extent) and if problems of asymmetric information between insurers and insureds are not too large (see below), insurance companies will supply such contracts and will transform the risk into a predictable cost, to a large extent.

In the insurance domain, the demand for insurance represents a very fruitful application of the economics of risk aversion. Friedman and Savage (1948) had already shown that risk aversion is a necessary condition to produce a demand for insurance as soon as the insurance premium is “loaded,” i.e., more expensive than the actuarial value of the insured loss. A loading of the insurance premium is often observed and rationalized as a mean either to

cover insurance costs or to provide a profit to the insurer, or both. In fact, a loading may also be seen as a consequence of a lack of competition among insurers since the financial surplus provided by the loading – if any – supplements the financial income provided by the invested “technical” reserves of the insurer. If the latter income is high enough, competition among insurers should drive down the loading to a negative value.

The seminal paper on this topic was produced by Mossin (1968), who obtained two main results: (1) partial insurance coverage is optimal for an expected utility maximizer when the insurance premium incorporates a proportional loading (notice that this result was also present in Arrow (1963) and Smith (1968)) and (2) the demand for insurance decreases when wealth increases if the amount at risk remains fixed and the insured has decreasing absolute risk aversion (DARA). The second result is not controversial as long as the two required hypotheses are clearly indicated. But the first result seems to contradict casual observations. Most of the time, the insureds seem to prefer full insurance, although the premium is loaded and a proportional loading is common practice. With a lump sum loading, full insurance is optimal provided the loading does not exceed a certain threshold above which the individual prefers not to insure at all. If partial insurance is observed, this is often due to a limit being imposed on insurance coverage by the insurer, in his or her attempt to mitigate the effects of moral hazard and adverse selection (see below), not to a preference for partial insurance on the insured’s side.

Different explanations have been provided for Mossin’s result in numerous research papers (see Loubergé 2000, and Rees and Wambach 2008 for extended surveys of insurance economics; and Schlesinger 2000, for a specific presentation of the demand for insurance). The most interesting explanation is the recognition that Mossin’s analysis is based on the implicit assumption that the individual faces only one risk, whereas in reality, insureds are confronted with several risks having various characteristics: some of these risks are independent, others not; some of them are uninsurable, others may be insured, partially or fully; and still others have to be insured fully at a regulated price, due to social insurance provisions. Hence, given that the objective is to maximize the expected utility of final wealth, which is affected jointly by these various risks, the demand for insurance should be analyzed in a portfolio setting, not in isolation. Indeed, for given DM’s preferences and given insurance pricing, the decision to insure a given risk partially, fully, or not at all will depend on three elements:

- The insurable risk being considered
- The other risks faced by the DM, their relationship with the first risk, and their joint influence on final wealth
- The constraints imposed on risk transfers by the fact that some risks are not insurable (incomplete markets for insurance) and others are subject to mandatory insurance

The portfolio approach to insurance has proved particularly fruitful in this context. This portfolio approach was initially developed to study the optimal management of an insurer or reinsurer, seen as a financial intermediary (see Kahane and Nye 1975; Kahane 1977; Loubergé 1983). The portfolio approach was then used to reconsider models “à la Mossin” by Doherty and Schlesinger (1983), Mayers and Smith (1983), Turnbull (1983), Doherty (1984), von Schulenburg (1986), and Gollier and Scarmure (1994), among others. More recently, Rey (2003) considered the case where the “background” uninsurable risk is a health risk. The main tenet of this approach is that a risk should not be considered and managed per se, independently of the other risks faced by the individual or the institution. When investing

funds in the financial market, a risk-averse DM will take into account the imperfect correlations between the payoffs of the different traded assets. He or she will choose an optimal diversified portfolio that maximizes the expected utility of his or her final wealth and reflects his or her degree of risk tolerance (see Markowitz 1959). Similarly, in the insurance domain, the extent of coverage chosen for a given insurable risk will take into account the other risks and their joint influence on the DM's overall situation. For example, it may be optimal for him or her to insure a risk fully, even if the premium is loaded, due to a positive correlation between this risk and other risks for which no insurance is available. By insuring the insurable risk fully, although it would have been optimal to insure this risk partially if considered in isolation, the DM insures indirectly the uninsurable risk (see Doherty and Schlesinger 1983). A nice example is credit risk insurance for a small entrepreneur. His or her final wealth depends on the demand for his or her services that varies with the overall economic activity. This business risk is uninsurable. The entrepreneur faces another risk which may be insured, the risk that his or her customers do not pay when payments become due (credit risk). The two risks are positively correlated and it may thus be optimal for the entrepreneur to purchase full insurance for the credit risk even if the premium incorporates a proportional loading. Using the concept of prudence, Eeckhoudt and Kimball (1992) have also shown that the insurance purchasing decision is not independent of the other uninsurable risks faced by the DM, even if these risks are stochastically independent of the insurable risk.

These improvements in the theory of insurance demand closely paralleled similar advances in the theory of risk aversion under multiple sources of risk, e.g., Kihlstrom et al. (1981); Ross (1981) and Doherty et al. (1987). They were then followed by many papers examining comparative statics properties of insurance demand under "background risk" such as Meyer (1992), Dionne and Gollier (1992), Eeckhoudt et al. (1991, 1996), Gollier and Pratt (1996), Tibiletti (1995), Meyer and Ormiston (1996), Guiso and Jappelli (1998), and Meyer and Meyer (1998).

This literature fits well into the premises that have been chosen for the present survey – concentrate on the behavior toward risk observed for an individual decision maker. However, it should be stressed that insurance economics covers also other fruitful applications of the economics of risk to insurance problems: in particular, the study of insurance and reinsurance companies operations when risks cannot be fully diversified away, and the functioning of insurance markets when asymmetric information prevails between insurers and insureds. Issues raised by these considerations were reviewed in the handbook edited by Dionne (2000), and more recently in a series of papers published in *The Journal of Risk and Insurance* (September 2009) and in a survey study by Rees and Wambach (2008). These insurance issues go much beyond the optimal behavior of a risk-averse DM. They address societal issues, such as how should the economy deal with large risks having macroeconomic consequences, for instance changes in human longevity, large-scale catastrophes, and climate change.

A final set of issues concerns the problem of asymmetric information. Asymmetric information among market participants produces two kinds of imperfections in the market mechanism: moral hazard and adverse selection. Moral hazard occurs when the behavior of an agent (e.g., an insured) may have an impact on the outcome of a contract between this agent and a principal (e.g., an insurer), but the principal cannot observe whether the outcome is only due to the occurrence of an exogenous state of nature or whether the agent's behavior has played a role. Adverse selection occurs when the agent's characteristics have a statistical impact on the outcome of the contract, but the principal is unable to observe these characteristics. In both cases, the market mechanism is biased and the principal internalizes this bias in his or her

decisions to participate (or not) to the exchange, and to which extent. In the limit, the market does not exist (markets are not complete), or it works with second best arrangements, such as partial risk transfers or signaling by the agent that he or she is endowed with the “good” characteristics. Insurance markets are primary examples of markets where moral hazard and adverse selection are predominant, but financial markets and labor markets also offer good examples. What are the economic consequences of asymmetric information among market participants in the markets for risk transfers? If some markets work imperfectly or even do not exist for reasons of moral hazard and adverse selection, does this contradict the results derived from the Arrow–Debreu model of competitive allocation of risks among individuals? Should the public authorities intervene? How and with which expected consequences? To be able to address these questions with an appropriate economic toolkit, more advances in the economics of risk will be useful.

## Conclusion

---

While many topics have been left aside (as indicated in the introduction) we have covered in this survey two fundamental aspects of the economics of risk.

In the first sections we have reviewed well-known results, while in sections [Higher-Order Risk Attitudes: Prudence and Temperance](#) and [Relative Risk Attitudes](#) more recent developments about fundamental concepts have been analyzed. We have restricted these developments to models of one-dimensional utility, although, as already mentioned in section [Higher-Order Risk Attitudes: Prudence and Temperance](#), these developments start having implications for models of choices in a joint context of risk and multivariate arguments of utility (for instance, health and wealth).

The economics of risk has had a deep influence in many fields of economic theory. In the earlier years of its development (the 1960s and 1970s), it appeared as a specialized topic in microeconomic theory – the theory dealing with the behavior of economic agents and their interaction in markets. Nowadays, problems of risk, uncertainty, and information have been pervasive in all areas of microeconomics and finance. They have also started to have a tremendous impact at the macroeconomic level, as witnessed by developments in global finance and banking, or by the challenges of “sustainable development.” For these reasons, the concepts presented in the first sections of this survey are now part of the fundamental education of any economist. Given the limitations of this work, we have been unable to devote much space to applications, but we have at least provided a flavor of the direct applications that the economics of risk has found in insurance. The reference list below will hopefully help the interested reader to complete the brief account provided by this survey.

**Abstract:** One of the central questions in a legal trial is whether the suspect did or did not commit the crime. It will be apparent that absolute certainty cannot be attained. Because there is always a certain degree of uncertainty when interpreting the evidence, none of the evidence rules out all hypotheses except one. The central question should therefore be formulated in terms of probability. For instance, how probable is it that the suspect is the offender, given the situation and a number of inherent uncertain pieces of evidence? The answer to this question requires the estimation, and subsequent combination, of all relevant probabilities, and cannot be provided by the forensic expert. What the forensic expert can provide is just a piece of the puzzle: an estimate of the evidential value of her investigation. This evidential value is based on estimates of the probabilities of the evidence given at least two prespecified hypotheses. These probabilities can subsequently be used by the legal decision maker in order to determine an answer to the question above, but they are, of course, not sufficient. They need to be combined with all the other information in the case. A probabilistic framework to do this is the Likelihood Ratio approach for the interpretation of forensic evidence. In this chapter we will describe this framework.

## Introduction

---

Imagine yourself being stopped by the police in a random traffic alcohol control. You did not drink a drop of alcohol, and you obtain a negative result on the breath analysis. However, you see the driver of the car in front of you taken into custody because of a positive test result on the breath analysis. You have read a recent popular scientific journal article in which the properties of breath analysis were discussed, and you remember that the test being used is correct in more or less 99% of the time. So, if the breath alcohol concentration is above the legal limit, there is a 99% chance of a positive test result, and, if the breath alcohol concentration is below the limit, then there is a 99% chance of a negative test result. Could you give an estimate of the probability that the breath alcohol concentration of the driver in the car in front of you is indeed above the legal limit? Is it a high probability or a low one?

It is tempting to give an answer to this question, and this answer is likely to be quite a high probability that the driver's alcohol concentration is above the legal limit. The truth of the fact is, actually, that an answer to this question cannot be given based on the information provided. An important part of the information that is needed is missing, and this part consists of the relative frequency of drivers that truly have an alcohol concentration above the legal limit. Aspects like driving style and prior speeding fines could of course also contribute. What we can legitimately conclude from the given information is the "evidential value" (to use the forensic science terminology; see Robertson and Vignaux 1995; Aitken and Taroni 2004) of the breath analysis (outside the field of forensics the term "relative risk" is often used for a similar statistical quantity). The evidential value helps in estimating the relevant probability, but it is certainly not enough. In our example the evidential value turns out to be equal to 99 (the exact calculation will be described later in section [Bayes's Rule](#)), and implies that a positive test result is 99 times more likely if a person has a breath alcohol concentration above the limit, than when it is below the limit. In other words, one could say that the positive test result supports the hypothesis that the breath alcohol concentration above the limit compared to the hypothesis that it is below the limit.

To illustrate the fact that the evidential value is not enough for estimating the probability that a random driver with a positive result indeed has a breath alcohol concentration above the limit, have a look at the data presented in [Table 6.1](#). [Table 6.1](#) presents two hypothetical

**Table 6.1**

Breath analyses in two populations with, respectively, 1% and 15% drunk driving

Sample 1	Positive result (+)	Negative result (-)	Total	Sample 2	Positive result (+)	Negative result (-)	Total
<i>ndd</i>	99	9,801	9,900	<i>ndd</i>	85	8,415	8,500
<i>dd</i>	99	1	100	<i>dd</i>	1,485	15	1,500
Total	198	9,802	10,000	Total	1,570	8,430	10,000

situations in which the breath test has been applied to test random samples of 10,000 persons from two populations. The first sample is an exact representation of a population in which 1% of the drivers are drunk-driving (*dd*) and 99% are not drunk-driving (*ndd*), and the second sample of a population in which 15% of the drivers are drunk-driving. The breath analysis test that has been applied has the properties mentioned above, and gives a positive result (+) or a negative result (-).

For the first sample, it is relatively easy to calculate that 99 persons will obtain an incorrect positive result (1% of 9,900), and that an equal 99 persons will obtain a correct positive result (99% of 100). So, for all 198 persons obtaining a positive test result, 99 are correct. The probability of drunk-driving given a positive test result is thus estimated as  $Pr_{\text{sample1}}(dd|+)$  = 99/198 = 0.50. For the second sample, on the other hand, 85 persons will obtain an incorrect positive result (1% of 8,500), and that 1,485 persons will obtain a correct positive result (99% of 1,500). So, for all 1,570 persons obtaining a positive test result, 1,485 are correct. The probability of drunk-driving given a positive test result is thus estimated as  $Pr_{\text{sample2}}(dd|+)$  = 1,485/1,570 = 0.95.

Thus, we cannot provide an estimate of the probability solely based on the properties of the breath analysis test [i.e.,  $Pr(+ | dd)$  = 0.99 and  $Pr(+ | ndd)$  = 0.01]. We need information on the prevalence of drunk-driving in the relevant population. The lower the prevalence, the lower the probability of drunk-driving given a positive test result [ $Pr(dd|+)$ ]. If we do base the estimate of the relevant probability solely on the properties of the breath analysis test, the obvious estimate will be equal to  $Pr(dd|+)$  = 99%, based on the fact that the test is correct in 99% of the cases. We would, however, then implicitly assume that the prevalence of drunk-driving is 50%. In other words, one out of every two drivers is drunk-driving. Both situations (i.e., “very low probability of drunk-driving” and “equal prevalence”) are illustrated in **Table 6.2**. Sample 3 comes from a population with 0.1% drunk-driving, and Sample 4 comes from a population with 50% drunk-driving. It is, again, relatively easy to see that the probability of drunk-driving, given a positive test result is equal to  $Pr_{\text{sample3}}(dd|+)$  = 99/1,098 ≈ 0.09 in Sample 3, and equal to  $Pr_{\text{sample4}}(dd|+)$  = 4,950/5,000 = 0.99 in sample 4.

What we have tried to make clear with this simple example, using a breath analysis test and population data, is that the probability of drunk-driving for a certain person depends on more than just the test result. The same test result may result in different probabilities that the person was in fact drunk-driving.

So, how does all this relate to forensic evidence interpretation? Well, imagine a case where a trace is compared to a possible source, for example, a fiber is compared to a suspect’s sweater. The answer to the question “How probable is it that the trace originated from this particular source?” cannot be provided by the forensic expert, since the expert will not be aware of all

**Table 6.2****Breath analyses in two populations with, respectively, 0.1% and 50% drunk driving**

Sample 3	Positive result (+)	Negative result (-)	Total	Sample 4	Positive result (+)	Negative result (-)	Total
<i>ndd</i>	999	98,901	99,900	<i>ndd</i>	50	4,950	5,000
<i>dd</i>	99	1	100	<i>dd</i>	4,950	50	5,000
Total	1,098	98,902	10,0000	Total	5,000	5,000	10,000

relevant information in the case. What the forensic expert can provide is an estimate of the evidential value based on estimates of the probabilities of the evidence given at least two hypotheses: quantities that are comparable to  $Pr(+ | dd)$  and  $Pr(+ | ndd)$ . They need to be combined by the legal decision maker with other evidence in the case.

The truth of the fact is that statistics and probability theory is not the most favorite topic of the average lawyer, although the tide is turning (Robertson and Vignaux 1995; Kaye 2010). Journals like “Jurimetrics” and “Law, probability and risk,” books (Aitken and Taroni 2004; Buckleton et al. 2005; Saks and Koehler 2005; Finkelstein and Levin 1990; Gastwirth 2000; Redmayne 2001) and conferences (e.g., International Conference on Forensic Inference Statistics, see <http://www2.unil.ch/icfis/>) try to fill the gap between the legal decision maker (i.e., the lawyers) and (forensic) statisticians. Forensic statistics is a broad field of expertise, ranging from applications of data analysis methods to determine, for example, sample sizes, to the development of methods for the evaluation and interpretation of forensic evidence.

The quantitative nature of DNA evidence stimulated these developments. The so-called Likelihood Ratio approach (LR approach) for the interpretation of evidence has proven very successful for DNA evidence, and can be regarded as a bridge between statistics and criminal law. The LR approach provides a measure of the evidential value, and explicitly defines the roles of the expert and the legal decision maker. At present this approach is actually being applied in the interpretation of DNA evidence, automatic speaker recognition, and speed calculations for colliding cars, where quantitative evidence is often available. It is expected that, eventually, for other forensic evidence such as fingerprints, glass, and comparative studies like handwriting and signature analysis such explicit calculations will be possible. We will later see that the LR method can be useful for assessing evidential value, even if numbers are lacking.

The aim of this chapter is to describe the LR approach for forensic evidence interpretation, and to discuss the main issues that arise in applying the approach in practice. We will start with another illustrative example taken from medical sciences, and subsequently discuss forensic applications. Special issues, such as combination of evidence and the effect of domain-irrelevant context information, will be treated in the last section.

## Interpretation of Forensic Evidence by Means of the Likelihood Ratio

The Likelihood Ratio approach is making strong progress in the forensic sciences as a method to evaluate the value of evidence. This section will discuss the details of this method. But let us first take a look at another illustrative example, this time from the medical sciences.

## An HIV Test

Let us assume that a certain HIV test will always result in a positive result for someone who has been infected with the HIV virus (i.e., a true positive test result). Let us assume, furthermore, that for a small number of subjects who have not been infected, the result will also be “positive” (i.e., a false positive test result). Now, consider Anna taking this specific HIV test, and obtaining a positive test result. The question that we will be investigating is: “What is the probability that Anna is actually infected with HIV, given the fact that she obtained a positive test result?”

The doctor is taken as the expert here, and the expert’s finding is the positive HIV test of Anna. This result (i.e., the positive test) is exactly what is to be expected of the specific test if Anna actually has been infected with HIV. But, on the other hand, if Anna has not been infected with HIV, the test result may also be an example of a rare, but possible, false positive result. Luckily, most of the persons without HIV obtain a negative test result, but some do obtain an incorrect positive test result. Anna could be one of those persons. However, taken altogether, we can state that a positive test result is much more probable if Anna has been infected [ $Pr(+ | hiv) = 1$ ], than when she is not infected [ $Pr(+ | no\ hiv) = \text{small}$ ].

Of course, Anna did undergo the HIV test in order to find out whether or not she has been infected with HIV, so she is interested in the doctors’ diagnosis. The doctor’s diagnosis, obviously, does depend on the test result, but it is not the only relevant piece of information that she uses. There is more information about Anna available to the doctor, and the doctor was already aware of this information before she knew the test result. The fact is that Anna belongs to an HIV risk group, namely, that of drug users who have used contaminated needles. So, even before the test was carried out, the doctor could already estimate the probability of infection to be quite high, and at least much higher than in the case of Anna not belonging to a risk group. This so-called prior probability (i.e., the probability of HIV infection prior to conducting the test) is adjusted upward because of the finding that the test is positive. The result is called the posterior probability, and with respect to Anna, this is the probability Anna has been infected “after” the positive test result is revealed. Two factors should therefore play a role in the diagnosis of the doctor: the prior probability of Anna being infected with HIV, and the test result. Adjusting the prior probability on the basis of new information is expressed mathematically in the LR approach. Since the prior probability differs for different persons, the same test result may lead to different diagnoses for different persons (i.e., a different posterior probability).

Does this make sense? Yes it does! In general, if a number of hypotheses may explain the same observation, the probability that one of these hypotheses actually is true is not only determined by the fact that the result indeed has been observed. The prior probability of the hypotheses plays a role too. The positive test result, in Anna’s case, may be explained by an HIV infection but may also be a false positive. The probability that Anna actually has been infected is not only determined by the fact that the test is positive, but also depends on the risk factors for Anna, or, in other words, on the prior probability that Anna is HIV positive.

The LR approach formalizes this line of reasoning. Anna’s risk factors affect the probability she has been infected with HIV even before she has been tested. This prior probability may be high or low, but will be adjusted upward if the test turns out to be positive. How this actually works can be described by means of a relatively simple, but extremely important, mathematical formula: Bayes’ rule. Bayes’ rule may be of aid in many decision problems like those encountered in medicine, as well as forensics.

## Bayes' Rule

The Likelihood Ratio approach is a direct application of the well-known *Bayes' rule*. Bayes' rule (or Bayes' theorem) was developed in the eighteenth century by the English clergyman Reverend Thomas Bayes (Bayes and Price 1763). The variant we will be using considers the ratio of the probabilities of two hypotheses (i.e., the odds). If the ratio is, for instance, equal to ten to one (i.e., 10:1), the first hypothesis is ten times as probable as the second hypothesis. This ratio of probabilities of the hypotheses can be considered before certain findings (i.e., the evidence) are taken into account (prior odds) and after they have become known (posterior odds). Bayes' rule shows how, in this context, the ratio of the probabilities changes due to the findings:

Prior odds  $\times$  Likelihood Ratio = Posterior odds

in term of probabilities:

For ease of notation explicit mentioning of the background information  $I$  is omitted here (cf. Aitken and Taroni 2004). This information is assumed known in all probabilities.

In order to illustrate the use of Bayes' rule, let us use the breath analysis test data from Sample 4 described in the introduction. We concluded that, in this case, the probability of drunk-driving ( $dd$ ) given a positive test was equal to  $Pr_{\text{sample4}}(dd|+) = 0.99$ . The calculation of this probability can also be obtained by using Bayes' rule.

We define:

- Hypothesis 1: The driver was drunk-driving ( $dd$ )
  - Hypothesis 2: The driver was not drunk-driving ( $ndd$ )
  - Evidence: The driver has a positive result on the breath analysis test (+)

and we assume (corresponding to Sample 4 in [Table 6.2](#))

- $Pr_{\text{sample4}}(dd) = 0.5$
  - $Pr_{\text{sample4}}(ndd) = 0.5$
  - $Pr_{\text{sample4}}(+ | dd) = 0.99$
  - $Pr_{\text{sample4}}(+ | ndd) = 0.01$

The prior odds of Hypothesis 1 versus Hypothesis 2 are thus equal to Prior odds<sub>sample4</sub> = 0.5/0.5 = 1, and the LR is equal to 0.99/0.01 = 99, resulting in Posterior odds<sub>sample4</sub> = 1 × 99 = 99. So the odds of drunk-driving versus not drunk-driving, after a positive test result, are equal to 99:1 which corresponds to  $Pr_{\text{sample4}}(dd|+) = 99/(99 + 1) = 0.99$ .

With this in mind, it is easy to show what the posterior probability will be if we take different prior odds, for instance those of Sample 1. Prior odds<sub>sample1</sub> = 0.01/0.99 ≈ 0.0101, resulting in Posterior odds<sub>sample1</sub> = 0.0101 × 99 ≈ 1. So the odds of drunk-driving versus not drunk-driving, after a positive test result are equal to 1:1 which corresponds to the  $Pr_{\text{sample1}}(dd|+)$  = 1/(1 + 1) = 0.5 that we saw in the introduction. Again this illustrates that the same test result may lead to different posterior probabilities for different persons.

In the next section we argue that the forensic expert should report the LR (i.e., the evidential value), and that she should not report on the posterior probability. Let us focus on an example taken from forensic sciences: matching DNA profiles.

## A DNA Match

---

A trace containing DNA is found at the scene of a crime, which may belong to the offender. In order to facilitate calculation, this example will assume the DNA material to be of very poor quality, such that only a small part of the DNA profile can be visualized. This partial profile shows, among other things, that it concerns a man. The forensic DNA expert concludes that the suspect's DNA profile matches the partial profile from the crime scene trace. She determines that the probability that a randomly selected other man, unrelated to the suspect, will match the partial DNA profile found at the scene of crime [i.e., the “*random match probability*”] is equal to 0.001 (i.e., 0.1%). How probable is it that the DNA found at the crime scene originates from the suspect? Just as was the case in the breath analysis and HIV example above, the DNA expert cannot give a direct answer to this question. What the DNA expert will do is “translate” this question into two mutually exclusive, not necessarily exhaustive, hypotheses:

- Hypothesis 1: The suspect is the donor of the DNA material.
- Hypothesis 2: An unknown man, unrelated to the suspect, is the donor of the DNA material.

Subsequently, the expert will compute the Likelihood Ratio, defined as the ratio of the probability of a match given that the suspect is the donor of the DNA material (Hypothesis 1) versus the probability of a match given that an unknown man, unrelated to the suspect, is the donor of the DNA material. Based on the assumption that no mistakes have been made in the chain of custody from finding the trace up to reporting of the DNA match, the scientist will reason as follows:

- If the suspect is the donor of the trace, their profiles will match. The probability of the finding of the DNA analysis is therefore equal to 1 if Hypothesis 1 is true [i.e.,  $Pr(\text{match}|\text{suspect is donor}) = 1$ ].
- If an unknown other man is the donor of the DNA material, it would be fairly coincidental that this material matches the suspect's profile. The chances of this occurring are 1 in 1,000. The probability of the finding of the DNA analysis is therefore 0.001 if hypothesis 2 is true [ $Pr(\text{match}|\text{unkown man is donor}) = 0.001$ ].

The ratio of the probability of the findings given the two hypotheses (i.e., the LR) is therefore  $Pr(\text{match}|\text{suspect is donor})/Pr(\text{match}|\text{unkown man is donor}) = 1/0.001 = 1,000$ . In this simple example, it is clear that the LR is thus equal to 1/random match probability. This LR implies that the match is 1,000 times more likely if Hypothesis 1 is true than if Hypothesis 2 is true. The results (i.e., the match between the suspects DNA profile and the DNA profile of the crime scene trace) are thus much better explained by Hypothesis 1, than by Hypothesis 2. In other words, the result offers more support for the first hypothesis than for the second.

## How Likely Is It That the Suspect Is the Donor of the DNA Material Found at the Scene of Crime?

The issue is again that the answer depends, as it did in the HIV example, not just on the results of the DNA analysis, but also on the prior odds of the hypotheses. Or, in terms of Bayes' rule, the answer depends on the LR as well as the prior odds. The LR is determined by the rarity of the DNA profile, expressed in the random match probability. The prior odds are determined on the basis of other information in the case; this could be tactical information, or other forensic evidence. For example, suppose a crime took place aboard a container ship at full sea, and only ten other men can be the donor of the DNA in the trace. Moreover, assume all these men to equally qualify as donors of the DNA trace, but the only DNA profile available is that of the suspect. In this case, the odds in favor of the suspect being the donor before the DNA analysis is taken into consideration are 1 to 10. The prior odds of Hypothesis 1 versus 2 are therefore  $0.1$ . Bayes' rule ( $\text{prior odds} \times \text{LR} = \text{posterior odds}$ ) shows that the posterior odds are equal to  $0.1 \times 1,000 = 100$ . This means that, after the DNA analysis is taken into consideration, the odds are 100 to 1 in favor of the suspect being the donor of the trace material and not one of the other members of the crew. ➤ *Table 6.3* illustrates how the probability that the DNA belongs to the suspect depends on both the rarity of the DNA profile and the number of men aboard the ship, or, in other words, on both the LR and the prior odds. From this table it may be inferred that the rarer the DNA profile, the larger the LR, and, consequently, the stronger the DNA evidence against the suspect. Also, the fewer men aboard the ship, the larger the prior odds, and hence the larger the posterior odds.

In the HIV example, the doctor can make a statement on the posterior odds of HIV infection, because she has specialist knowledge on both the prior odds and the LR. The DNA

■ **Table 6.3**

**The table illustrates the effect of the DNA match on the odds of Hypothesis 1: “The suspect is the donor of the DNA material” versus Hypothesis 2: “One of the other men aboard the ship is the donor of the DNA material.” We consider four different prior odds, corresponding to, respectively, 1, 10, 100, and 1,000 other crewmembers. The final column is calculated from the posterior odds. The random match probability of the DNA profile of the trace is 1 in 1,000 versus 1 in 1 billion, corresponding to LRs of 1,000 and 1 billion**

Random match probability	LR	Prior odds	Posterior odds	Probability suspect is donor
1 in 1,000	1,000	1:1	1,000:1	0.999
		1:10	100:1	0.99
		1:100	10:1	0.909
		1:1,000	1:1	0.5
1 in 1,000,000,000	1,000,000,000	1:1	1,000,000,000:1	0.999999999
		1:10	100,000,000:1	0.99999999
		1:100	10,000,000:1	0.9999999
		1:1,000	1,000,000:1	0.999999

expert, on the other hand, only has specialist knowledge of the relative frequency of the DNA profile, i.e., of the LR. The DNA expert will usually not have specialist knowledge or a complete overview of the other information of the case, which determines the posterior odds. She will not wish to express an opinion in this respect. This means, in line with the previous examples, but in sharp contrast to common understanding, that a DNA expert does not calculate the probability that the trace originates from the suspect (or from someone other than the suspect). This posterior probability, as we have seen, depends on the prior odds. The DNA expert limits herself to a conclusion about the LR. As the LR is in the present case equal to 1/random match probability, she will, in practice, only report this probability.

## Fallacies

---

Suppose that the DNA profile of a suspect, Peter, matches with the partial DNA profile of a bloodstain found at a crime scene. The donor of the trace must be a man, and the random match probability equals 1 in 1,000. The prosecutor argues as follows:

- 1p The probability that a randomly chosen man matches this profile is 1 in 1,000.
- 2p The probability that someone else is the donor of the bloodstain is thus 1 in 1,000.
- 3p The probability that Peter made the bloodstain is thus close to 1 (i.e., 99.9%).

The lawyer in this case, on the other side, walks a different route and reasons:

- 1l Approximately 8 million men live in the Netherlands.
- 2l There are about 8,000 other men that match the partial DNA profile.
- 3l In a total of 8,001 men with this DNA profile, including Peter, the probability that Peter made the bloodstain is thus 1/8,001 (i.e., 0.012%).
- 4l The evidential value of the match is very small.

Who is right? Unfortunately neither of them, because both fell prey to notorious fallacies! The prosecutor made a fallacy that has been termed the prosecutor's fallacy (Thompson and Schuman 1987). The fallacious argument here is that the probability under Argument 1p is definitely not the same as the probability under Argument 2p. Argument 1p refers to the frequency of the partial profile in the relevant population of men (i.e.,  $P(\text{match}|\text{randomly chosen man is the donor})$ ), while Argument 2p is about the probability that the bloodstain is not Peter's, given the match (i.e.,  $P(\text{randomly chosen man is the donor}|\text{match})$ ). As we saw in the example of section ➤ A DNA Match this last probability is a posterior probability that not only depends on the frequency of the partial profile in the population but also on the prior probability that Peter is the donor of the bloodstain. The probability under Argument 2p cannot be based on just the random match probability.

The lawyer in the DNA case fell prey to a fallacy in the literature known as the defense attorney's fallacy (Thompson and Schuman 1987). Here the fallacious argument is that the matching partial DNA profile is of little value. The reasoning is however based on some implicit assumption. First, the defense lawyer assumes that the offender must be among the population of Dutch men, which is obviously a fairly arbitrary assumption about the group of potential offenders. Second, he assumes that each person within this population has an equal probability of being the offender. All men are equally likely the offender, regardless of their age, location, or

health. However, while these assumptions may be true, it is definitely fallacious to conclude that the evidence is of little value. Because, no matter how large the population of possible offenders, this population is decreased in number with a factor of 1,000 due to the matching DNA profile.

## Non-DNA Forensic Evidence

---

With its roots in DNA evidence the usefulness of the LR approach is fortunately not limited to this type of evidence. In general, the LR approach has been, and is, frequently applied for all types of forensic evidence where there is some kind of uncertainty affecting interpretation, such as shoe marks, fingerprints, signatures, bullets, and photographs. As was the case for DNA evidence, the experts start with a translation of the main question into a set of (at least) two mutually exclusive hypotheses. Ideally these hypotheses are given to the expert by the legal decision maker, prosecution or defense lawyer, or they follow seamlessly from the information provided in the case. Sometimes the specific hypotheses are the result of extensive communication between the lawyer and expert. While the forensic investigations are led by these hypotheses, the important point to consider is that each of these hypotheses already has some probability of being true attached to it, as per the previous examples. The ratio of these probabilities defines the prior odds of the hypotheses. It is based on other evidence and tactical information in the case, for instance, information that the suspect had a financial dispute with the victim. Thus, an estimate of this ratio falls outside the field of expertise of the forensic expert that is investigating the new forensic piece of evidence. What the forensic expert can do is to provide estimates of the probabilities of the evidence given each of the relevant hypotheses, just like for DNA evidence. The shoe print examiner, for instance, in seeing a match on a special feature between the footprint at a crime scene and a shoe of a suspect, could give his subjective estimate of the probability of finding this specific feature if a shoe, other than that from the suspect made the trace.

It is the task of the forensic expert to give her conclusion on the LR, that is, her conclusion on the ratio of probabilities of the evidence, given the hypotheses. Based on all the other evidence and information in the case, the legal decision maker could make an estimate of the prior odds of the hypotheses, and could subsequently use the LR provided by the expert to update the prior odds. As an example, if the evidence is equally probable to be obtained under both hypotheses the LR will have a value of 1. Multiplication of the prior odds by this LR does not affect the size of the prior odds. This is what we would call “neutral evidence,” and the posterior odds of the hypotheses will be equal to the prior odds of the hypotheses. Neutral evidence thus offers no support for either hypothesis. If, on the other hand, the evidence is much more probable given Hypothesis 1, than given Hypothesis 2, the LR will be much larger than 1. That is, if

$$Pr(\text{evidence}|\text{hypothesis 1}) > Pr(\text{evidence}|\text{hypothesis 2}),$$

than  $LR > 1$  and this would thus be evidence supporting Hypothesis 1 with respect to Hypothesis 2. The prior odds will consequently be multiplied by a number much larger than one, resulting in posterior odds that are much larger than the prior odds. The opposite is also true when the LR is much smaller than 1. The evidence would then be supporting Hypothesis 2.

So, in summary, the LR method takes the LR as a measure of evidential strength with respect to the hypotheses. The role of the forensic expert is limited to reporting the evidential strength to the legal decision maker. It is the role of the latter to assess the probabilities of the hypotheses, by updating her prior beliefs about the odds using the expert's LR. Hence, assessments of the probability of guilt, but also of the probability of forensic hypotheses such as the probability that a trace originated from a particular source, are made by the legal profession, not by the expert. Moreover, any decisions based on these assessments are outside the province of the forensic expert. Thus from a decision perspective, the forensic expert has a very different role than many other experts, like for instance a doctor.

## Nonnumerical Likelihood Ratios

---

In some fields the forensic scientist can actually compute LR based on hard data and a statistical model. The best example is forensic DNA analysis, but other fields are developing toward numerical LRs (e.g., fingerprint analyses, glass analysis). Many fields of expertise exist, however, where numerical LRs cannot yet, if ever, be computed because the relevant data are lacking, and the forensic expert cannot numerically compute the probabilities. The forensic expert provides a more or less subjective estimate of the probabilities based on her knowledge, expertise, and experience in the field. This estimate may be partially dependent on some data, and generally it will not be very precise. To distinguish between a LR based on solid data and statistics, and a LR based on subjective opinion, many forensic laboratories use a set of verbal qualifiers to report the latter LR. Assume, again, for example, that a forensic shoe print examiner compares a shoe mark found at the scene of a crime with the shoe of a suspect. The expert will, in such cases, consider at least two hypotheses, for example:

- Hypothesis 1: The suspect's shoe made the mark.
- Hypothesis 2: Another shoe with a similar sole pattern and size made the mark.

The similarities and differences identified between the shoe of the suspect and the shoe mark found at the crime scene constitute the evidence. The shoe print examiner will be able to (subjectively) estimate the probability of evidence, given that the suspect's shoe made the mark and given that another shoe with a similar sole pattern and size made the mark. The term probability is used in this context as a criterion for the extent to which the findings are "striking" or "fit" the hypotheses. If the evidence is more in line with Hypothesis 1 than with Hypothesis 2, it constitutes evidence in support of Hypothesis 1. A striking similarity, such as a long cut in the shoe sole whose shape and position correspond with a "line" in the shoe mark will be more in line with Hypothesis 1 than Hypothesis 2. The better the findings fit with Hypothesis 1 relative to Hypothesis 2, the stronger the evidence will be. In the interpretation of her findings, the scientist will therefore establish how probable it would be to observe the findings if Hypothesis 1 is true, and when Hypothesis 2 is true. In such cases, she could conclude, for example, that:

- "The findings of the investigation are much more probable if the mark was made by the shoe of the suspect than if the mark was made by another shoe with a similar sole pattern and size."

It may also be the case that the findings are more probable in the event that the second hypothesis is true, for example if the shoe was secured immediately after the crime was

committed, but the long cut cannot be “found” in the shoe mark. The evidence is then supporting Hypotheses 2. For example:

- ▶ “The findings of the investigation are much more probable if another shoe with a similar sole pattern and size made the mark than if the shoe of the suspect made the mark.”

Another example is a case in which a forensic biometrical expert examines some vague CCTV images of a person robbing a bank. The observed similarities and differences of certain biometrical features of the body and the face between a suspect and the images of the perpetrator are taken here as the evidence. The relevant hypotheses may be:

- Hypothesis 1: The suspect is the perpetrator.
- Hypothesis 2: Another person, not related to the suspect, is the perpetrator.

The expert subsequently compares the probability of the evidence (i.e., the observed similarities and differences) under the two hypotheses and concludes, for instance, “the evidence is much more probable if Hypothesis 1 is true than if Hypothesis 2 is true,” or, in other words, “the evidence is much more probable if the suspect is the perpetrator, than if another person, not related to the suspect, is the perpetrator.” This constitutes a verbal approach to conclude that the numerator of the LR is much larger than the denominator of the LR, and implies that the LR is very large. The expert bases her conclusion only partly on numerical data, because the data available may be a very small, not representative set of the relevant population. If the expert observes a butterfly tattoo on the right cheek of both the perpetrator and the suspect, for instance, she may give a subjective estimate of the rareness of this feature, without being able to give a numerical estimate (e.g., 1 out of every 50,000 adult men has a butterfly-like tattoo on the right cheek). This last estimate would require a population study of tattoos.

It is very important to note that the conclusion (A) “the evidence is much more probable if Hypothesis 1 is true than if Hypothesis 2 is true” does not imply conclusion (B) that it is very probable that Hypothesis 1 is true, or any other probability statement about hypotheses since this would also require prior probabilities. The prior probabilities are not part of conclusion (A). Whatever the prior odds are, conclusion (A) implies that the posterior odds will be higher than the prior odds.

Interpretation of such verbal conclusions appears to be quite difficult, and the forensic service providers using the LR approach spend much time and effort teaching and explanation such conclusions. There is, however, quite a broad consensus among forensic scientists that the LR approach is the preferred approach for presenting forensic evidential strength, and that posterior odds and posterior probabilities are outside the province of the expert. This consensus has not yet been reached among legal practitioners, as illustrated by several UK cases (*R v Doheny and Adams [1997] 1 Crim App R 369*, and recent cases like *R v T [2010]*). The fact that verbal LRs are difficult to interpret should, however, not be so surprising. People just have great difficulties in interpreting (ratios of) conditional probabilities, and this is possibly worsened if (ratios of) conditional probabilities are expressed verbally. Beyond that, much has been written on the statistical and mathematical skills of the legal decision maker, which hardly have had any education in statistics during their education.

So, it may not be clearly defined what exactly is the definition of a verbal conclusion, and these definitions may not be constant for all fields of expertise. Some authors have argued for using some sort of numerical scale corresponding to the verbal conclusions

(see Lucy 2005; Evet 1998). Forensic laboratories in Ireland and the UK use such a scale (AFSP 2009). Sensitivity tables, such as presented by Robertson and Vignaux (1995), that show the effect of a certain LR on various values of the prior odds could also aid in interpretation.

## Numerical Likelihood Ratios Based on Continuous Data

Up till now we have only considered nonnumerical LRs, as well as numerical LRs data based on discrete data, for which we could compute the probabilities. However, quite often evidence is obtained from measurements on continuous data. For instance, suppose that we are comparing glass fragments. One glass fragment is found in the clothes of a person suspected of smashing a window and subsequent burglary. The other six fragments are reference samples taken from the broken window by the police. Suppose that we are comparing the refractive index of these fragments to the refractive index of the glass fragment found in the clothes. If we measure each fragment once, we are then comparing six measurements of the reference samples to a single measurement of the fragment found in the clothes, on a continuous scale.

The form in which the evidential value is determined for continuous data is similar to that for discrete data (Aitken and Taroni 2004). Since continuous measurements are being considered of both the crime scene material and the suspect material, respectively  $y$  and  $x$ , the probabilities of the evidence given the relevant hypotheses are replaced by probability density functions  $f$ . In the glass example,  $y$  is a vector of six measurements, and  $x$  is a single number. The LR now becomes, in general,

$$\frac{f(\text{evidence}|\text{Hypothesis 1})}{f(\text{evidence}|\text{Hypothesis 2})} = \frac{f(x, y|\text{Hypothesis 1})}{f(x, y|\text{Hypothesis 2})}$$

which is after mathematical simplification (not presented here), and assumption of independence of  $x$  and  $y$  given Hypothesis 2 (so-called conditional independence assumption), equal to

$$\frac{f(y|x, \text{Hypothesis 1})}{f(y|\text{Hypothesis 2})}.$$

The numerator of this LR is a so-called predictive distribution that considers the distribution of the crime scene measurements, conditional on Hypothesis 1 being true and the measurements on the suspect material. The denominator is a marginal distribution, which considers the distribution of the measurements on the crime scene material conditional on Hypothesis 2. In evaluating such a LR two sources of variation need to be considered, the within source variation (the numerator), and the between source variation (the denominator). With respect to the glass fragment, in the numerator it is considered how well the refractive index of the fragment fits within that of the window. Inhomogeneity of the refractive index within the glass window and measurement uncertainty play a role. In the denominator, it is considered how well the refractive index of the fragment fits other possible sources of the fragment. The rarity of the refractive index of the fragment plays an important role. Instead of a ratio of two probabilities, the LR now consists of a ratio of two probability densities. We refer to Aitken and Taroni (2004) for a detailed introduction to the appropriate approaches for Likelihood Ratios for continuous data, univariate as well as multivariate. Multivariate observations result for instance from analyzing the elemental composition of the glass.

## Special Issues

---

### The Prior Odds

---

The Likelihood Ratio approach can be thought of as a sequential information processing system for determining the probabilities of the corresponding hypotheses. The ratio of these probabilities, the odds, changes each time a piece of information is added, as specified by Bayes' rule. The prior odds, based on the tactical information and other evidence in the case, are multiplied by the LR of the evidence under consideration. If, subsequently, a new piece of evidence is evaluated, the "old" posterior odds become the new prior odds. This process is called updating, and goes on until all evidence has been evaluated. With every piece of evidence we consider the odds of the hypotheses before processing this information (the prior odds), and after (the posterior odds). The posterior odds after the first piece of evidence become the prior odds of the next piece of evidence. This process requires that the hypotheses that are considered for each piece of evidence are exactly the same. It is important to note that "true" prior odds do not exist, because they depend on which evidence is evaluated first. Similarly, the posterior odds and the LR itself are relative terms: They depend on the information assumed to be known at the time of information processing. The information may include legal evidence, but also more general, tactical, information such as the location of the crime.

In practice it is usually impossible for the legal decision maker to determine the prior odds precisely. However a rough distinction between large and small may well be possible. Consider, for example, a case concerning a suspect gun, where the question is whether a bullet from the crime scene was shot with this gun, or with another firearm. The hypotheses could be formulated as:

- Hypothesis 1: The bullet was shot with the suspect's gun.
- Hypothesis 2: The bullet was shot with another firearm.

It will be clear that the prior odds of Hypothesis 1 versus 2 are much larger in the situation that gun and bullet are both found on the crime scene, than when the bullet is found at the crime scene, and the gun in a safe deposit on the other side of the world. It has been argued that the Bayesian framework for interpreting evidence is useless because the starting point, the prior odds, is unclear. It is certainly true that it is difficult to deal with this if one actually wants to use the framework for calculations. However, one can turn the argument around and argue that legal decision making is a difficult process by nature. The Bayesian framework makes problems such as the existence of prior odds transparent. It is important to realize that using another reasoning framework cannot make the problem disappear. When one is interested in the posterior odds, like a legal decision maker, dealing with prior odds cannot be avoided. That the Bayesian framework makes this problem visible is an advantage, not a disadvantage. Hence, dealing with prior odds is a problem that is inherent to legal decision making, and any framework of reasoning that does not make this clear is useless.

### Choosing the Hypotheses

---

A hypothesis can be seen as a possible scenario that offers an explanation of a given event in a criminal lawsuit. As will have become clear from the above, the hypotheses play a crucial role

in the determination of the evidential value of the evidence under consideration, and the explicit formulation of the hypotheses is critical. Since the task of the expert is to provide (an estimate) of the probability of the evidence given the hypotheses, small changes in the formulation of the hypotheses will result in different LRs and consequently in a different evidential value. Often, especially in the more complex cases, hypotheses are determined through extensive interaction between the expert(s) and the legal decision maker. Given the fact that in the majority of cases at least one of the hypotheses reflects the scenario that is in favor of the suspect(s), the suspect and his defense lawyer should play a role here. The legal decision maker is aware of all information in the case, and did come, in the first place, with a specific question to the expert. The expert on the other hand is aware of all relevant scientific issues that need to be taken into account in formulating the hypotheses. In order to review the most relevant issues in formulating hypotheses, we will now discuss the hypotheses for the examples from prior sections (i.e., DNA and the shoe print).

Let us start with the simple example concerning a small biological trace where the forensic DNA expert found the suspect's DNA profile to match the partial profile from the crime scene. In such DNA cases the hypotheses are often straightforward, though this need not always be the case. The hypotheses we have formulated before are on the so-called source level. Source-level hypotheses give possible explanations to the corresponding evidence by stating who, or what, the source is of the trace that has been found. In this case the first hypothesis is easy to formulate since one of the questions the legal decision maker wants to answer is whether the suspect is the donor of the trace; therefore, the first hypothesis will be:

- Hypothesis 1s: The suspect is the donor of the DNA material.

The second hypothesis then provides an alternative explanation on the source level that is not accounted for by the first hypothesis. Since the trace did contain gender information, this is included in the alternative hypothesis that is formulated as:

- Hypothesis 2s: An unknown man, unrelated to the suspect, is the donor of the DNA material.

So, if the suspect is not the donor of the trace, it must have been another man, unrelated to the suspect, who left the trace. These hypotheses thus only provide information as to who is the donor of the crime scene trace. If the question was not about the source of the trace but whether some activity led to the trace the hypotheses may be formulated as, for instance:

- Hypothesis 1a: The suspect has been in close physical contact with the victim.
- Hypothesis 2a: The suspect has never been near the victim.

And, if the question was about the offense itself, the hypotheses may be:

- Hypothesis 1o: The suspect physically abused the victim.
- Hypothesis 2o: An unknown man, unrelated to the suspect, physically abused the victim.

Hypotheses can thus be formulated at different broad levels, the so-called hierarchy of propositions (Cook et al. 1998). The first level is the source level (s), the second level is the activity level (a), and the third level is offense level (o). As we climb higher on the hierarchy, the hypotheses more closely reflect the offense that is considered by the legal decision maker, and more factors come into play. On the source level of the DNA case the forensic expert will determine the random match probability of the crime scene trace in the relevant population.

At this level he may also consider issues like relatedness or laboratory errors. However, the fact that somebody is the donor of a trace does not necessarily imply that he or she performed some specific kind of activity, or crime. The trace may be there as a consequence of numerous types of activities, many of them being unrelated to the crime. Besides requiring measurement, observation, and analysis of information about the occurrence of the evidence in the relevant population, hypotheses on the activity level require judgments on how the trace ended up at the crime scene. In general, hypotheses on the activity level require more information than hypotheses on the source level. Usually the activity level requires estimates of the probability that traces are transferred during the activities considered. Moreover, estimates are required of the probability that these traces persist on the receptor and subsequently recovered by the police or forensic examiner. The resulting LR analysis usually becomes intractable when all this information is incorporated. Bayesian networks have been proposed for analyzing such complex structures (Taroni et al. 2006).

Often many hypotheses can be formulated in a given case. In forensic DNA comparison of a mixed DNA profile from a crime scene with the DNA profiles from two suspects A and B, for instance, possible hypotheses could be:

- The DNA mixture consists of DNA from A and B.
- The DNA mixture consists of DNA from A and an unknown person unrelated to A or B.
- The DNA mixture consists of DNA from B and an unknown person unrelated to A or B.
- The DNA mixture consists of DNA from two unknown persons not related to A or B.
- The DNA mixture consists of DNA from A and the brother of B.

Because it is often impossible to consider all hypotheses that could make sense in a specific case, and a large number of such hypotheses lead to an illegible report, the expert limits the number of hypotheses, and usually chooses just two hypotheses. The exact formulation of hypotheses is important, and subtle differences in wording can have a major effect on the resulting LR. Another restriction is that scientific hypotheses should be mutually exclusive, which implies that if one of the hypotheses is correct, the other(s) should be incorrect. They need not be exhaustive (contrary to what is stated in AFSP 2009). Finally, legal constraints prevent the use of hypotheses regarding the guilt of the suspect. In summary, the hypotheses should be formulated according to the following rules:

- At least two hypotheses should be considered.
- Each hypothesis needs to be relevant for at least one of the parties involved.
- The LR depends on the exact formulation of hypotheses.
- The hypotheses are mutually exclusive, but not necessarily exhaustive.
- The hypotheses do not explicitly consider the guilt of the suspect.
- Careful consideration should be made regarding the alternative hypothesis, since it explicitly defines the relevant population (cf. the “reference class problem,” Colyvan and Regan 2007).

## Combining Evidence

In the beginning of this section, the Likelihood Ratio approach was described as a sequential information processing system in which the prior odds can be combined with multiple pieces of evidence. Combining evidence is indeed an important aspect of the Likelihood Ratio

approach. The Likelihood Ratio enables the combined evaluation of multiple pieces of evidence in an intuitive and simple way. It is helpful to split the discussion of combining evidence into two factors: (1) conditionally independent versus dependent evidence and (2) same hypotheses versus different hypotheses. For the ease of presentation, we will focus on the combination of two pieces of evidence,  $E_1$  and  $E_2$ , but extension to multiple pieces of evidence is straightforward.

The easiest way of combining evidence is when the hypotheses are the same and the evidence is conditionally independent. This is, for example, the case if a DNA profile is obtained from a finger mark, and the evidence is a matching DNA profile ( $E_1$ ), and a matching fingerprint ( $E_2$ ) with hypotheses:

- $H_1$ : The suspect is the donor of the fingerprint.
- $H_2$ : An unknown man, unrelated to the suspect, is the donor of the fingerprint.

Since knowing a person's DNA profile used for forensics purposes does not tell us much about his fingerprint, we may treat them as independent pieces of information. If we make the crucial assumption that the DNA and the fingerprint are from the same donor, the subsequent LR is simply the product of the two separate LRs:

$$LR_{E_1, E_2} = \frac{P(E_1, E_2 | H_1)}{P(E_1, E_2 | H_2)} = \frac{P(E_1 | H_1)}{P(E_1 | H_2)} \times \frac{P(E_2 | H_1)}{P(E_2 | H_2)} = LR_{E_1} \cdot LR_{E_2}$$

If the evidence is not (conditionally) independent the LR becomes more complicated:

$$LR_{E_1, E_2} = \frac{P(E_1, E_2 | H_1)}{P(E_1, E_2 | H_2)} = \frac{P(E_1 | H_1)}{P(E_1 | H_2)} \cdot \frac{P(E_2 | E_1, H_1)}{P(E_2 | E_1, H_2)} = LR_{E_1} \cdot LR_{E_2 | E_1}$$

On the other hand, if the evidence is considered to be conditionally independent, but the hypotheses are not the same, the evidence cannot be combined statistically unless one formulates hypotheses on a different level in the hierarchy. If the evidence in a burglary case consists of glass fragments on a hammer of a suspect that match the broken window ( $E_1$ ), and paint fragments on the broken window match the paint of the hammer ( $E_2$ ), the evidence cannot be combined on the source level. Indeed, the hypotheses would then be formulated as:

- $H_{1,E1}$ : The glass fragments originate from the broken window at the crime scene
- $H_{2,E1}$ : The glass fragments originate from another float glass object and
- $H_{1,E2}$ : The paint fragments originate from the suspect's hammer
- $H_{2,E2}$ : The paint fragments originate from another object

However, the evidence can be combined on the activity level that does not only address the source of the fragments, but also the activity that was performed during the crime. In this case hypotheses on the activity level could be formulated as:

- $H_{1a}$ : The hammer of the suspect smashed the crime scene window.
- $H_{2a}$ : Another object smashed the crime scene window.

The evidence (i.e., matching glass and paint fragments) can now be combined, but the resulting LR is a qualitatively different one than on the source level, since it addresses the LR of a different set of hypotheses. However, the activity-level hypotheses may more closely correspond to the level at which the evidence needs to be evaluated in court. In evaluating

evidence on the activity level, it will be clear that more factors come into play and need to be taken into account by the forensic experts (see Aitken and Taroni 2004; Taroni et al. 2006). Bayesian networks are currently viewed as the method of choice to derive the evidential value in these types of cases.

An interesting question from a legal and philosophical perspective may be whether the expert is allowed at all to combine evidence, especially if part of this evidence falls outside his field of expertise. This occurs, for instance, in cases where the pathologist bases his conclusions on the results of the toxicologist. In another case in the Netherlands, for example, involving a man that was accused of injuring a boy by driving over him, a fiber expert, a chemist, and an expert specialized in shape comparison combined their conclusions and jointly signed the report. The defense lawyer in this case raised the question of whether this was allowed. Both the court and the higher court accepted the report, however.

## Uncertainty

---

The likelihood ratios presented above are based on ratios of two probabilities, the values of which are usually estimated using samples taken from the relevant populations. We focus here on discrete data. For continuous data the focus should be on estimation of the probability densities, and the corresponding confidence interval will be more complex. Nevertheless, a natural consequence of sampling is sampling error, which results in the estimates not being exactly equal to their population values. As a consequence, the LR estimated by a forensic expert does contain some uncertainty. The estimated LR is thus more, or less, precise depending on the size of the samples. As described by James Curran regarding DNA evidence

► ...The pertinent question is "how different could the frequencies (i.e., probabilities) be and what effect will this have on the LR?" In order to answer this question it is necessary to try and quantify the uncertainty about the allele frequencies. This uncertainty is often expressed in statistical literature as a confidence interval.... The Bayesian counterparts are the credible interval...Unfortunately, measures of sampling error are not commonly presented in court (Curran 2005, p 116).

Much work needs to be done on modeling, and presenting, uncertainty of LRs for forensic evidence, especially for continuous data. The main issue can be illustrated effectively with the following example. Consider a case in which the police encounter an echo in a questioned audio fragment, and suspects the two callers to be inside the same car while calling, presumably for giving each other an alibi. The police subsequently sent the audio fragment to the forensic laboratory in order to obtain an estimate of the strength of the evidence (i.e., the echo in the audio fragment [E]) concerning the question did caller and receiver share the same vehicle? Together with all parties involved the following set of hypotheses was formulated:

- $H_1$ : Caller and receiver of the phone call were inside the same car.
- $H_2$ : Caller and receiver of the phone call were not inside the same car.

In such a rare case with a considerable lack of relevant data, the forensic expert working on the case could decide to perform an experiment in which audio fragments of phone calls are recorded with exactly the same mobile phone under two conditions. Here, the experiment consists of 41 phone calls recorded under the first condition (i.e., caller and receiver inside the

same car), with the result that in 40 of these calls an echo was present. In the other condition 43 phone calls were recorded (i.e., caller and receiver not inside the same car), and in just one of these calls an echo was present. An obvious estimate of the probability of the presence of an echo under each of the two conditions is obtained by:

$$P(E|H_1) = 40/40 + 1 = 40/41 \approx 0.976$$

$$P(E|H_2) = 1/1 + 42 = 1/43 \approx 0.023$$

One immediately sees that the presence of an echo is much more likely if caller and receiver are inside the same car ( $H_1$ ), than if they are not inside the same car ( $H_2$ ). A straightforward measure of the strength of the evidence is subsequently obtained by the LR, being equal to the ratio of the probabilities of the evidence under the two hypotheses as described above:

$$LR = P(E|H_1)/P(E|H_2) = 0.976/0.023 \approx 42,$$

The probabilities are estimated by means of relatively small sample sizes. Although the estimates of  $P(E|H_1) \approx 0.976$  and  $P(E|H_2) \approx 0.023$  are the current best estimates, the true, but unknown, values of probabilities may be smaller or greater than the obtained estimates due to sampling fluctuation. The true likelihood ratio may consequently be smaller, or greater, than the value of 42. To illustrate the relationship between uncertainty and sample size, one may think of the same probabilities [i.e.,  $P(E|H_1) \approx 0.976$  and  $P(E|H_2) \approx 0.023$ ] being the result of much larger sample sizes, for instance, 4,100 and = 4,300. We intuitively expect (and indeed can prove) that the uncertainty will be smaller.

Assessing the uncertainty in LRs has received quite some attention in the statistical literature (Brown et al. 2001; Dann and Koch 2005; Koopman 1984) and attention in the forensic literature is increasing (e.g., Curran 2005; Curran et al. 2002; Morrison 2010). Several methods have been proposed and, from a statistical perspective, it is not always easy to choose the best approach. The choice should depend, among other things, on the required coverage (and length), on the population proportions, on the obtained sample size, and perhaps on ones preference for a “frequentist” of “Bayesian” estimation procedure. Without going into detail, a 95% (frequentist) confidence interval based on the Score method results, for the results of the experiments mentioned above, in a lower bound of the LR of 8, and an upper bound of 237. A 95% (Bayesian) credible interval using a Jeffrey’s prior results in a lower bound of the LR of 9, and an upper bound of 382.

There has been a fundamental discussion among forensic statisticians about the meaning of uncertainty of the LR. Some have adopted the view that the calculated LR should not be considered as an estimate of some “true” but unknown LR. Consequently, it is argued that there is no sense in studying the uncertainty of the LR. We believe there are strong arguments for the notion of a “true” but unknown value of the LR, given the relevant hypotheses and background information, and that it is important to consider the uncertainty. Ignoring the uncertainty can be strongly misleading. The question remains, however, which method should be used in a given case, and what the forensic expert should report. Should she report the best estimate (i.e.,  $LR = 42$ ), should she report the interval, both, or should she only report the lower or upper bound? We refer again to James Curran

- ▶ ‘...demonstrating that these errors have been calculated is the only correct and convincing response to the almost predictable questions about the size of the database and the validity of the results. The most appropriate comment on the subject perhaps comes from Buckleton

(2004) "An analyst who is prepared for such a cross examination will definitely present better evidence to the court than one who chooses to answer, 'would it make a difference?'" (Curran 2005, p 116).

Please note that we have addressed here mainly the issue of uncertainty due to sampling error, assuming the correct populations have been defined in the hypotheses. Other factors exist that result in uncertainty. For instance, uncertainty about the appropriate relevant population, or reference class, may also be important to take into account. Colyvan and Regan (2007) note with respect to this:

- ▶ 'Uncertainty will always be prevalent in legal decisions. Mathematical models of evidence provide some relief from uncertainty but can suffer from reference-class problems. This introduces a source of meta-uncertainty, which may well be impossible to eliminate. Decision theory, however, is in the business of recommending the best course of action in the face of uncertainty and thus can provide a valuable framework for approaching legal decisions and their associated uncertainties.'

## Context Effects and Bias

---

An important but slightly different aspect from the aspects of the interpretation of forensic evidence we touch upon in this chapter is that of context effects and cognitive bias. Cognitive processes play an important role in human action and consequently also in expert judgment. Brain and cognitive processes enable us to prioritize and group large amounts of information, and draw conclusions, despite possibly ambiguous and incomplete information (see Dror 2009, for an excellent discussion in the forensic context). They allow us, for instance, to distinguish our next door neighbor from a burglar in the dark, or to cross a busy street. These processes, that form the basis of human intelligence and expertise, however, also lead to specific vulnerabilities. Human intelligence and, in particular, expertise include aspects of mental representations that may also result in selectivity and biased information processing.

The capabilities and vulnerabilities expressed by Dror are inherent to human cognition, and thus two sides of same coin. Eliminating one cannot be done without sacrificing the other. What we can do in the forensic context is to check the vulnerabilities and minimize their effects by proper training and the development of appropriate methods and procedures. The vulnerabilities we will focus on here are so-called cognitive biases. These are the human tendencies to draw conclusions in certain situations based on cognitive factors rather than on observations or evidence. For instance, a firearm examiner can be biased by knowing that large amounts of drugs were found at the suspect's house. The term often used in the literature for designating this bias, is the term "observer effect." In forensic science, the term context effect is frequently used to indicate that the results of a forensic investigation can be partly determined by the circumstances in which the research is conducted, and especially by (irrelevant) case information known to the forensic expert (Thompson 2009). Frequently in the forensic literature, the term "confirmation bias" is used as a synonym. The interested reader is referred to Saks et al. (2003), and Risinger et al. (2002), for a more thorough treatment of the topic and for more references from the psychological literature. In this section we will shortly reflect on the methods that can be used in practice to reduce the effect of the context on forensic expert judgment. Such

methods may especially be important for forensic disciplines that rely on more subjective judgments for which no quantitative LR can be computed based on representative data.

The question that arises is of course whether these effects do actually occur in the practice of forensic evidence evaluation. Dror and Cole (2010) give an overview of studies of context effects in the forensic sciences. The few studies that have been carried out by forensic scientists and behavioral scientists partially contradict each other. Hall and Player (2008), for example, come to the conclusion that it is not such a big issue. Other studies, however, show a clear effect. Two studies are worth discussing. First, William Thompson (2009) shows, in an ad hoc experiment, that knowledge of the DNA profile of the suspect by forensic DNA experts may affect the interpretation of the disputed (partial and complex) DNA profile. By focusing on the DNA profile of the suspect it may occur that not all information is properly taken into account. Second, the well-designed experiment by Dror and colleagues (Dror et al. 2006) provides evidence for context effects in forensic fingerprint experts. Five experts were given a finger mark and fingerprint that they had already previously evaluated in a real case as a match (i.e., identification). This time, however, fingermark and fingerprint were presented in a context strongly pointing toward a non-match. Four of the five experts who participated in his experiment concluded that finger mark and print did not match, and they thus drew a different conclusion than they had previously drawn based on exactly the same mark and print. One might argue, of course, that these are two fairly limited experiments, and that several studies contradict each other. On the other hand, one might also argue that if even the smallest chance of bias exists it would be best for all of the forensic examinations to be performed in such a way that the effect of bias is minimized.

The context information that can result in bias may be of several different forms: (1) “base rate” information, (2) domain irrelevant case information, and (3) information obtained from the reference material. The first is information that is, in principle, independent of the particular case and the specific investigation, but which can have an effect on the expectations of the researcher. Due to the work of the police investigators, most evidence presented for forensic evaluation is incriminating, thereby making it in advance already tend toward a certain conclusion, and then unconsciously looking for information that supports the expected conclusion. In fact, this is one of the arguments used in the discussion whether judges in the Netherlands should specialize in criminal law or whether they should work in different areas of the law: it is feared that seeing a large number of cases in which the suspect usually is clearly guilty will cloud the judgment.

Domain irrelevant case information is all information that is not explicitly necessary for the expert performing the research. A confession, for instance, is almost always irrelevant information for a forensic fingerprint examiner.

The third form of biasing information is inherent in the way investigation is conducted, and was described in the previous paragraph. If the evidence is analyzed simultaneously with the reference material, the interpretation of the relevant features of the evidence may become partly determined on what the expert has seen in the reference material. Thompson (2009) mentions with respect to this the “Texas Sharp Shooter fallacy” named after a legendary Texan

- ‘...who fired his rifle randomly into the side of a barn and then painted a target around each of the bullet holes. When the paint dried, he invited his neighbors to see what a great shot he was. The neighbors were impressed: they thought it was extremely improbable that the rifleman could

have hit every target dead centre unless he was indeed an extraordinary marksman, and they therefore declared the man to be the greatest sharpshooter in the state.'

The effect of context information can be reduced as much as possible by keeping such information away from the experts carrying out the investigation. Tactical information, reports and other descriptions of the circumstances of the case, and results of other investigations are then not known to the expert carrying out the investigation. Easier said than done, this could be accomplished by using a stepwise procedure, where the person doing the intake of the case and the coordination is not the same as the person performing the actual investigation. Furthermore, to prevent target shifting, the evidence should be interpreted as much as possible, before the expert looks at the reference material. In summary, the expert doing the forensic investigations should be as blind as possible to all irrelevant case information. The addition of fake cases, with opposite conclusions, to the case flow could be a possible solution to the effect of base rate information. Although effective in theory, it is clear that this is not very practical solution because of the difficulty to create realistic cases, with the experts actually not being aware of the corresponding case being a fake case. Forensic scientists frequently build up a collection of "scary cases," cases with unexpected results, and use this collection to train new colleagues. Such cases are also discussed at conferences and in the literature. This may induce an important "exemplar effect," which has never been to topic of detailed study.

In the literature, the evidence lineup (Risinger et al. 2002) is sometimes advocated to overcome context effects. An evidence lineup is comparable to the well know Oslo (eye-witness) confrontation approach. Despite the high face validity the usefulness of the evidence lineup is severely limited in practice due to the selection of the fillers (i.e., reference material). Many of the recommendations of the evidence lineup can be traced back to the authoritative publication of Risinger, Saks, Thompson, and Rosenthal in 2002, but already in 1984 and 1987 Miller published on its application to handwriting research. A thorough analysis of the evidence lineup seems however to learn that its usefulness in investigating criminal cases is relatively small. In contrast the others, Risinger et al. themselves seem to be well aware of the difficulties where they write

- ▶ 'Proper evidence lineups present some nontrivial problems of design, requiring the Evidence and Quality Control Officer both to determine what would constitute appropriately similar foil specimens and to arrange to obtain them. This process would obviously be easier for some types of examinations than for others. Unfortunately, it may often be most difficult precisely where it is most needed, in those areas, such as handwriting identification, with the least instrumentation and greatest subjectivity' (pp. 49–50).

---

## Further Research

In this chapter we have described the LR approach for the evaluation and interpretation of forensic evidence. It has become clear that the forensic experts should report on the LR, and by doing so they report on the probability of the evidence given the relevant hypotheses. The legal decision maker should use this information, and combine it with all other information in the case to come to a verdict. While the basics of the LR approach are clear and the definition of the LR is straightforward, determination and reporting in

practice is not without difficulties, and much research is needed. We will now shortly address the most important issues in future research.

First of all, research should focus on methods to compute quantitative LRs for all forensic disciplines. In DNA analysis, reporting quantitative LRs (or the random match probabilities) is rather standard. For other areas like fingerprint analysis and forensic glass comparison, among some others, it is expected that numerical LRs can be reported in the near future. For many other areas computing quantitative LRs will remain science fiction for quite a long time. It is expected, therefore, that the evidential value will remain to have a considerable amount of subjectivity, in the sense that the evidential values are not derived from theory and hard data. Purely objective science is an illusion in every area – however, we should aim for it. Research should focus on how best to define the relevant populations, how to collect the data, and how to compute LRs based on those data. Deriving appropriate formulas that include measures of uncertainty, proper sampling strategies, and protocols to avoid context effects is indispensable.

A recent development in forensic science is a decision analysis perspective (Taroni et al. 2010). One of the topics considered is that in general forensic scientists tend to prefer erring in favor of the suspect over erring in favor of the prosecution, and they rather underestimate the strength of the evidence than overstate it. Consequently, when reporting confidence intervals or credibility intervals one may prefer erring on one side rather than erring on the other side. This may result in asymmetric intervals around the point estimate. Furthermore, decisions about the research strategy (which items of evidence are investigated, which analyses are performed in these items and in what order) are interesting to study from a decision analysis perspective. Practical software for performing such analyses is the Bayesian network software.

Given the fact that often multiple pieces of evidence are investigated in a given case, combination of evidence will also need to be considered in future research. Bayesian networks (Taroni et al. 2006) could be of great aid, especially if independence is violated and if statistical combination can only be performed on the activity level, with possibly much more factors affecting the result than on the source level. Bayesian networks could also aid in the understanding of the conclusion by the legal decision maker. Communication of results and conclusions such that all scientific details are properly addressed and understood by the legal decision is one of the major future challenges for all scientist and practitioners working in forensics.

**Abstract:** This chapter outlines a number of risks of nanotechnology and considers whether scientists can be held responsible, and if so, to what extent. The five risks discussed are representative of different kinds of risks and the list is not comprehensive: nanoparticles, privacy, grey goo, cyborgs, and nanodivides. The extent to which scientists can be held responsible for harms resulting from their research depends on the nature of science and here two models are outlined and assessed; the linear model and the social. The relationship of moral values to scientific research is examined with respect to both models and four interfaces are considered: the issues of concern to ethics committees, moral values in the acceptance or rejection of hypotheses, setting research agendas, and scientific responsibility. This leads to a discussion of responsibility itself, and on the basis of this, the five risks noted at the beginning of the chapter are revisited and an assessment given of the moral responsibility of scientists in each case.

## Introduction

---

Science and technology are often credited with making our lives much better through improved health, labor saving devices, better transportation, and so on. On the other hand, science and technology are often blamed for many of the problems of the developed world: various health problems, pollution, environmental degradation, breakdown of communities, and weapons of mass destruction, to name a few. In other words, science and technology are responsible for much that is good but also much that is bad. But what can be said about the responsibilities of individual scientists or groups of scientists? Should they be held responsible for the harms that sometimes result from their work? This chapter will attempt to sort out some of the issues relevant to risk and scientific responsibility. It will first consider a number of types of risks associated with nanotechnology and then outline two models of science, each of which has different implications for responsibility. This leads into a more detailed look at responsibility before a return to nanotechnology risks.

## Some Risks of Nanotechnology

---

Not much can be done in life without taking risks. Living is risky. From the moment of conception, we are surrounded by risks, many of which could prove fatal. But most, luckily, do not eventuate and most of those that do leave us relatively unscathed. We still worry about them of course, and this is probably a good thing, within reason. Preventative action can be taken and many avoided. Science and technology in general are risky enterprises, with the twin problems of unintended consequences and dual use. Worries are particularly prevalent in new and emerging technologies, and nanotechnology is no exception (for convenience, nanotechnology is used here to include nanoscience as well). In this chapter, a number of different kinds of risks of nanotechnologies will be considered. These various kinds of risks highlight different aspects of risk, risk perception, risk management, and so on.

Some of the things discussed as risks here may not be considered as risks by all, but each will be justified as a potential risk in the relevant discussion. The risks pertain to nanoparticles, grey goo (defined later), privacy, cyborgs and nanodivides.

Before examining these, it is instructive to look at an overview of nanotechnology and risk from a recent report. Four generations of nanotechnology are distinguished with potential risks posed by each.

## First Generation

Passive (steady function) nanostructures, for example, nanostructured coatings and non-invasive; invasive diagnostics for rapid patient monitoring *From 2000 –*

*Potential risk:* For example, nanoparticles in cosmetics or food with large scale production and high exposure rates.

## Second Generation

Active (evolving function nanostructures), for example, reactive nanostructured materials and sensors; targeted cancer therapies *From 2005 –*

*Potential risk:* For example, nanobiodevices in the human body; pesticides engineered to react to different conditions.

## Third Generation

Integrated nanosystems (systems of nanosystems), for example, artificial organs built from the nanoscale; evolutionary nanobiosystems *From 2010 –*

*Potential risk:* For example, modified viruses and bacteria; emerging behavior of large nanoscale systems.

## Fourth Generation

Heterogeneous molecular nanosystems, for example, nanoscale genetic therapies; molecules designed to self assemble *From 2015 to 2020*

*Potential risk:* For example, changes in biosystems; intrusive information systems (Renn and Roco 2006, p. 14; for a further discussion of the generations see Davis 2009).

The potential risks mentioned do not overlap completely with those to be discussed in this chapter. Risks of nanoparticles of course are mentioned explicitly in the first generation and are implicit in the second. While no mention is made of grey goo, it was thought to be a problem of self-assemble so would be a fourth generation issue. Cyborgs would fit into the third generation. Intrusive information systems, mentioned in the fourth generation, are related to the privacy question, but this is not only a future issue, it is here already, or so it will be argued. The nanodivide does not rate a mention.

## Nanoparticles

Most of the discussions of the risks of nanotechnology concern manufactured nanoparticles and if nanotechnology has any risks, many would consider these to be the only ones (for an overview see Seaton et al. 2010). In most cases, the issue is not that it is known that particular nanoparticles are health or environmental risks, but rather that not enough is known yet to understand their effects properly. Nanoscale particles, commonly said to those particles in the 1–100 nm range, have properties different from larger particles of the same material, due at least partly, to their greater surface area relative to size. According to Seaton et al. “Surface area is the metric driving the pro-inflammatory effects” and “In cells, high surface area doses appear to initiate inflammation through a number of pathways but oxidative stress-responsive gene transcription is one of the most important.” (Seaton et al. 2010, p. S123). However, their effects in the body are not yet well understood. This has led to calls for products containing these particles to be withdrawn for the market and a moratorium on further development until more research into their safety has been undertaken (FoE 2007). One concern is with products such as cosmetics and sunscreens that are applied to the skin. Some worry that the nanoparticles could pass through the skin and lodge in various parts of the body where they could cause harm.

Faunce et al., for example, suggest that the evidence so far is inconclusive whether or not titanium dioxide and zinc oxide, both used in sunscreens and known to be harmful to cells, can penetrate the skin (Faunce et al. 2008). Another concern is that threadlike particles that can be inhaled might have the same effects as asbestos and lead to serious lung disease (Bell no date). Nanoparticles in the air are of course nothing new and by and large cause no ill effects. The worry is that some manufactured particles of certain shapes might not be so benign (see Schmid et al. 2006, pp. 344 ff. for a detailed discussion). The use of nanotechnologies in food is also causing some concern and has been the focus of a recently published report in Great Britain. According to this report, potential application in the food industry include “creating foods with unaltered taste but lower fat or sugar levels, or improved packaging that keeps food fresher for longer or tells consumers if the food inside is spoiled” (House of Lords 2010, p. 5). It continues by saying that little is known of the potential dangers because of the paucity of research in the area.

## Grey Goo

---

Lest the mere mention of grey goo takes away all credibility from this chapter, let me say at the outset that it is being discussed, not because it seems to be a real possibility, but because it highlights some relevant aspects of risk. The potential problem of grey goo arises in the context of one kind of nanotechnology, molecular manufacturing, something that receives less attention in the literature now than it did a number of years ago. Molecular manufacturing is a “bottom up” approach where things are created or manufactured by the manipulation of atoms and molecules (see Drexler 2006; Treder and Phoenix 2007). Drexler (1996) envisaged tiny robots, or nanobots, that would have the ability to self-replicate indefinitely, and the grey goo problem would be the result if they were not suitably controlled. In this “bottom up” approach to nanotechnology, self-replicating robots could manufacture just about anything. The problem was seen to be that if the research continued, there would be a possibility of these nanobots actually being developed and therefore the possibility that they might escape from the environment in which they were developed for a particular task and consume everything around them without the possibility of containment. This “grey goo” risk seems now to be minute because of both theoretical and practical problems with certain approaches to molecular manufacturing (see Smalley 2001; Drexler 2001; Phoenix and Drexler 2004).

The issue here is that while the risk appears to be minute and certainly not a short or medium term one, the results could be catastrophic. Whether such risks should be considered at all is a moot point. If they are only possible in the very distant future, the risks of biological and nuclear weapons used in war or terrorism, or environmental degradation, and extreme climate change seem likely to decimate us before grey goo gets its chance.

Richard Posner argues, however, that even if the risk is tiny, given that the result would be catastrophic, the risk should be taken seriously. He expresses skepticism about the scientists’ claims that it will almost certainly never happen “given the record of scientists’ ‘never’ predictions” (Posner 2004, p. 36).

## Privacy

---

New monitoring and surveillance technologies are not commonly classified as risks, but they do pose threats to personal privacy so it is not unreasonable to classify them in this way.

They are not risks in the same way as the potential toxicity of some nanoparticles are risks to health or the environment. There is, however, the potential for harm through loss of autonomy and increased vulnerability to control. Moreover, just as manufactured nanoparticles are already in use and some evidence exists, as seen earlier, of dangers, so technologies such as certain computer technologies are already threatening privacy. These new monitoring and surveillance technologies therefore do pose risks. The problem is that the more that is known about a person, the greater the ability of those with the information to harm that person. This is the reason for strict controls on certain kinds of personal information, for example medical records. It is not so much that it necessarily matters what others know about one. The central issue is how the information that they do have is used.

That developments in nanotechnology, particularly in nanoelectronics, will enhance monitoring and surveillance techniques and capabilities is almost certain. Faster processing of increasing amounts of data on smaller devices and evermore powerful and sensitive sensing devices will ensure this. These technologies are not being developed, for the most part, with the explicit aim of reducing personal. The drivers are increased productivity and efficiency (e.g., RFIDs in warehouses, Kelly and Erickson 2005), and particularly security against potential terrorist attacks.

## Cyborgs

---

Technological and scientific developments enabling human enhancement employ many techniques, perhaps the most prominent being genetic engineering and the use of drugs. In one aspect of enhancement, however, nanotechnology does have an important role, and that is the development of cyborgs; the merging of humans and machines. Computer technology is of course vital here but developments in nanoelectronics to further miniaturize computing and sensing devices and the creation of new materials will be an essential element in the continued research and development of cyborgs (see Roco and Bainbridge 2002, for an early discussion).

The merging of machines with humans poses risks in a number of ways. It might threaten human integrity and it might have adverse effects on individuals or communities or both. This case is rather different from the previous ones. In the first two the potential harm is physical with no doubt that it is harm. The third is a little more contentious but a reduction in privacy and autonomy usually must be justified by an increase in other goods, for example security. So, other things being equal, there is a perception that their loss is regrettable. It is less obvious, however, that loss of human integrity is a harm and even if it is, that combining technology with humans is a cause of the loss. The lack of clarity is at least partly because human integrity is not easy to define. It depends on beliefs about what it is to be human. It is not normally thought that someone who wears spectacles, contact lenses, a hearing aid or has a pacemaker is less human because of that reliance on technology. The worries occur with technological enhancements rather than technologies for therapy. It is enhancements that threaten human integrity. This therapy-enhancement distinction, however, does not stand up well to close scrutiny. The claim then that the technologies in question pose a risk to human integrity is contentious and depends both on what it is to be human and what constitutes enhancement. But nevertheless, it is considered by many to be a risk. The risk of other harms to individuals and communities is also contentious but more comprehensible. Just two will be mentioned here. Jürgen Habermas (2003)

raises the concern that if certain sorts of enhancements are available, parents will feel obliged to have their children enhanced just as today they feel obliged to give their children the best education that they can afford. The problem with enhancements is that they may not be reversible and the children may grow up with enhanced abilities that they do not want and therefore have less autonomy to do what they really want to do. Another issue is that if a range of enhancements is possible and different people are enhanced in different way, then communication may become difficult between these different people and social cohesion will suffer (see Savulescu and Bostrom 2009; Lin and Allhoff 2008 for further discussion).

## Nanodivide

---

A final worry is that nanotechnology will help increase the divide between the developed world and the developing world. The term “digital divide” is used to name the gulf between those with and those without adequate information and communication technologies. Likewise, “nanodivide” names what some see as the potential for nanotechnology to further disadvantage poorer peoples relative to the richer. Most of the technologies will be for those already well-off. Those are the people who can afford to buy new technology and so products will be developed for them. These harms to the developing world are relative; the poorer parts will become relatively poorer simply because the richer parts will be richer in absolute terms. Another aspect of the nanodivide concern is that products will be developed and produced in rich countries that replace natural products now produced in poorer countries. This concern was raised by the ETC group (2004) in relation to synthetic rubber production that would replace natural rubber. The creation of a nanodivide is not seen as a risk by all. Some argue, for example Peterson and Heller (2007), that nanotechnology will in fact provide extensive benefits to developing countries, but others, for example Joachim Schummer (2007), show cause to doubt this.

Before looking at whether scientists or the scientific community more generally is morally responsible for harms resulting from these risks, we consider the scientific enterprise itself. This will provide a background for the discussion.

## Models of Science

---

To a large extent the model that is held of scientific research determines what constitute the moral responsibilities of scientists. Two such models will be considered, the linear and the social models. These can be interpreted as either descriptive, that is as science is actually done, or as normative, that is, as it ought to be done. Here it will be suggested that as a description of how science is actually done, the linear account is not accurate and that the social model is the better one from the moral standpoint. This will become clearer when the role of values in science is discussed.

### The Linear Model

---

This model, it is often said, dates back to Francis Bacon and sees a progression from pure science through applied science and technology, to products. It maintains that scientists are the

best judges of what research should be pursued and that society benefits most when the scientists are given free reign to follow the search for knowledge wherever it may lead. A strong advocate was Michael Polanyi, who wrote in 1962:

- ▶ During the last 20–30 years, there have been many suggestions and pressures towards guiding the progress of scientific inquiry in the direction of public welfare.

...

Any attempt at guiding scientific research towards a purpose other than its own is an attempt to deflect it from the advancement of science. . . . You can kill or mutilate the advance of science, you cannot shape it (Polanyi 1962).

Another enthusiastic supporter was Vannevar Bush who had a large influence on science policy in the USA. He wrote:

- ▶ Scientific progress on a broad front results from the free play of free intellects, working on subjects of their own choice, in the manner dictated by their curiosity for exploration of the unknown. Freedom of inquiry must be preserved under any plan for Government support of science . . . (Bush 1945).

This view still has currency, at least amongst many scientists, and seems to be that held by the Australian scientist Sir Gustav Nossal who, speaking of scientific research, writes:

- ▶ To free the human spirit from ignorance and superstition must be good, no boundaries should be placed around such a search (Nossal 2007, p. 6).

Much research, however, eventually leads to technologies useful to, or possibly detrimental to, individuals and society, therefore:

- ▶ This is why the distinction between science (which seeks to know) and technology (which seeks to apply knowledge) is so crucially important. Of course technology must be subjected to societal and democratic norms (Nossal 2007, p. 7).

He seems to imply here that scientific research should not be subject to such norms, that is, that scientific research is value-free with respect to moral values.

In summary, this model asserts that science progresses best when scientists are given free reign to follow their research interests and that this also leads to the best results for society.

## The Social Model

---

The linear model is held by many, especially scientists, but is not unchallenged. It can be argued, as already noted, that not only is it not the way that science works, that is, it is factually wrong, but it is not even the best way for science to work; it is not something at which we should aim. Albert Einstein reflects this view in a talk to students:

- ▶ It is not enough that you should understand about applied science in order that your work may increase man's blessings. Concern for man himself must always be our goal, concern for the great unsolved problems of the distribution of goods and the division of labor, that the creations of your mind may be a blessing, and not a curse, to mankind. *Never forget this in the midst of your diagrams and equations* (Einstein 1931).

The social model differs from the linear in a number of ways. Most importantly, on the social modal science is not value-free and this will be discussed in the following section. Here, we will focus on two aspects of this model: first, the involvement of society in decisions about what research should be undertaken, that is, scientists should not have completely free reign; and second, that there is no sharp distinction between pure science on the one hand and applied science and technology on the other.

First, should society have a role in setting the research agenda? The European Commission has recently published two documents that advocate broader society involvement in decisions on what research should be undertaken. In their “Code of Conduct for Responsible Nanosciences and Nanotechnologies Research,” one of the clauses states:

- ▶ 4.1.13 Member States, N&N research funding bodies and organizations should encourage fields of N&N research with the broadest possible positive impact. A priority should be given to research aiming to protect the public and the environment, consumers or workers . . . (Commission of European Communities 2008).

This clause clearly advocates a research agenda that gives the greatest benefits to the greatest number of people. More importantly for our purposes, it advocates a research agenda that is not determined just by scientists’ interests or by profits. It introduces a social element. Similarly, in the *Global Governance of Science* report it is argued that:

- ▶ In a world of competing goods and limited resources – in which sciences not the only good and all research programs are not equally able to be funded – the governance of means must be complemented by a governance of ends (Global Governance of Science 2009, p. 41).

In other words, the curiosity of scientists is not enough to set the research agenda; the results, or ends, of the research must be taken into account.

In that report, John Dewey is referred to approvingly as someone who advocated this broader view of science. While it is true that he does maintain that scientists have a “supreme intellectual obligation” to society, and says, for example:

- ▶ The wounds made by applications of science can be healed only by a further extension of applications of knowledge and intelligence; like the purpose of all modern healing the application must be preventative as well as curative. This is the supreme obligation of intellectual activity at the present time. The moral consequences of science in life impose a corresponding responsibility (Dewey 1934, p. 98).

His position, however, is a little more subtle than stated in that report. One of his main arguments is that the “supreme intellectual obligation” is to develop the ability to think scientifically, critically, and rigorously, which in turn will benefit society.

If research is aimed at improving life, whether it be better health, cleaner energy, greater profits, or whatever, serious questions must be asked concerning the kind of research that should be done and who should make the decisions. With respect to publicly funded research, the decisions are commonly made by governments, at least broadly by setting research priorities. In Australia for example, the priority funding areas in 2011 are:

- An environmentally sustainable Australia
- Promoting and maintaining good health

- Frontier technologies for building and transforming Australian industries
- Safeguarding Australia (ARC 2009).

Philip Kitcher, however, argues that governments are not the best bodies to decide what research should be done, but neither does he believe that, in a democracy, all decisions should be left to the scientists either. His suggestion is this:

- ▶ . . . we need an institution that would offer a serious map of what scientific research has achieved and what possibilities it opens up for us. There's no reason why a group of senior scientists, perhaps scientists nearing the end of distinguished research careers, could not produce, in joint deliberation, a relatively accurate overall picture. They could then present that picture to representatives of different human constituencies in different human societies, representatives who would thus come to understand the lines along which future inquiry might be conducted. This *Scientific Forum*, . . . could then be set the task of trying to devise an appropriate research agenda that would take seriously the tutored preferences of all the represented groups. . . . perhaps under the aegis of UNICEF (or UNESCO) or some similar group, . . . (Kitcher 2007, pp. 183–184).

Kitcher's argument is a general one that applies to all sciences. It can be questioned whether his suggestion is practical. Often it may only be the scientists who are involved in the research who understand enough to really know what the future direction of the research should be. This is probably true with respect to the details of the research agenda but at a higher, "big picture" level his suggestion has plausibility. If Kitcher and the European Commission are correct about the desirability of research agendas being set with social goals in mind and not merely as a result of scientists following their own interests, or of profits, then of course there must be consideration of those social goals. This is one place that moral values enter into scientific research. We turn now to these values as a way of highlighting some important issues relating to responsibilities for risks.

The second difference between the linear and social models mentioned earlier is that the former but not the latter wants to maintain a strict division between pure science on the one hand and technology on the other. While there are obviously differences in degree, as described, for example, by Mario Bunge (1988), any sharp difference is difficult to maintain. Kitcher (2001) supports this view and argues for "the myth of the pure" (my emphasis), that is, that it is a myth that some science is so pure that it is not contaminated by applied science or technology. Advocates of technoscience also see no sharp distinction (Hottois 2005). If it is true that science and technology are closely related there are at least two consequences for the argument in this chapter. First, ethical and social values permeate science to a greater degree than is often recognized and second, it has implications for the responsibility of scientists.

Just one argument for the relationship will be given here that has relevance for scientific responsibility (for others see Kitcher 2001). We will assume that the results of most, if not all, successful scientific research will be published. Once it is published it is in the public domain and can be used in future research by anyone. We can assume too that most successful research that leads to discoveries will have uses apart from merely increasing human knowledge and reducing ignorance. If this is so, it is almost certain that those discoveries will be used in the development of new technologies and that these technologies will be used, hopefully for good but possibly also for harm. This link between science and technology is not a logically necessary one and there is nothing deterministic in any strong sense, about the science leading to the technology. It is not logically inevitable, but given what we know about the way that people

typically behave, particularly in a capitalist society, there is a kind of factual inevitability about the link. This factual inevitability is underpinned by a normative inevitability that resembles what Bruce Bimber calls normative technological determinism (Bimber 1994). It is not determinism at all but has that appearance because the technological development is driven largely by the unquestioned values of efficiency and productivity so always moves in the direction that those two values direct. In the science-technology link, publishing is driven by various values: desire to increase knowledge or to improve the world in some other way; continued or future employment; prestige of one's institution or oneself. Once the knowledge is available to all, if it is at all useful the values of productivity and efficiency will almost ensure that technology will be developed and used.

## Values in Research

---

In order to understand better the place of moral responsibility in each model, it is useful to look at the role of ethical issues in each a little more closely. Each of these models has some different ethical implications. In order to explore these, it will be useful to outline the place of values in scientific research.

It is sometimes claimed by defenders of the linear model that research, especially pure research, is value neutral with respect to moral values, and that values enter only at the level of technological development, something that we have already questioned. What is meant is that while the results of the research can be used for good or ill and so are value-laden, those values do not permeate the research itself. That research merely generates new knowledge. It is in the use of that knowledge that values reside.

This view, it seems, is not accepted by Nossal:

- ▶ I have always believed that scientific research is richly value-laden, that the search for new knowledge gives expression to a deep human yearning, that seeking to know more about the natural world is an unalloyed good (Nossal 2007, p. 6).

The values acknowledged here are satisfying human yearning for knowledge and gaining knowledge itself. While research is value-laden in this sense, it is not what is commonly meant when it is claimed is that scientific research is value-laden with moral values.

Obviously, broader social values come into play at the stage of technological development, particularly pertaining to the products that should be developed, to their design, and to their use.

The social model incorporates many of these latter values into the scientific enterprise. At the very least, research should be directed to human needs more generally and not limited to increasing knowledge. It is at this stage that the difference of ethical import of the models lies. The tentative suggestion is that at the research stage on the linear model the main value is increasing human knowledge; on the social model, other social values are equally and perhaps even more important.

But this is a preliminary conclusion only and slightly misleading at that. Nossal's values, it must be noted, are not strictly part of scientific research itself but are values that underlie, or lead to, at least some kinds of research. The same could be true of the social values mentioned. Moral and social values are important in science overall, it is sometimes argued, but they are not part of science proper. If this is so then the linear and social models are not incompatible because they are focusing on different things; the linear model on the research itself and the social on the scientific enterprise more generally.

In order to spell out in more detail the relationship between ethical values and science, we will consider a number of areas where they potentially meet, called here interfaces.

## The Science/Ethics Interface

---

Ethical concerns arise at various stages of the scientific enterprise and here four interfaces between the two will be considered.

### Interface 1

---

Ethics in science is often limited to what ethics committees oversee and this is largely the way that research is undertaken: will the research harm human or animal subjects, is it safe for the researchers, are intellectual property rights being respected, and so on. However, this is only one interface between ethics and science, and perhaps the only one that defenders of the linear model will accept.

### Interface 2

---

A second, and contested, interface is the relationship between values and decisions to accept or reject hypotheses. Richard Rudner (1953) criticizes the view that no values are part of the research itself. His central argument is that a core part of scientific research is to accept or reject hypotheses and that this decision making cannot be divorced from the scientist's values. Values must come into play because risks of harmful consequences of certain theories. The greater the potential risk the greater must be certainty that the hypothesis is true so the scientist must make a value judgment regarding the degree of certainty. Is the certainty great enough to warrant accepting the hypothesis? So scientific research *qua* scientific research is not value neutral.

A potential problem with Rudner's argument is that it is not clear that the value judgments enter at the level of hypothesis acceptance or rejection. The commitment to certain standards of rigor for acceptance or rejection could be a value stance taken prior to undertaking the research, an argument advanced by Hugh Lacey (1999). According to Lacey, deciding what level of certainty is appropriate in a particular instance is a questioning of the generally accepted standard rather than a decision based on a value judgment as part of the research itself. What Rudner has shown is another of the "important aspects of the 'touch' (or ... 'constant rubbing') of science and values" (Lacey 1999, p. 73). This is close to what in this chapter is called the *interface* between science and ethics.

One problem with Lacey's approach is that the actual value free domain of science is extremely narrow. Another and more important one is that it does not avoid Rudner's objection to decisions being free of value judgments. The generally accepted standards that are being questioned might be outside the research proper, but the questioning itself is part of the role or scientist *qua* scientist. If the scientist is worried about the risks of being wrong, his or her rejection of the standards in this case might be well founded, and clearly based on a value judgment regarding acceptable risk.

A similar point is made Heather Douglas (2009) in her much more nuanced account of values in science. Douglas considers three categories of values: ethical, social, and cognitive. All have a role to play, albeit, most of the time an indirect rather than a direct one. While ethical values should not directly influence which hypotheses should be accepted, for example, a vegetarian scientist should not let his or her vegetarianism influence the acceptance or rejection of an hypothesis about the benefits of meat eating, ethical values can be important indirectly, for example, in cases where the scientist must make a judgment regarding certainty given high risk, as Rudner argues.

### Interface 3

---

It was noted earlier that Nossal argued for the value-ladenness of scientific research. Research has built-in values; satisfaction of a human need and the goodness of expanding knowledge. This is another interface and one where the two models diverge from an ethical standpoint. On the social model, Nossal's two values are not enough and could be overridden by other social values. Research should be for the good of society more generally and the agenda for research should be set with priorities, some projects being much more important and urgent than others. For example, in the situation where the burning of fossil fuels is increasing levels of carbon dioxide in the atmosphere to a worrying degree, nanotechnology research perhaps should have clean energy as a much higher priority than, say, research into better sun screens or drug delivery devices (Weckert 2010). On this model, the priorities should be set by the government or some other bodies representing society generally, as mentioned in the earlier discussion of the social model.

### Interface 4

---

The fourth interface concerns responsibility. Which researchers are responsible for benefits or harms of research will depend, at least partly, on which model is held. There is little argument that use of technology carries responsibilities with it. If I use some technology in a way that harms others I can be held morally responsible. Responsibility for technological development is more contentious. If I develop some product that is used in harmful ways my responsibility for the harm is less clear. I can always fall back on the claim that the technology is not the problem; rather the problem is in the use. Finally, the responsibilities of scientists who undertook the research that enabled the technology to be developed and used for harm are more contentious again. In fact, it is commonly denied that they carry any responsibility at all for such harm. Their responsibilities are limited to issues of doing the research well. This account of scientific responsibility is closely tied to the linear model where there is a clear distinction between science and technology, something dismissed earlier. The distinction is seen as the boundary for moral responsibility and legitimate societal or governmental control or interference.

On the social model, responsibility goes all along the chain, back to even the pure science, something that does seem to be implied in statements above. Values external to the science itself come into play right at the beginning. Those further removed from the consequences will have diminished responsibility but they cannot avoid it completely. This of course leads to what can be seen as a completely untenable position and perhaps even a *reductio ad absurdum* of the

proposed view; given the dual use dilemma that most research can be used for good or harm (Selgelid 2009), scientists are morally blameworthy then, even when their research is undoubtedly intended to promote nothing but good. They would be blameworthy regardless of what they did, an absurd position. A closer look at moral responsibility shows that the situation is not quite so dire although things may be a little less comfortable than on the linear model.

The discussion of this section has focused on a number of points where moral values become important in science and highlighted differences between the linear and social models with respect to these values. The differences largely are a function of what is taken to be the scope of science. The linear model restricts it just to the research activity itself whereas on the social model the research in its societal context is the focus. Values relating to what research should be undertaken and to the effects of the research on society therefore become important and essential parts of science itself. This difference clearly has implications for scientific responsibility, as seen in the previous argument. More must be said now about responsibility.

## Moral Responsibility

---

The word “responsibility” has two distinct senses that are important for our purposes. First, there is the *causal* sense: if it is said that lightning was responsible for a fire, what is meant is that lightning caused the fire. It is ambiguous, however, to say that someone was responsible for fire. This might just mean that that person caused it or it could mean that he or she is praiseworthy or blameworthy for lighting it. This second sense is *moral* responsibility. Someone is morally responsible for an action if he or she played a causal role in the action and if it is appropriate to attribute praise or blame for causing it. A person who is responsible in the causal sense is not always responsible on the moral sense.

In order to be held morally responsible for some harm, a person must at least (1) have caused it or knowingly allowed it to happen when it could have been prevented and (2) must have intended to cause it, or allowed it through negligence or carelessness. Condition (1) would frequently be satisfied on the grounds that there is a causal link between some research and some harm. Without the research, the harm would not have been possible. Condition (2) however, hopefully is seldom satisfied. Scientists rarely *intend* to cause harm. The second part of the condition though gives some pause for thought. A scientist cannot avoid all moral responsibility simply because no harm was intended. If no, or insufficient, thought is given to possible harmful consequences, some moral responsibility would be present.

It might be objected, reasonably, that this picture is overly simplistic because research now is not usually conducted by just one person. Normally it will be undertaken by a team, possible a very large one. In such cases, the argument goes, nobody can be held morally responsible. This is the problem of collective responsibility, a problem that arises when groups cooperate to achieve some end, whether it be scientific research, conducting a war, or developing computer software (Miller 2008).

Because many people are involved in typical scientific research projects, when something goes wrong, it is not always easy to say who is morally responsible, and who, if anyone, ought to be held accountable and liable for any damages. One solution is just to say that the group, or organization, is responsible. In everyday talk we do this frequently, a good example being British Petroleum’s (BP) responsibility for oil spill in the Gulf of Mexico in 2010. Two problems are worth pointing out here. One is a degree of unfairness. Not everyone in a group is equally

responsible or even responsible at all. Not all BP employees played a role on the explosion and spill. The second problem is that moral responsibility is something that can only be attributed to autonomous human beings, not organizations.

While it is probably true that in most cases where there is collective responsibility no individual will bear the entire blame, it does not follow that moral responsibility cannot be attributed to many individuals. Many can therefore be held accountable to varying degrees. Not everyone in a research or development team will necessarily bear the same level of responsibility for faulty products or other harms resulting from the research and development, and some perhaps will have no responsibility at all. A careless researcher or developer can bear responsibility as can someone who is negligent in the testing of products or harmful uses of research outcomes. In most cases, ultimate responsibility must be borne by the leaders of projects whose role is general oversight the whole process. Responsibility cannot be avoided simply because a large team is involved.

A further aspect of collective responsibility must be noted. While not all individuals are at fault and those that are, not all equally so, there is a sense in which all, with only several exceptions, can plausibly be held accountable. If I do nothing to try to change the situation of my team's or company's carelessness, I am helping to perpetuate a climate in which faults, mistakes or accidents are more likely to occur. So I can and ought to be held accountable to some extent, even though I did not cause the events, or intend them to happen. In Larry May's terms, I can be morally tainted even if I cannot be blamed for the event itself (May 1991). The exceptions are where I have protested or attempted to change the situation, or am not in a position where I could do anything, for example, if I could not reasonably be expected to know of the situation. Given this, all, or most, members of a group, team or company can be held collectively responsible for research.

## Risk and Moral Responsibility in Nanotechnology

---

In the first section of this chapter, various risks or potential risks associated with nanotechnology were outlined. In the second, two models of science were considered and each of these had different implications for scientific responsibility. Next, a little more was said about moral responsibility itself. In this section we will return to the five areas of risk discussed in the first section and in each case examine the responsibility for the management of the risks and for harms caused. Various levels can be distinguished for moral responsibility in these cases: scientific researchers, developers of technologies, users of the technologies, and regulators. Our primary interest is in the moral responsibilities of scientists and the scientific enterprise generally.

### Risk with Nanoparticles

---

As we saw earlier, the main focus of discussions of risks in nanotechnology has been on those associated with the potential toxicity of various manufactured nanoparticles. Given that the particles are at the core of the research, a strong case can be made that some moral responsibility attaches to the researchers if those particles cause harm to health or the environment. If praise for the benefits of this research is appropriate, then blame for the harms is too. But of

course it is not so simple. The research, it is fair to assume, is aimed at the benefits whereas the harms are unfortunate and unintended consequences. If the benefits derived from the particles cannot be realized without the potential for harm, then one primary responsibility of the scientists is to make clear what the potential risks are and another is to undertake further research to see if the risks are real and, if they are, to try to find ways to mitigate them (see Maynard 2006) on addressing risks. While the scientists are attributed more responsibility in the social model, even in the linear one they do not escape completely. An important scientific responsibility in this model is to increase knowledge, and increasing knowledge of the toxicity of nanoparticles and their movement and accumulation in human bodies and the environment is a vital part of this knowledge.

More direct moral responsibility can be attributed to developers and manufacturers of products containing potentially toxic nanoparticles, providing of course they have been given sufficient information from the researchers about potential toxicity. Take sunscreens for example mentioned earlier. Some contain nanoparticles and debate continues over their safety. Do the particles penetrate the skin and if they do, what harm do they cause? If harm is indeed caused then the products should be taken off the market (Faunce et al. 2008), and if they are not, those producing them are morally responsible for the harms. But again, just as in the case with the researchers, more must be said. If the producers are not warned by the researchers then they can hardly be held responsible providing that they have taken measures to find out. If there are no products that are anywhere near as effective in preventing skin cancer and other sun related problems, then the risk may be worth taking and they bear little, if any, responsibility. Another issue is labeling of the products. If the labels state clearly that the product contains nanoparticles with a warning of potential risks, then much of the responsibility is shifted onto the user. This suggests that some of the responsibility also lies with regulators. They have a responsibility to warn the public of dangers. This of course raises another issue, that of difficulties in regulating nanoparticles or products containing them.

## Risk with Grey Goo

This case is different from the previous one in three respects. First it is extremely unlikely, second it is not a short or medium term concern and third, the consequences would be catastrophic. If it did occur and the consequences were as predicted by some, no question of moral responsibility would arise simply because nobody would be left alive. The responsibility question then is whether scientists have a responsibility not to undertake research into self-replicating robots that could lead to grey goo, or at least whether there is a responsibility to undertake research into controlling the self-replication process simultaneously with the research into developing it. The second of these is the more plausible given that the first would deny the world of any benefits as well. On the social model this is clearly true, but even on the linear, as in the previous case, there is a responsibility to increase knowledge of the dangers and how to mitigate them.

This leads to a final consideration is the “If we don’t someone else will” argument. One version of this is something like “this activity might be harmful or otherwise morally dubious, but it will be done by someone so we might as well do it. It is unfair to hold us responsibility for the harms because they would occur whether or not it did it.” This can easily be used as an excuse but other versions have more plausibility. Suppose that we would do it more carefully

and safely than others so that any harmful consequences are reduced? An even stronger argument can be made. Perhaps, there is a moral responsibility for us to undertake the activity, in this instance the research, *in case* others do so because if they succeed we have a way of controlling the nanobots if something does go wrong. Undertaking the research may in fact be the best way of managing the risks even though it might be better if the research were done by nobody at all. This “If we don’t someone else will” argument is more complex than the account given here and is most plausible on consequentialist grounds. Much more needs to be said, but for the purposes here, there are to be instances where it is justified and this may be one of them (Glover 1975; May 1991).

## Privacy

---

Personal privacy, and therefore autonomy, is being threatened by new technologies, including nanotechnology. The risks are real, not merely potential although they have the potential to become much worse. Results of scientific research led to the development of various technologies that enhanced capabilities for monitoring and surveillance and therefore to the threats to personal privacy and the harms that can follow from that. The scientists therefore have a direct causal link with the harms but the claim that they also have moral responsibility is more tenuous and on the linear model they probably have none at all. Monitoring and surveillance have many legitimate uses and the more effectively and efficiently they are carried out, the better in many cases. This is a standard dual-use case where research is undertaken to produce some good, in this case, legitimate surveillance, but then is used for ill, illegitimate surveillance, as well. Another factor is that illegitimate surveillance in itself does not necessarily cause harm, rather it is the use that is made of the information gained that is often used for harm. Moral responsibility here rests primarily with users of the technology. It is less clear here than in the previous examples how more scientific research could improve the situation.

## Cyborgs

---

As discussed earlier, the risk here is primarily to human integrity, if a risk exists at all. If human integrity suffers then those undertaking the research do bear moral responsibility. Because the purpose of the research is to enhance human performance in some way by the integration of human and machine any harm to integrity cannot be claimed to be an unintended consequence or a result of dual-use. Loss of integrity in this instance is constituted in combining human and machine. The best way to manage the risk therefore is not to do the research in the first place. This way of looking at it, however, hides two important considerations. The first is that useful medical devices result from this kind of research and second, a distinction must be drawn between research into the technology itself and that into linking the technology and humans. The first point draws on the therapy-enhancement distinction. If this is a viable distinction, then research into therapy is justifiable, and if the same research is used for enhancement, then this is a dual-use issue and the researchers bear no responsibility. The distinction, however, is the subject of much dispute so reliance on it does not solve many issues. The second point concerns different kinds of research required for human enhancement. Researchers working on computing or other necessary technology bear little if any responsibility.

Even if their work led to the development of computers onto which the contents of human brains were downloaded, their responsibility is limited to the development of the computer, not the uses to which it is put. However, those engaged in research into how best to link humans and computers for the purposes of enhancing capabilities do bear responsibility. The mitigating consideration here is that it is not clear that loss of human integrity occurs or that any harm at all results from this enhancement.

## Nanodivide

---

It is difficult to attribute moral responsibility for any nanodivide to those involved in research into and development of technologies and products creating that divide. It is primarily a political problem. The research is done and technologies developed and if the distribution of the resulting benefits is unfair, that is hardly the fault of the researchers and developers. The situation, however, is not so clear where the research benefits the well-off only or benefits them at the expense of the less affluent. In medical research 90% of funding goes to diseases of 10% of the world's population and a similar situation occurs with private funding of agricultural research. It could be argued that researchers do have a responsibility to do more to help the less developed parts of the world. Furthermore, some research will probably be detrimental to some poorer areas, for example into synthetic rubber. While in these cases some responsibility may lie with the scientists, governments and other research funding bodies bear a greater responsibility.

## Conclusion

---

As with all technologies, nanotechnologies come with risks as well as benefits. Scientists clearly have a responsibility to help alleviate some of the risks, particularly with respect to nanoparticles. They have the twin responsibilities of undertaking the research and insisting that funding is available to do it. If molecular manufacturing becomes a reality they will have similar responsibilities to ensure that appropriate research is done to minimize its risks. Scientific responsibility is less in the other risks areas discussed in this chapter. It is not so much extra research that will lessen risks to privacy, but rather restrictions on the uses of developed technologies and products. Whether or not cyborgs pose risks depends largely on views of human nature and nanoscientists, as scientists, cannot do much about that. This situation is similar with respect to the nanodivide, although in this case it can be argued that more research should be undertaken in areas that are likely to decrease the divide. If we want the benefits of nanotechnology, we must cope with the risks, and the scientists whose research generates those risks have an important role to play in the management of at least some of them.

## Further Research

---

With the continued development of technologies such as nanotechnology, synthetic biology, and genetic engineering, with their potential for altering not only the environment but also

human beings, further research is required to understand better the consequences of these developments. The research into social and ethical issues must be interdisciplinary and based on sound science and a knowledge of actual technological developments and realistic assessment of potential developments. A strong focus on what is required from science and technology is necessary with respect to improving life for all if harms are to be minimized and benefits maximized. This research has begun but more is required, particularly in relation to understanding responsibility for harms and the role of technology in the good life.

## Acknowledgment

I would like to thank the Ethics Centre of South Australia and the Ian Wark Research Institute (Particle and Material Interfaces) at the University of South Australia, for giving me a Research Fellowship in Ethics in 2008. The discussions there were valuable in the formation and development of the ideas in this paper.

**Abstract:** One of the fundamental ethical concerns about biomedical research is that it exposes participants to risks for the benefit of others. Therefore, a key ethical requirement for biomedical research studies is that they have an acceptable risk-benefit profile. Yet, despite widespread endorsement of this requirement, how it should be implemented remains controversial. The present paper critically reviews recent debates about risk and risk-benefit evaluations in biomedical research. It traces the history of risk-benefit evaluations in research, which were traditionally conceived of as an extension of the risk-benefit assessment occurring in clinical care. From there, the paper presents and evaluates the four existing ethical frameworks for risk-benefit evaluations: the component analysis, the integrative approach, the agreement principle, and the net risks test. It is argued that the net risks test is superior to the alternative approaches, but fails to offer guidance for evaluating the ethical acceptability of risks that participants incur for research purposes only. This leaves two of the fundamental problems of risk-benefit evaluations in research inadequately addressed, namely, (1) how to weigh the risks to the individual research participant against the potential social value of the knowledge to be gained from a study and (2) how to set upper limits of acceptable research risk. Discussions about the “minimal” risk threshold in research with participants who cannot consent, such as children or patients with dementia, go some way to specifying upper risk limits in this study context. However, these discussions apply only to a small portion of research studies. The paper ends by highlighting several important questions that future research will need to address.

## Introduction

---

Progress in clinical care relies on the development of new preventive, diagnostic, therapeutic, and palliative methods. To determine whether potential new interventions represent an advance over current methods, they need to be tested in clinical research studies. Some such interventions might provide clinical benefit to the individuals who participate in these studies; however, most have no clinical effect and can even make participants worse off than they would have been outside the potential trial. For instance, many of the procedures necessary to evaluate the safety and efficacy of new interventions – such as blood draws, imaging procedures, or biopsies – offer essentially no clinical benefit to participants. The same is true in the early stages of drug development, which typically involve healthy volunteers who will not gain any clinical benefits. Similarly, though basic science research in biomedicine – for example, natural history studies or research in pathophysiology or - biomchemistry – is crucial for the development of new clinical interventions, it uses research interventions that offer participants no clinical benefits. As conventionally understood, the only benefit from performing these interventions is the generalizable knowledge intended to improve the care of future patients.

The conduct of biomedical research therefore serves as an example of one of the most fundamental quandaries in moral theory: when is it acceptable to expose individuals to some harm or risk of harm for the benefit of others? This question is not only of great theoretical interest, but also of tremendous practical importance. Conceptions of acceptable research risk influence both the extent to which participants are protected from risks of harm as well as the amount and type of research that is being conducted. A high threshold of acceptable research risk implies that most biomedical research will be carried out, but the risks to individual participants are likely to be excessive in at least some studies. By contrast, a very low threshold of acceptable risk will preclude a lot of research from being conducted, some of which is likely

to involve acceptable risks. This could unnecessarily restrict progress in clinical care and our understanding of disease. Risk-benefit evaluations in research therefore need to strike an appropriate balance between protecting participants from excessive risks, while allowing acceptable research to proceed.

To be ethically appropriate, biomedical research studies must satisfy a number of ethical requirements, including the requirement of a reasonable risk-benefit ratio (Emanuel et al. 2000). Most commentators, and essentially all research guidelines and regulations, agree that it is acceptable to expose research participants to some risks for the benefit of others, provided that (1) the risks to participants are minimized and reasonable in relation to the potential benefits for them and/or the potential social benefits gained from the generalizable knowledge produced by the study, and (2) the risks to participants who cannot consent are no more than “minimal” when the study offers no prospect of direct clinical benefit for them (Levine 1986; Emanuel et al. 2000; World Medical Association 2008). These requirements provide a general framework for risk-benefit evaluations. However, they offer little concrete guidance for how to make the judgments they mandate. Thirty years ago, the influential Belmont Report, which lays out the fundamental ethical principles for research involving human subjects, emphasized the “metaphorical” nature of most approaches to evaluating whether the risks and potential benefits of biomedical research studies are “balanced” or produce “a favorable ratio” (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1979). More than 20 years later, a similar document stated that then-current regulations uniformly mandate evaluation of research risks and benefits, but fail to explain how this should be done or make additional guidance available (National Bioethics Advisory Commission 2001). This verdict still holds true today.

Compared to the informed consent process for research participation – a topic that has generated a vast body of literature – risk-benefit evaluations in research remain an understudied area of inquiry. Nonetheless, scholars in bioethics have made significant progress in clarifying key questions and concepts for evaluating research risks and potential benefits over the past decade. For instance, several ethical frameworks for risk-benefit evaluations have now been proposed (Rajczi 2004; Weijer and Miller 2004; London 2007; Wendler and Miller 2007). Upper limits of acceptable research risk, especially in the context of pediatric research, have sparked significant debate (Freedman et al. 1993; Kopelman 2004; Resnik 2005; Wendler 2005; Ross and Nelson 2006). Commentators have also explored whether there should be any upper limits on the research risks to which competent, consenting adults may be exposed (Miller and Joffe 2009). The present paper will trace these recent debates. Although significant progress has been made, the paper argues that two of the fundamental questions of risk and risk-benefit evaluations in research remain inadequately addressed. First, how should we weigh the risks that the individual research participant assumes purely for research purposes against the potential social value of the knowledge to be gained from a study? Second, how can we justify and delineate upper limits of acceptable research risk? The entry ends by highlighting several important questions that future work will need to address.

## History

The acceptability of research risks has been a concern in the scientific community long before the current ethical and regulatory framework for biomedical research emerged in the second

half of the twentieth century. Investigators designed and conducted experiments with human subjects following longstanding moral traditions, which evolved from the early eighteenth century onward (Halpern 2004). By the early decades of the twentieth century, there was widespread agreement that research is ethical only when it rests on recognized scientific theories and is methodologically sound, given that scientifically invalid studies cannot advance medical knowledge or contribute to the collective good. Researchers were committed to testing medical innovations on animals before introducing them into clinical practice; researchers would also suspend or delay human applications if the risks of an intervention proved too serious in animal studies. In an attempt to reduce risks to participants, many investigators would try risk-laden interventions on themselves before embarking on tests with research participants. Moreover, the use of an investigational intervention was considered justified only when its risks were thought to be lower than the risks of the natural disease that the intervention was designed to prevent or treat. With regard to consent, investigators sharply distinguished between research with healthy subjects and research with patients as well as between therapeutic and nontherapeutic research. Consent was obtained in “nontherapeutic” research and in research with healthy subjects because the research offered no prospect of clinical benefit for participants. By contrast, when participants were also patients and the research intervention was expected to yield clinical benefits, investigators acted consistently with the reigning norms of clinical care, which did not require consent for providing beneficial treatments.

While the historical record attests to these moral traditions regarding risks in research participation, it also reveals tremendous inconsistency in whether and how this moral framework was implemented (Halpern 2004). This is in part due to the ambiguities inherent in the past traditions. For instance, the distinction between research and treatment as well as therapeutic and nontherapeutic research is often blurry, making it difficult to determine when consent ought to have been obtained. However, the inconsistency in implementing the traditional norms regarding research risk also traces back to investigators acting in violation of these norms. In many ways, the current system of independent oversight for research has evolved in reaction to a history of egregious abuse of research participants (Jonsen 1998).

The atrocious experiments with prisoners in Nazi concentration camps often resulted in the planned death of research subjects (e.g., high altitude experiments) and left countless subjects disfigured or permanently disabled (e.g., freezing experiments, sulfonamide experiments). Numerous studies involved such severe pain that they have been equated to medical torture. All experiments were conducted against the will of participants (Mitscherlich and Mielke 1949). The Nuremberg Code, which sets out ten ethical principles for the conduct of research, was written in response to these abuses as part of the allies’ verdict in the Nuremberg trials. Among other things, it states that the “voluntary consent of the human subject is absolutely essential” (Annas and Grodin 1992). In 1964, the World Medical Association followed suit and published the Declaration of Helsinki, which was a response to the Nazi experiments as well as a reaction to the Nuremberg Code (World Medical Association 1964). This document laid out a somewhat different set of ethical principles for biomedical research. Notably, the 1964 Declaration of Helsinki reintroduced the traditional distinction between therapeutic and nontherapeutic research and weakened the Nuremberg Code’s strict consent requirement for so-called therapeutic research. The Declaration also allowed research with participants who cannot give their own informed consent, provided that the consent of guardians or relatives is obtained.

Shortly after the Declaration of Helsinki was promulgated, a Harvard physician publicized a series of cases of abusive research performed in the USA (Beecher 1966). One of the listed studies, conducted by Drs. Chester Southam and Emanuel Mandel, involved the injection of cancer cells under the skin of elderly incapacitated patients. In 1966, the Southam study led the US National Institutes of Health (NIH) to require independent peer review for all of the research receiving NIH funding. This requirement built on prior practices of independent review for research occurring within the NIH Clinical Center, which focused on higher risk studies with healthy volunteers. External review was intended to ensure an independent risk-benefit evaluation, as well as adequate provisions for investigators to obtain the voluntary and informed consent of research participants (Jonsen 1998). The decision made by the NIH marks the establishment of the system of independent ethical and regulatory oversight for research that we know today.

The independent review of research protocols became a legal requirement for biomedical research – first in the USA and subsequently in most countries around the globe – after another research scandal shocked the American public. (However, the system of regulatory oversight in the USA is particular in the sense that research regulations pertain only to federally funded research, as well as to research data that are submitted to the Food and Drug Administration for obtaining market approval for new interventions.) In 1972, the infamous Tuskegee syphilis trial was publicized in the *New York Times*. The Tuskegee trial was a natural history study of syphilis that involved approximately 600 black men who were largely poor and uneducated. The study began in 1934 when syphilis was an incurable disease. However, it continued to follow the natural progression of syphilis even after penicillin became widely available as an effective treatment in the late 1940s. Trial participants were never told of their disease and never treated for it. They were also never informed that they were participating in a research study and that treatment for their condition could have been provided (Jonsen 1998). The Tuskegee study led to the establishment of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, the organization that wrote the influential Belmont Report (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research 1979). The Belmont Report enumerates the guiding ethical principles for the US Code of Federal Regulations for the protection of human subjects, which was first adopted in 1981 and served as a template for research regulations in many other countries. The Belmont Report also advanced the general ethical framework for research risks and potential benefits that remains widely recognized today (see  [Introduction](#)).

The recent history of research ethics and research oversight is insightful for the current state of the art regarding risk-benefit evaluations in at least two ways. First, one must remember that the current ethical framework for risk in research was largely developed in reaction to cases of blatant abuse and mistreatment of research participants. This probably helps to explain why the norms governing risk in research – and research more generally – can seem so “exceptional” when compared to the norms that govern risk in other areas of life, such as work or transport (Sachs 2010; Wertheimer 2010). Second, risk-benefit evaluations in biomedical research – and again, the ethics of research more generally – have a long tradition of being influenced by the norms that govern clinical care. Some of the clinical traditions, such as the distinction between therapeutic and nontherapeutic research and the application of clinical norms in so-called therapeutic studies, have now been widely rejected by commentators and guidelines – including the Declaration of Helsinki, which was revised several times since 1964 (Levine 1999; World Medical Association 2008). However, discussions continue about the distinction between

therapeutic and nontherapeutic research *interventions* and the appropriate role of “clinical equipoise” for evaluating the risk-benefit profile of therapeutic procedures (Weijer and Miller 2004; Wendler and Miller 2007). Much of this debate is fueled by a controversy about the clinical orientation of research ethics. This finding is unsurprising given that many participants in biomedical research are also patients and many investigators are also clinicians, which can give rise to dual roles and dual loyalties. However, it will become clear throughout this paper that the appeal to clinical norms is often inappropriate in the research context.

## Current Research

---

Before reviewing the recent debates about risk-benefit evaluations and upper limits of acceptable research risk, it is helpful to begin with several preliminary remarks regarding relevant concepts and terminology. First, although the term risk-benefit assessment or risk-benefit analysis is commonly used, it is strictly speaking a misnomer (Levine 1986). Risk-benefit evaluations are performed before the study begins; hence one cannot be certain what impact – harmful or beneficial – the study will have. Unlike the term “benefit,” however, the term “risk” captures the likelihood of harm. Therefore, a more precise terminology would be “risk-potential-benefit” evaluations of biomedical research. Because this expression is so unwieldy, the present entry will nonetheless use the term risk-benefit evaluations.

Second, because risk-benefit evaluations are performed before a study begins, the validity of these judgments must be determined *ex ante*. The fact that a study resulted in knowledge of important social value does not change the risk-benefit ratio in retrospect. As the physician-investigator Henry Beecher famously noted, “an experiment is ethical or not at its inception. It does not become ethical *post hoc*” (Beecher 1966). Conversely, the fact that a study seriously harmed some subjects does not necessarily imply that the study exposed participants to excessive risk (Emanuel and Miller 2007). Indeed, assuming we allow research that poses very low risks of serious harm, it follows that some serious harm eventually will occur in the context of ethically acceptable research.

Third, research risks and potential benefits are both a function of two more basic components: (1) the likelihood that a harmful or beneficial event or experience will occur as a result of a research intervention, and (2) the extent to which the event or experience, should it occur, sets back or advances the individual participant’s and/or society’s interests. For example, an allergy skin test might pose a risk of 13–26 per 100,000 performed tests of evoking a mild allergic reaction, which involves self-limiting hay fever symptoms or urticaria requiring antihistamine treatment. If these symptoms occur, they might be considered a small setback to a participant’s interests. Risk-benefit evaluations thus require *empirical judgment* about how likely it will be for different harms or benefits to result from the given research interventions within a study, as well as the study as a whole. Separate evaluation regarding how robust and relevant the available data are to make these judgments are also required. Risk-benefit evaluations also require *normative judgment* regarding the magnitude of the respective harms and benefits to participants, should they occur, and how much value the collected data would have for society at large.

It is widely agreed that risk-benefit evaluations should comprise judgments about all types and degrees of potential harm for participants, including physical, psychological, social, and economic harms (Levine 1986). However, commentators disagree as to whether all types of

potential benefit for participants should be included. Current ethical and legal guidance, as well as common wisdom in bioethics, focus exclusively on the potential *clinical* benefits of research interventions (Macklin 1989; King 2000). This might seem peculiar for readers without a medical background. However, the focus on potential clinical benefits is probably explained by the fact that risk-benefit evaluations in research have traditionally been conceived of as an extension of risk-benefit assessment in clinical care. In the clinical setting, the risks of a procedure need to be outweighed by the procedure's potential clinical benefits because clinicians are obliged to act in the patient's best clinical interests (hence the focus on potential clinical benefits). Recently, however, some commentators have argued that risk-benefit evaluations in research are distinct from risk-benefit evaluations in clinical care and thus the potential economic, social, or psychological benefits participants might realize during the study should also be factored into the risk-benefit calculus. Examples of these benefits might include payment, praise, or feelings of altruism (Jansen 2009; Sachs 2010; Wertheimer 2010); however, this view remains controversial (see [Further Research](#)).

Fourth, risk-benefit evaluations involve a set of judgments that go beyond a direct assessment and weighing of research risks and potential benefits. The term "risk-benefit evaluation," strictly understood, refers to absolute judgments about risks and potential benefits. However, risk-benefit evaluations in research have complex comparative and normative aspects. They typically start with a determination of whether the proposed study achieves the necessary minimum level of social value, given widespread endorsement of the view that research without any social value cannot justify exposing participants to any risks, however small (Emanuel et al. 2000). Efforts to reasonably reduce or minimize the risks to research participants and to enhance the potential benefits for them and society are generally seen as part of the evaluation process as well. Moreover, the risks and potential clinical benefits of so-called therapeutic research interventions need to be evaluated in comparison to the risks and benefits of available alternative treatments, if there are any available. Inclusion of these complex comparative and normative judgments into the process of evaluating research risks and potential benefits can seem confusing and might stand in the way of rigorous conceptual and normative analysis. However, including these judgments makes sense from a practical perspective. The existing ethical frameworks for risk-benefit evaluations are intended to serve as practicable guidance. Such guidance must ensure that investigators, sponsors, ethics committee members, and others systematically address all aspects related to evaluating the risks and potential benefits of biomedical research studies.

## Empirical Evidence on the Practice of Risk-Benefit Evaluations

---

In most countries, research ethics committees (RECs) are responsible for implementing the requirement that biomedical research studies have a reasonable risk-benefit ratio. However, surprisingly little research has investigated how RECs make these judgments. The few empirical studies that are available have produced concerning results. A semi-structured interview study from the Netherlands examined how REC members evaluate the risk-benefit profile of research protocols. In this study, only 6 of 53 reviewers indicated that they use a systematic approach; instead reviewers reported that they largely rely on their intuitive judgment (Van Luijn et al. 2002). While intuition plays an important role in risk-benefit evaluations, reliance on *mere* intuition – where one attempts to determine the risk-benefit profile of procedures and studies

based simply on how risky and beneficial they seem, without any appeal to intervening steps, analysis, or empirical data – increases the chances for mistakes. Extensive research from psychology shows that intuitive risk judgments are subject to systematic cognitive biases (Tversky and Kahneman 1974; Slovic 1987; Weinstein 1989). For example, people tend to judge familiar activities as less risky than unfamiliar activities. This bias increases the chances that those familiar with a research intervention will judge it to be low risk, while those not familiar with the intervention will judge it to be higher risk.

Indeed, several studies have found significant variation in how RECs evaluate the risks and potential benefits of research interventions and protocols. A follow-up study from the Netherlands found that 43 REC members varied greatly in their risk-benefit judgments about a vignette breast cancer study (van Luijn et al. 2006). Thirty percent believed that the risks of the study outweighed the benefits, 21% believed that the benefits outweighed the risks, and 35% assigned approximately equivalent weights to the study's risks and potential benefits. A survey of 188 REC chairpersons in the USA found a similar variation in risk judgments. Respondents were asked to categorize different research interventions based on the regulatory definition of minimal risk in the US Code of Federal Regulations (see [Risk Limits in Research Without Informed Consent](#)). To offer one example, 23% categorized allergy skin testing as minimal risk in healthy 11-year-olds, 43% categorized the same procedure in the same population as a minor increase over minimal risk, and 27% categorized it as more than a minor increase over minimal risk (Shah et al. 2004). A comparable study from Germany, which asked REC chairs to classify several research interventions as minimal or greater than minimal risk, reported similar findings (Lenk et al. 2004). Consistent with these findings, paradigm cases of minimal risk research were reviewed very differently by different RECs (Hirshon et al. 2002; McWilliams et al. 2003; Green et al. 2006a; Mansbach et al. 2007). It seems unlikely that the actual risks of research interventions, such as allergy skin testing, vary to this extent between research sites. This suggests that the current variation in risk-benefit evaluations is at least to some extent unjustified. Some RECs may be underestimating the risks posed by research interventions, thereby failing to protect participants from excessive risks. Other RECs may be overestimating the risks, thereby inadvertently blocking acceptable research. These findings expose the pressing need to develop practicable guidance for risk and risk-benefit evaluations in biomedical research.

## Existing Ethical Frameworks for Risk-Benefit Evaluations

---

Ever since research ethics became a field of inquiry in the mid-1960s, the following has been a key question: under which conditions are the risks to individual participants acceptable in light of the potential social benefits of the research? It is therefore surprising that scholars have only started to systematically address this question over the past decade. The following section critically reviews the existing four ethical frameworks for risk-benefit evaluations in biomedical research. The discussion will reveal that approaches to evaluating the risks and potential benefits of research studies have increasingly shed their clinical orientation. The first framework that was proposed, the component analysis, distinguishes between “therapeutic” and “nontherapeutic” research interventions and essentially requires that “therapeutic” interventions comply with the norms of clinical care. The integrative approach maintains the distinction between “therapeutic” and “nontherapeutic” procedures, but offers a different normative

justification for it. By contrast, the two remaining frameworks – the agreement principle and the net risks test – formulate the same ethical requirements for all research interventions. These approaches are guided by the idea that biomedical research is fundamentally different from clinical care and thus needs to satisfy its own set of ethical requirements. The four existing frameworks for risk-benefit evaluations differ primarily in how to evaluate the risks and potential benefits of so-called “therapeutic” research interventions, which offer participants a prospect of direct clinical benefit.

## Component Analysis

---

The first systematic approach to risk-benefit evaluations was developed by the physician and philosopher Charles Weijer in a paper commissioned, and subsequently endorsed, by the US National Bioethics Advisory Commission (Weijer 2001). Several other versions of this paper exist, as well as papers foreshadowing it (Weijer 1999, 2000, 2001; Weijer and Miller 2004; Miller and Weijer 2006; Freedman et al. 1992). However, the present discussion is primarily based on the commissioned paper. The approach is labeled “component analysis” because it requires independently evaluating the risks and potential benefits of each intervention or procedure involved in a research study, as opposed to making a global risk-benefit assessment of the study as a whole.

While the requirement to independently assess the risks and potential benefits of each research intervention is shared by most approaches to risk-benefit evaluations, component analysis has the distinctive feature of dividing the individual research interventions included in a study into two groups: therapeutic and nontherapeutic. Therapeutic research interventions are understood as those that are administered with therapeutic intent or warrant, such as investigational drugs. Nontherapeutic procedures are administered solely for the purpose of answering scientific questions. For example, blood draws, biopsies, or imaging procedures are often performed purely for research purposes in order to test the safety and/or efficacy of an investigational drug.

Component analysis takes the difference in intent or warrant to be morally significant. It stipulates that the risks of therapeutic interventions be justified only by the intervention’s potential clinical benefits for the individual research participant, whereas the risks of nontherapeutic interventions are justified by the knowledge gained from including the interventions in the study. Component analysis thus calls for “rigorous separate moral calculi” to evaluate the risks and potential benefits of therapeutic and nontherapeutic research interventions (Weijer 2001).

Therapeutic interventions must meet only one ethical requirement. Just like regular clinical procedures, therapeutic research procedures are ethically acceptable only if they promote participants’ clinical interests. To satisfy this requirement, the risk-benefit profile of therapeutic research interventions must be at least as favorable for the individual participant seen as the risk-benefit profile of the established standard of care, if one exists. Clinical equipoise is an indicator of when this requirement is met. Component analysis thus regards clinical equipoise as a (derivative) ethical requirement for therapeutic research interventions.

Clinical equipoise is commonly defined as the “honest, professional disagreement among expert clinicians” regarding which of one or more treatments or interventions is to be preferred from the point of view of the patient-participant (Freedman 1987a). It is assumed that

a disagreement of this sort will appear when the available evidence suggests that the interventions under consideration have comparable risk-benefit profiles. For example, the equipoise requirement allows randomization between an experimental and a standard treatment only when expert clinicians disagree about which of the treatments, and any other available treatments for the condition in question, has a more favorable risk-benefit profile. If one of the available interventions is clearly superior, the equipoise requirement – and hence component analysis – mandates that investigators provide the better treatment to all research participants. In this situation, component analysis precludes the conduct of the trial.

In contrast to therapeutic research interventions, component analysis requires that nontherapeutic interventions meet three distinct ethical requirements. First, the risks associated with nontherapeutic interventions must be minimized, to the extent that doing so is consistent with sound scientific design. Minimizing risks can involve avoiding unnecessary research procedures, identifying less risky methods to test a study hypothesis, or excluding participant groups who are at increased risk of being harmed. Second, the risks posed by nontherapeutic interventions must be reasonable in relation to the knowledge to be gained from the study. Third, in research involving vulnerable populations – commonly defined as research with participants who cannot give their own informed consent, such as children or patients with dementia – the risks of nontherapeutic interventions must be no more than a “minor increase” over the minimal risks posed by daily life activities. No upper limit of risk is specified for the use of nontherapeutic interventions in research with competent, consenting participants.

## Critical Appraisal of Component Analysis

---

Component analysis was the first systematic account of risk-benefit evaluations in biomedical research and thus a crucial step toward improving the unstructured approach used by most RECs. It rightly mandates the evaluation of individual research interventions, rather than making a global risk-benefit judgment about a research study as a whole. However, there are several fundamental problems with component analysis.

First, the distinction between therapeutic and nontherapeutic research interventions is not always clear (Wendler and Miller 2007). For example, an investigational drug in the earliest phase of drug testing is not administered with therapeutic intent because the goal is to gather preliminary data about drug safety, not efficacy. Administering so-called phase 1 drugs therefore seems to be a clear example of a nontherapeutic research intervention, especially as the trials in which they are used typically enroll healthy volunteers who do not stand to gain any clinical benefits from participating in a study. However, available data suggest that phase 1 drugs against cancer offer a prospect of direct clinical benefit for study participants (Miller and Joffe 2008). Thus, in some cases, it would not be unreasonable for investigators to offer these drugs with therapeutic intent or warrant. It is therefore unclear whether phase 1 cancer drugs are therapeutic or nontherapeutic interventions. Similarly, most research interventions offer participants at least some chance of potential clinical benefit. For example, CT scans of the brain that are performed solely for research purposes sometimes detect a treatable brain cancer (Yue et al. 1997; Katzman et al. 1999). Again, it is unclear whether these interventions qualify as therapeutic or nontherapeutic.

Second, even if the distinction between therapeutic and nontherapeutic interventions could be clarified, it does not seem morally relevant for evaluating the risks and potential benefits of research interventions (Wendler and Miller 2007). The goal of risk-benefit evaluations is to ensure that research interventions and studies do not expose participants to excessive risks of harm for the benefit of others. Whether a given level of research risk is excessive depends on the magnitude of the risks, the level of corresponding potential benefits for the participant, if any, and the level of potential social benefit from performing the intervention and study. It does not depend on whether the risks result from a therapeutic or a nontherapeutic intervention. Component analysis contends that “separate moral calculi” are necessary to prevent the risks of nontherapeutic interventions from being justified by the potential clinical benefits of therapeutic interventions (Weijer 2001). However, while this argument supports making a separate risk-benefit evaluation for each research intervention performed in a study, it does not support the use of different methods to make these evaluations. The differential ethical requirements for therapeutic and nontherapeutic research interventions therefore seem to lack a compelling normative justification (Wendler and Miller 2007).

Third, absent a compelling justification, component analysis leads to inconsistent risk-benefit evaluations (Wendler and Miller 2007). By formulating differential ethical requirements for therapeutic and nontherapeutic interventions, component analysis essentially introduces different thresholds of acceptable “net” risk in biomedical research (net research risks are risks that are not, or not entirely, offset by potential clinical benefits for participants; see  [The Net Risks Test](#)). Component analysis allows competent participants to consent to significant risks without any compensating potential clinical benefits as long as the risks result from a nontherapeutic intervention (e.g., a liver biopsy performed for research purposes only). There is no threshold for risks that result from nontherapeutic interventions provided that participants consent and the risks of the intervention have been minimized and are reasonable in relation to the social value of the study. By contrast, component analysis does *not* allow competent participants to consent to risks, even if they are outweighed by compensating potential clinical benefits for them, if the risks result from a therapeutic intervention that has a less favorable risk-benefit profile than available alternative treatments (e.g., a slightly less effective, first-generation cancer drug in a trial comparing the effectiveness of first- and second-generation treatments). This is due to the fact that therapeutic interventions must satisfy the requirement of clinical equipoise and hence cannot have even a slightly less favorable risk-benefit ratio than available alternative treatments. However, considering that the main goal of risk-benefit evaluations is to protect participants from being exposed to excessive risks for the benefit of others, it is inconsistent to allow significant net risks to competent participants for some research interventions, but not for others. Component analysis introduces a further inconsistency by – probably unintentionally – requiring that only the risks of nontherapeutic interventions, but not the risks of therapeutic procedures, be minimized.

Finally, the particular requirement of clinical equipoise for therapeutic interventions seems flawed from an ethical point of view. By adopting a (partially) clinical perspective on evaluating research risks and potential benefits, component analysis introduces the equipoise requirement to ensure that it is acceptable for clinicians to offer research enrollment to their patients. The underlying assumption is that physician-investigators, just like regular clinicians, have an obligation to act in the best clinical interests of research participants. Therefore, offering participation in research must be consistent with this obligation. Component analysis

contends that physician-investigators, by offering research enrollment, continue to act in their patients' best interests when there is a state of genuine uncertainty as to whether the experimental treatment or the standard treatment is superior (i.e., the risk-benefit profile of both treatments is seen as comparable).

The appeal to the ethical norms that govern clinical care in the context of research has been heavily criticized (Miller and Brody 2003). Central to this criticism is the observation that key elements of research – notably, research interventions lacking clinical benefits and the random assignment of different treatments (“randomization”) – are incompatible with a focus on the patient's best interests and individualized decision-making that is characteristic of clinical care (Miller and Brody 2003; Miller and Brody 2007). It has therefore been argued that clinical medicine is a fundamentally different activity than clinical research, and that the norms governing one practice do not apply to the other. To illustrate this point, it is helpful to contrast the fundamental ethical norms governing clinical care and biomedical research. Clinical care aims to benefit the individual patient. Hence, the central ethical principle governing this practice is that clinicians benefit their patients and not harm them. In contrast, biomedical research aims to benefit society by generating generalizable knowledge intended to help future patients. The central ethical principle governing research is that investigators should not exploit research participants by exposing them to excessive risks of harm for the benefits of others. Notably, this principle does not exclude duties of beneficence in research with sick patient-participants. However, the duty not to exploit participants is primary, and investigators' obligations of beneficence are constrained by achieving the scientific aims of a study (Miller and Brody 2007; Joffe and Miller 2008). Acknowledging this fundamental difference between the normative foundations of clinical care and biomedical research appears essential for developing an adequate framework for risk-benefit evaluations. Component analysis fails to do this.

## The Integrative Approach

The integrative approach was developed as an alternative framework for risk-benefit evaluations in biomedical research (London 2006, 2007). According to its author, philosopher Alex John London, traditional research ethics rests on one of two mistaken assumptions: (1) biomedical research is an inherently utilitarian endeavor and (2) moral constraints on the conduct of research are grounded in role-based obligations of either clinicians or researchers. The proposed alternative is to view biomedical research as a cooperative endeavor that is based on liberal-egalitarian ideals. On this view, research is one element within a larger social division of labor that is aimed at creating and maintaining social institutions that foster and advance the basic interests of each community member. The egalitarian component of this view is that each community member has a just claim to equal treatment regarding his or her basic interests. The liberal component is that a basic interest is defined as the fundamental interest in cultivating and exercising those human capacities that are necessary for developing a conception of the good, as well as formulating and pursuing a life plan based on this conception. Basic interests are contrasted with personal interests which individuals have given the particular conception of the good they have developed.

Based on this liberal-egalitarian perspective, the integrative approach sets out two requirements for research risks to be ethically acceptable. First, research risks must result from the least

amount of intrusion into subjects' personal and basic interests necessary for facilitating sound scientific inquiry. Second, research risks must be consistent with an equal regard for the basic interests of research participants as well as members of the larger community whose interests the research is intended to serve.

The second requirement is further specified by two "operational criteria" and a "practical test" to check the first criterion. The first operational criterion specifies the general requirement of equal regard for everyone's basic interests for the group of research participants whose basic interests are compromised by sickness, injury, or disease. Although this is not stated explicitly, the first operational criterion likely applies to research interventions that offer potential clinical benefits for participants. The criterion requires that "therapeutic" research interventions – borrowing the language of component analysis – must protect and advance the basic interests of research participants in a way that does not fall below the threshold of competent clinical care. The proposed practical test to delineate this threshold is to establish that expert clinicians are uncertain about the superiority of the given treatment options, including the investigational drug and/or placebo – a test that has great resemblance to the equipoise requirement in component analysis.

The second operational criterion specifies the requirement of equal regard for everyone's basic interests for those research interventions that pose risks to participants' basic interests without offering potential clinical benefits for them. This criterion requires that "nontherapeutic" interventions pose risks to the basic interests of the individual participant that are no greater than the risks to the basic interests that are accepted in the context of other socially sanctioned activities. To serve as appropriate comparators, these other activities must be similar in structure to research. The integrative approach sets out four necessary requirements for structural similarity: (1) the risks associated with the comparator activity do not add to the activity's social value (the risks are a "necessary evil"); (2) the activity is subject to active public oversight, which is intended to ensure that the risks posed by the activity have been deemed socially acceptable after due reflection; (3) individuals bear the risks of the activity primarily for the benefit of others; and (4) the activity must involve a principal–agent relationship in which one person (the agent) acts in the interests of another (the principal; in the research context, the investigator is seen as the agent and the participant as the principal).

## Critical Appraisal of the Integrative Approach

---

The integrative approach sets out to provide an alternative framework for risk-benefit evaluations in biomedical research. However, in terms of substantive normative content, its overlap with component analysis is striking. Once the complicated set of basic concepts, normative justifications, operational criteria, and practical tests is disentangled, the integrative approach formulates requirements that are highly reminiscent of those in component analysis. It is possible and helpful to recategorize the integrative approach into four ethical requirements that are needed for an acceptable risk-benefit ratio. First, the research must have social value. Second, the risks of all research interventions must be minimized. Third, the risk-benefit profile of research interventions that offer potential clinical benefits for participants – therapeutic procedures using the terminology of component analysis – must be at least as favorable as the risk-benefit profile of the established standard of care if one exists. To make this determination, a slightly modified version of the equipoise requirement is proposed. Fourth, the risks of research interventions that offer no

potential clinical benefits – or nontherapeutic procedures – must be no greater than those of socially sanctioned activities that are relevantly similar to research.

This recategorization shows that the basic setup of the integrative approach is very similar to component analysis. Both approaches distinguish between therapeutic and nontherapeutic research interventions and both require a state of clinical equipoise regarding the risk-benefit profile of therapeutic interventions. However, in contrast to component analysis, the integrative approach explicitly requires that risk-benefit evaluations begin with a judgment about the social value of the research. It also requires that the risks of all research interventions, not only nontherapeutic procedures, be minimized. Both additions are a significant improvement over component analysis. Furthermore, the integrative approach and component analysis advance different substantive limits for the risks of nontherapeutic interventions. Component analysis requires that the risks of nontherapeutic interventions must be outweighed by the potential social benefits of the research, and for research with vulnerable populations, the risks must be no greater than a minor increase over minimal risk. Hence, component analysis sets an upper risk limit for nontherapeutic interventions only when the interventions are performed in participants who cannot give their own informed consent. In contrast, the integrative approach limits the risks of nontherapeutic procedures for *all* participants – including competent, consenting participants – by requiring that the risks be no greater than the risks experienced in activities that are socially sanctioned and structurally similar to research.

The integrative approach is interesting for two reasons. First, of the existing ethical frameworks for risk-benefit evaluations, it is the only one that explicitly sets an upper limit of acceptable research risk for research with competent, consenting participants (see ➤ [Further Research](#)). The underlying idea is that limits to research risks should not be derived from utilitarian considerations. A utilitarian approach to risk-benefit evaluations would recognize risk limits only in cases where the study's potential benefits for participants and/or for society do not outweigh the risks. It follows that a study of tremendous social value could involve very high risks to participants. The integrative approach rejects this line of thought in favor of a “commitment to moral equality” (London 2006). In order to safeguard equality in the research context, the integrative approach permits research participants to assume risks to their basic interests only when the level of risk is no greater than the level of risk involved in other socially sanctioned activities that are structurally similar to research. Due to the absence of a general theory of acceptable research risk, risk comparisons are a common strategy for delineating upper risk limits. However, although such comparisons are the only viable approach at this point, risk comparisons are fraught with two fundamental problems. First, risk comparisons are circular to the extent that independent normative criteria for evaluating the risks of other activities are missing – there is no way of determining whether the risks of the comparator activity are acceptable. A specific problem for the integrative approach is that the risks of activities similar to research might be justified on utilitarian grounds, thus reintroducing a utilitarian thread that the framework wants to avoid. Second, it is difficult to determine when risks comparisons are valid. What exactly makes an activity relevantly similar to biomedical research? The integrative approach proposes four criteria, but further analysis is needed to determine whether these four criteria are both necessary and sufficient for establishing structural similarity.

The upper limits of acceptable risk as set out in the integrative approach pose a further problem. It is widely recognized that greater social value is necessary to justify higher risks to participants. However, the integrative approach merely requires that a given study have some

social value without exposing participants to greater risks than activities that are structurally similar to research. The integrative approach therefore fails to incorporate considerations of how a study's potential benefits for society should relate to the risks posed on individual subjects. This is problematic because studies of acceptable but relatively minor social value are permitted as long as the involved risks are not greater in other accepted and relevantly similar activities. Considering that volunteer fire fighting and paramedic services are the two comparator activities explored by London, the integrative approach likely leads to exposing participants to excessive risks in at least some research studies with relatively small potential social benefit.

Taking into account the relationship between individual risks and potential social benefits does not commit one to pursuing the greatest happiness for the greatest number of people, which is the utilitarian calculus that London rightly rejects. To the contrary, in order to protect participants from excessive risks, it is necessary to set upper risk limits that recognize a limited or constrained proportionality of the risks to participants and the potential social benefits for society. For research risks not to be excessive, greater social value is necessary to justify higher risks to participants – up to the independent upper limit of acceptable research risk that even tremendous social value cannot justify.

The second reason why the integrative approach is interesting is that it offers a new normative justification not only for the distinction between therapeutic and nontherapeutic research interventions, but also for the differential ethical requirements that these two classes of interventions allegedly need to meet. The integrative approach explicitly rejects role-based obligations as a normative foundation for risk-benefit evaluations and thus moves away from the (partial) clinical orientation of component analysis. Instead, the integrative approach is based on the idea that the basic interests of all members of a community require equal consideration. In the research context, this purportedly implies that (1) therapeutic research interventions must not undermine the competent clinical care of research participants and (2) nontherapeutic interventions must not compromise the basic interests of research participants to a greater extent than socially sanctioned activities that are structurally similar to research.

This liberal-egalitarian justification raises a number of questions. Most fundamentally, a liberal-egalitarian conception of social justice is only one of several competing theories of justice. Egalitarian theories of justice, with or without a liberal slant, have not been shown to be decisively superior to sufficientarian or prioritarian theories of justice. But even if one accepts its liberal-egalitarian foundation, the integrative approach continues to raise questions. Similar to component analysis, it fails to give a compelling justification for why nontherapeutic research interventions are allowed to pose risks to participants' basic interests, while therapeutic interventions are not. Indeed, since the integrative approach is fundamentally based on equal consideration for the basic interests of all community members, the differential regard for participants' basic interests seems especially difficult to justify. Furthermore, the integrative approach appears to consistently give priority to equality (i.e., equal consideration for the basic interests of all community members) over liberty (i.e., respect for the personal interests of the individuals of whom the community is comprised). However, it is not clear why equality should be given priority in this way. For example, some individuals might have personal interests in participating in research that poses higher risks to them than the risks involved in socially accepted and structurally similar activities, whatever those activities turn out to be. What is the justification for not allowing these individuals to pursue their personal interests out of concern for equal to everyone's basic interests?

It is equally unclear why the principle of equal consideration for basic interests should preclude some individuals from being exposed to more risks than others. Whether everyone should be exposed to the same level of risks at least partially depends on how many people there are in a community, how many valuable projects there are to pursue, how many people the different projects require, and how many people are willing to engage in the projects. For example, imagine a community whose members are engaged in numerous valuable activities involving low risk for the individuals involved in them, and two activities of incredible social value that pose relatively high risks to the involved individuals. The integrative approach seems to prohibit these latter two activities on the basis of equal consideration for the basic interests of all community members. Yet it seems that the principle of equal consideration for basic interests should not necessarily exclude riskier activities if all community members support these activities, given their important social value, and agree to a fair principle by which the involved individuals are chosen.

## The Agreement Principle

---

The general framework for risk-benefit evaluations endorsed by most research regulations and guidelines requires that the risks exposed to individual research participants are outweighed by the potential benefits for them and/or for society. Philosopher Alex Rajczi rejects this requirement and proposes the “agreement principle” as an alternative approach to evaluating research risks and potential benefits (Rajczi 2004). Unlike the integrative approach, which puts equality first, the agreement principle gives clear priority to the liberty of individuals. The agreement principle is based on the “limited voluntarist” idea that a liberal state must allow citizens to invite others to engage in risky activities as long as a competent and informed decision-maker would accept such offers. In the research setting, this implies that the risks and potential benefits of biomedical research studies should be evaluated from the perspective of a competent and informed decision-maker.

The agreement principle does not specify substantive conditions under which research risks are acceptable. Rather, it formulates three requirements for competent and informed decision-makers that RECs should use to evaluate the risk-benefit profile of research studies. First, research risks and potential benefits should be evaluated from the perspective of competent and informed decision-makers who have a set of values that is, in the very least, minimally consistent, stable, and affirmed as their own. Second, the decision-makers must be fully informed about the nature of the protocol in question. Third, they must reason clearly about whether to enter the protocol using those values. According to the agreement principle, a research study has an acceptable risk-benefit ratio if a competent and informed decision-maker who satisfies these three requirements would enroll in the study.

## Critical Appraisal of the Agreement Principle

---

The agreement principle emphasizes the liberal presumption that people should be free to do what they wish with their lives, provided that their actions are based on competent and informed decisions. At least in liberal democracies, this presumption is likely to be endorsed by many people. The agreement principle does not reduce the ethics of research to the

requirements of informed consent; rather, it explicitly maintains the idea of independent risk-benefit assessment by requiring that RECs prospectively evaluate the risks and potential benefits of research studies from the perspective of a competent, informed decision-maker. According to the agreement principle, because liberal political systems are generally “limited voluntarist” about government intervention, the risk-benefit evaluations should take a “limited voluntarist” approach as well.

This justification for evaluating research risks and potential benefits from the perspective of a competent and informed decision-maker differs distinctly from a more common paternalistic framework. Empirical data show that many otherwise competent prospective participants exhibit a variety of decisional defects – for instance, a lack of requisite scientific and clinical knowledge and a tendency to overestimate the potential benefits and underestimate the risks of research (often termed the “therapeutic misconception” (Appelbaum et al. 1987)). These defects make it difficult for prospective participants to make informed decisions about research enrollment. The decisional defects have led some commentators to argue that requiring a favorable risk-benefit ratio is necessary to ensure that participants’ interests are protected during the informed consent process (Miller and Wertheimer 2007). In contrast to this paternalistic position, the primary concern of the agreement principle is not to protect participants’ interests. Rather, the principle aims to maximize individual liberty by limiting state intervention in those risky activities in which a competent and informed decision-maker would choose to participate.

In order to implement the agreement principle, RECs will have to make generalizations about competent and informed decision-makers. REC deliberations are therefore likely to be guided by what the average, normal – or perhaps “reasonable” – decision-maker would choose. However, it is unlikely that the average, normal person will knowingly engage in research that involves a high likelihood of serious harm, such as severe and permanent disability or death, only to promote medical progress. For example, most healthy volunteers would presumably not participate in a smallpox vaccine study that involves a disease challenge (to test the vaccine’s efficacy of preventing infection) when no effective treatment exists and the mortality rate from smallpox is approximately 30%. Or, perhaps some might, but only if the development of a smallpox vaccine had enormous social value and promoted their own interests in some way. Similarly, most patients would probably not engage in very risky research if it offered little prospect of clinical benefit for them and the research was still in its exploratory stages. This implies that the average person would enroll in a study only if the risks of participating in the research are not excessive and they are outweighed by the study’s potential clinical and/or social benefits. In other words, “traditional” risk-benefit evaluations are still needed to implement the agreement principle because they are central to the decision-making of average, competent individuals.

One might therefore assume that the agreement principle adds little to existing accounts of risk-benefit evaluations because it effectively endorses the requirement of a favorable risk-benefit ratio without adjudicating conceptual or normative differences in interpreting this requirement. Yet, the agreement principle differs from the other approaches because it is consistent with at least two research scenarios that would be prohibited by alternative frameworks for risk-benefit evaluations as well as the general framework endorsed by most research guidelines and regulations (see [● Introduction](#)). The first scenario is that some competent and informed decision-makers might agree to participate in research even if the potential benefits do not outweigh the risks. The second scenario is that some competent and informed decision-makers might agree to participate in research if a favorable risk-benefit ratio cannot

be established because the risks and/or potential benefits associated with the research are uncertain. Rajczi himself admits that it is unlikely for decision-makers to be willing to participate in research with an unfavorable or uncertain risk-benefit ratio. In the unusual cases where a competent and informed person would want to participate in such research, it remains unclear why RECs should adopt the perspective of these unique people when their responsibility is to ensure that research risks are reasonable for the average, normal person.

More fundamentally, it is difficult to see why research with an unfavorable risk-benefit ratio merits defense. Why would anyone be interested in such research other than the few competent and informed decision-makers who might agree to take part? Research without a favorable risk-benefit ratio also raises concerns that go beyond those related to protecting the interests of research participants. Although the normative justification for requiring a favorable risk-benefit ratio remains surprisingly underexamined, it seems that the requirement is also grounded, among other things, in the need to protect the professional integrity of physician-investigators, maintain public confidence in the research endeavor, and ensure that societal gains in health and well-being are not won at the cost of exposing participants to excessive risks – even when participants give their consent. The agreement principle does not capture these considerations.

Finally, unlike alternative approaches to risk-benefit evaluations, the agreement principle provides no way to evaluate the risks and potential benefits of research with subjects who are not competent and informed, like children or patients with dementia. Given the importance of conducting research to promote the health of these often underserved populations, this is a fundamental problem.

## Net Risks Test

The “net risks test” was developed by David Wendler and Franklin G. Miller in response to Charles Weijer’s component analysis (Wendler and Miller 2007). Like component analysis, it focuses on evaluating the risks and potential benefits of individual research interventions rather than the entire research study. However, the net risks test’s normative foundation is fundamentally different from component analysis. Component analysis grounds risk-benefit evaluations of so-called therapeutic interventions in the norms governing clinical care; on the other hand, for nontherapeutic interventions, it sets out a research-specific requirement of proportionality between the risks of such interventions and the potential social benefits of the research. By contrast, the net risks test evaluates *all* research interventions based on the same requirements.

The net risks test is grounded in the principle of nonexploitation, which is taken to be the fundamental ethical principle governing biomedical research. The principle of nonexploitation requires that research participants not be exposed to excessive risks of harm *for the benefit of others*. The net risks test is designed to ensure this requirement is met. Significant parts of the net risks test are therefore dedicated to separating research risks that participants assume for their own potential benefit (such as the risks posed by investigational drugs, which are often – but not always – outweighed by the potential clinical benefits) from research risks that participants are exposed to solely to achieve the scientific goals of the study so that future patients can potentially benefit (e.g., the risks of a biopsy performed to test the safety of an investigational drug). These latter types of risk are labeled “net” research risks – risks of harm that are not, or not entirely, offset or outweighed by the potential clinical benefits for

participants. If these net research risks are justified, they are justified by the social value of the information to be gained from the study – whether or not they result from a “therapeutic” or a “nontherapeutic” research intervention (if one were to apply this distinction from component analysis).

The net risks test approach specifies four requirements for evaluating the risks and potential benefits of biomedical research studies. First, the risks of each research intervention in the study should be minimized, and each intervention’s potential clinical benefits should be enhanced. Satisfying this requirement, however, should not compromise achieving the scientific aims of a study.

Second, a research intervention should neither imply an excessive exposure to risk for the individual participant nor an excessive decrease in potential clinical benefit if the participant is also a patient and alternative treatments exist. Implementing this requirement involves assessing whether any research interventions in the study pose “net” risks to the individual participant and, in a second step, evaluating whether these net risks are excessive. Interventions that pose no net risks require no further evaluation given that the risks of these interventions are offset by the potential clinical benefits for the individual participant.

To determine whether a research intervention poses net risks, it is helpful to distinguish three types of net risks (Rid and Wendler 2011). *Absolute net risks* arise when the risks of an intervention are not outweighed by the intervention’s potential clinical benefits. Absolute net risks are *pure* when the research intervention poses risks without offering any potential clinical benefits for participants and *impure* when a research intervention offers potential clinical benefits for participants, but the benefits do not outweigh the risks. For example, a lumbar puncture poses impure, absolute net risks when it is performed primarily for research purposes – it offers some clinically relevant information that would not be available in routine clinical care, yet the benefits of this information typically will not be important enough to outweigh the risks of the lumbar puncture. (If the benefits did justify the risks, the procedure would likely be part of standard medical care.) *Relative net risks* arise when the risks of a research intervention are outweighed by its potential clinical benefits, but the intervention’s risk-benefit profile is likely to be less favorable than the risk-benefit profile of available alternative treatments or procedures. Finally, *indirect net risks* arise when a research intervention itself has a favorable risk-benefit profile, but the intervention diminishes the typical risk-benefit profile of other research or clinical procedures that are provided as part of, or in parallel to, the study. For example, an investigational drug against liver cancer might alter the risk-benefit profile of diuretics, a standard treatment for the ascites frequently associated with this cancer.

Once a research procedure is found to pose any of these three types of net risks to participants, the net risks test approach requires that the level of net risks be sufficiently low. To implement this requirement, it must be determined that the given intervention’s net risks fall below the absolute upper limit of acceptable net risks for research interventions. Arguably, there are levels of net risks that even tremendous social value and the informed consent of participants cannot justify (see [The Debate About Upper Limits of Acceptable Research Risk](#)). For example, one might think it unacceptable to expose research participants to a 30% risk of death for purely scientific purposes, even if participants consent. If the net risks of an intervention clearly exceed these absolute upper limits of acceptable research risk – whatever they turn out to be – the intervention should not be included in the study. If the scientific goals of the study cannot be achieved without including that intervention, then the study as a whole should be rejected.

Third, if a research intervention poses any net risks, these net risks must be justified by the expected knowledge gained from using that intervention in the study. This requirement ensures that net risks to the individual research participant – provided that they do not exceed the absolute upper limits of acceptable net risks – are not excessive in relation to the potential benefits to society.

Fourth, the *cumulative* net risks of all research interventions in a study must not be excessive. This requirement is intended to block research studies that include numerous procedures posing excessive aggregate net risks even though each procedure poses acceptable levels of net risks when evaluated separately.

## Critical Appraisal of the Net Risks Test

---

When compared to the alternative approaches to risk-benefit evaluations, the net risks test has the clear advantage of offering a consistent approach to evaluating research risks and potential benefits. The agreement principle leads to counterintuitive results because it endorses research with an unfavorable risk-benefit ratio and offers no guidance for research with participants who cannot consent. Neither component analysis nor the integrative approach gives a sound justification for why the risks of so-called therapeutic and nontherapeutic interventions should be held to different normative standards. The net risks test avoids these problems by requiring a favorable risk-benefit ratio both in research with competent, consenting participants and participants who cannot consent and by stipulating the same ethical requirements for all research interventions in a study, whether or not the interventions could be classified as “therapeutic” or “nontherapeutic.” A further advantage of the net risks test is that it captures the fundamental ethical concern about risks in research, namely, that study participants are exposed to risks for the benefit of others. It isolates the research risks that are not, or not entirely, offset by potential clinical benefits for participants, and evaluates these net risks in light of the social value of the research. By requiring that the net risks not be excessive, the net risks test approach also sets a clear limit to the risks that individuals are allowed to assume for the benefit of others (although it fails to clearly specify this limit; see below). The net risks test therefore explicitly rejects a utilitarian calculus of aggregating the net benefit of a study. At the same time, the test recognizes a constrained or limited proportionality of the net risks to individual participants and the potential social benefits of the research. This captures the common intuition that higher social value is necessary to justify higher risks to participants, while certain levels of research risk – for example, a very high likelihood of death – cannot be justified even by tremendous social value.

Despite these advantages, a major shortcoming of the net risks test is that it fails to specify several of the key concepts it invokes (London 2006, 2007; Weijer and Miller 2007). When are research risks “excessive”? To what extent is the answer to this question influenced by the study context (e.g., participants’ ability to consent)? Under which conditions are the net risks of a research intervention “justified” by the knowledge to be gained from the study? It would be unreasonable to expect any framework for risk-benefit evaluations to develop algorithms or decision rules to address these questions that would yield only one verdict about the risk-benefit profile of each possible protocol. Given the complexity of risk-benefit evaluations, any framework will have to rely on intuition and normative judgment, while clarifying and constraining the role played by intuition.

It is also important to note that upper limits of acceptable research risk and the appropriate relationship between individual risk and potential social benefit pose unmet challenges in research ethics. For example, much of the criticism raised against the net risks test equally applies to component analysis. Like the net risks test, component analysis offers no specific guidance for determining whether the risks of “nontherapeutic” interventions are reasonable in relation to the potential social benefits of the research. Component analysis uses the “risks of daily life” standard to set upper risk limits in research with vulnerable populations, but although this standard is less vague than the concept of “excessive” risk used by the net risks test, it is far from widely accepted (see [❸ Risk Limits in Research Without Informed Consent](#)). Finally, to fairly assess the net risks test – and any other framework for risk-benefit evaluations – it is important to distinguish between the formal method that one uses to evaluate research risks and potential benefits from the substantive standards that they must satisfy. The formal method guides the process of evaluating the relation between risks and potential benefits (e.g., component analysis turns around the distinction between therapeutic and nontherapeutic research interventions, whereas identifying any risks posed by solely for research purposes is central for the net risks test), and the substantive standards specify acceptable levels of research risk (e.g., component analysis invokes the “risks of daily life” standard for minimal risk in research with vulnerable populations). A complete approach to risk-benefit evaluations will require both: a correct formal method and appropriate substantive standards for delineating thresholds of acceptable research risk. The net risks test appears to offer the proper formal method, but it fails to specify the substantive standards that are also necessary for evaluating the risks and potential benefits of biomedical research studies.

## Practical Implications of the Different Frameworks

---

One might wonder whether the discussion of the existing frameworks for risk-benefit evaluations produces any practical relevance. While it is difficult to see how the agreement principle could be applied in practice, the remaining three approaches to evaluating research risks and potential benefits are sufficiently practical. Which approach is chosen will likely have significant practical implications. To illustrate this point, consider a study comparing a first-generation drug and a second-generation drug against liver cancer (drug A and B). Because drug A is the first-generation drug, it is highly likely that drug A will have a less favorable risk-benefit ratio than drug B. However, the two drugs have never been compared directly. Since A costs a fifth of what B costs, the study aims to determine whether B is sufficiently better than A to justify its higher costs. If judged by the requirements of component analysis and the integrative approach, the study would be rejected as ethically unacceptable for lacking clinical equipoise – it seems highly unlikely that expert clinicians would disagree regarding whether A or B is preferable from the point of view of prospective participants. By contrast, the study could be approved under the net risks test provided that (1) receiving drug A rather than drug B an excessive decrease in potential clinical benefit and/or excessive increase in risk (hence, it is not associated with excessive net risks) and (2) the net risks to subjects are justified by the value of the information to be gained from the study. Data regarding the comparative and cost-effectiveness of various treatments is vitally needed in order to effectively manage scarce health-care resources. A prohibition of comparative and cost-effectiveness research when the associated net risks to participants are

not excessive can undermine the goal of achieving or maintaining universal access to health care. The practical implications of endorsing the net risks test over component analysis or the integrative approach can therefore be consequential.

## The Debate About Upper Limits of Acceptable Research Risk

---

As mentioned above, how to define and delineate upper limits of acceptable research risk constitutes one of the unmet challenges in research ethics. This finding is unsurprising if one considers that risk limits in research pose one of the fundamental quandaries in moral theory – namely, when it is acceptable to expose individuals to some harm or risk of harm for the benefit of others. Some research ethicists have argued that it is impossible to answer this question because we lack a common measure or scale to compare research risks and potential benefits as well as determine their relationship to each other (Martin et al. 1995). However, while weighing individual risks against potential social benefits is difficult and raises profound philosophical questions (e.g., about the “separateness” of persons, Rawls 1971), it is important to note that these judgments are not unique to the research context. Indeed, most policy decisions depend on making trade-offs between individual risks and potential social benefits. For example, in deciding whether a new highway should be built near an elementary school, city planners must weigh the potential benefits to commuters against the risks posed to the children and set some upper limit of acceptable risk for the project. Although these judgments are complex and less than fully understood, we have clear normative ideals for how policy makers and public officials should make such decisions: they should serve as “ideal social arbiters” who (1) carefully consider the risks and potential benefits for all affected parties, ensuring that the risks to individuals are not excessive but rather proportionate to the personal and/or societal benefits; (2) give everyone’s claims fair consideration; and (3) treat like cases alike across different areas of policy (Rid and Wendler 2011). This suggests that trade-offs between individual risks and potential social benefits are not exceptional for biomedical research, and that they can be made, and often are made, based on clear – albeit very general – normative standards.

A recent paper argues that these standards can be fruitfully transferred to the research context (Rid and Wendler 2011). When considering upper limits of acceptable research risk in the given study context, reviewers should seek to adopt the perspective of an ideal social arbiter. Would a fully informed and impartial social arbiter recommend the study in question? To provide further guidance and context for these deliberations, different approaches to defining and delineating upper limits of acceptable research risk have been discussed in the literature. They are presented in the following two sections.

### Risk Limits in Research without Informed Consent

---

There is widespread agreement that research risks should be limited if the informed consent from participants is not obtained (e.g., in research involving deception) or cannot be obtained (e.g., in research involving children or incapacitated adults). Most ethical and regulatory guidelines define the upper limit of acceptable risk in this context as “minimal” risk, although a few documents allow for a “minor increase over minimal” risk in certain pediatric research studies (Department of Health and Human Services 1991; Ad hoc group for the development of implementing guidelines for Directive 2001/20/EC 2008).

Despite the widespread endorsement of the minimal risk threshold, there is no widely agreed definition of minimal risk. Different definitions have been proposed in the literature or implemented in regulatory documents. Some aim to specify the meaning of minimal risk, for example, by citing the lexical definition of minimal – the “least possible” risk (McIntosh et al. 2000) – or by stipulating that risks are minimal if they do not involve any risks of serious harm (Nicholson and Institute of Medical Ethics 1986) or result only in a slight and temporary health impact (Council of Europe 2005). Other definitions invoke risk comparisons, stating that research risks are minimal if they do not exceed the risks posed by routine clinical or psychological examinations (Council for International Organizations of Medical Sciences 2002; Kopelman 2004; Resnik 2005), daily life activities (Department of Health and Human Services 1991; Freedman et al. 1993), or charitable activities (Wendler 2005). Yet other definitions of minimal risk appeal to the moral responsibility of decision-makers. For example, some commentators have argued that risks are minimal if they would be endorsed by scrupulous parents or caregivers (Ackerman 1980; Nelson and Ross 2005; Ross and Nelson 2006).

It is beyond the scope of the present paper to critically review each of the proposed definitions of minimal risk. Readers should note, however, that all of the prominent definitions are problematic in some way. In an Additional Protocol to the Convention on Human Rights and Biomedicine, the Council of Europe requires that minimal risks in research result in no more than a “very slight and temporary” impact on participants’ health (Council of Europe 2005). However, a risk of serious or lasting harm can be “minimal” if the likelihood is sufficiently low. For example, a blood draw is widely – and arguably appropriately – considered a minimal risk procedure although it poses a very small risk of serious infection or permanent nerve damage. Definitions of minimal risk that strictly exclude risks of serious harm ignore the fact that research risks are a function of both the likelihood of a harm occurring and the magnitude of that harm, should it occur. Any risk threshold must therefore be sensitive to the relationship between these two basic components of risk.

The Council for International Organizations of Medical Sciences endorses the “routine examinations” standard for minimal risk, which requires minimal risks to be “no more likely and not greater than the risk attached to routine medical or psychological examination[s]” in the study population (Council for International Organizations of Medical Sciences 2002). However, some routine examinations clearly pose more than minimal risks, while certain nonroutine procedures pose essentially no risks. For example, a colonoscopy is a “routine” procedure in older adults as it is widely recommended by professional organizations and routinely performed (Levin et al. 2008). However, in addition to other risks, diagnostic colonoscopies are associated with a 30–650 risk of colon perforation per 100,000 performed procedures; such an outcome would typically require surgical management (Damore et al. 1996). This incidence of colon perforation likely exceeds the acceptable likelihood of research harms of this magnitude for minimal risk procedures. By contrast, Reiki – a Japanese technique where a clinician transfers healing energy by placing his or her hands a few centimeters away from the patient’s body – is not a routine procedure. However, it seems highly unlikely that Reiki poses any risks to patients.

Finally, the US Federal Regulations use the risks of daily life standard for minimal risk, which stipulates that “the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves than those ordinarily encountered in daily life” (Department of Health and Human Services 1991). However, many daily life risks – for instance, the risk of a child having an accident at home – are unacceptably high. It would

therefore be wrong to use daily life risks *per se* as a standard for acceptable research risk. Furthermore, the risks of daily life activities are dissimilar to the risks in research because individuals are usually exposed to them for their own benefit, rather than for the benefit of others (Kopelman 2004; Wendler 2005). For example, if someone takes the car to see his or her family or friends, he or she incurs the risks of the ride for the pleasure of seeing their loved ones. By contrast, although some research participants may experience personal satisfaction from helping others, they fundamentally assume the risks of research interventions to advance scientific understanding and/or the treatment of future patients. Risk comparisons can be useful when delineating upper limits of acceptable research risk (Rid et al. 2010), yet for these comparisons to be valid, it is crucial that the comparator activities be relevantly similar to research.

In addition to the conceptual and normative challenges of defining the minimal risk threshold, a further challenge is that there are very few methods for implementing the proposed definitions. Most guidelines and regulations use examples to illustrate the given definition of minimal risk. For example, the Office of Human Research Protections in the USA offers a list of minimal risk procedures used for collecting biological specimens. The list includes, among other interventions, non-disfiguring hair and nail clippings, the collection of external secretions, and the collection of mucosal cells by buccal swab (Office for Human Research Protections 1998). Illustrative examples are highly valuable. However, the available documents typically do not justify why the listed interventions qualify as minimal risk procedures. This is problematic because users cannot verify that the listed interventions indeed pose minimal risks except by relying on their intuitive judgment. Without a systematic method for making minimal risk judgments, it is also difficult to evaluate the risks of interventions that are not listed and to take into account the variation in risk depending on how a procedure is performed.

The only existing approach for implementing minimal risk definitions is the “systematic evaluations of research risks” (SERR) method (Rid et al. 2010). SERR allows REC members to implement risk definitions that invoke risk comparisons, setting out a method to systematically delineate, quantify, and compare the risks of research interventions with the risks of appropriate comparator activities. By explicitly drawing on the available data, and by evaluating the risks of research interventions in comparison to the risks of other activities, SERR has the advantage of reducing the influence of cognitive biases that can distort our intuitive judgments about risk (Tversky and Kahneman 1974; Slovic 1987; Weinstein 1989). However, the application of SERR remains limited at this point because the available data on the risks of research interventions are scarce (Rid and Wendler *forthcoming*), and we lack systematic criteria for identifying appropriate comparator activities (although the integrative approach offers some preliminary guidance; London 2006, 2007).

## Risk Limits in Research with Informed Consent

While there is widespread agreement that research risks should be limited if the informed consent from participants is not or cannot be obtained, most existing guidelines and regulations set no explicit upper risk limits in research with competent, consenting adults, provided that the risks are reasonable in relation to the potential social benefits of the research. The notable exception is the Nuremberg Code (Annas and Grodin 1992). The Nuremberg Code

stipulates that “no experiment should be conducted where there is an *a priori* reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.” This statement appropriately directs attention to the sometimes serious risks associated with research. However, it runs into a similar problem as those definitions of minimal risk which require that minimal risk procedures pose no risk of serious harm. Like these definitions, the Nuremberg Code ignores that limits of acceptable research risk need to take into account both the likelihood of a harm occurring and the magnitude of that harm, should it occur. The Code excludes research studies only if serious harm to participants is certain to occur (“...death or disabling injury *will* occur [emphasis added]...”). However, this risk limit seems too permissive when one considers that many people would probably consider a high likelihood of death or serious injury imposed for purely research purposes – for example, a 30–40% risk of death – to be unacceptable.

Although explicit regulatory guidance on absolute upper risk limits is largely absent, the vast majority of RECs are unlikely to approve research studies that involve a high risk of death or serious injury, even when the research involves competent, consenting adults. Moreover, the fact that the public has had strongly negative responses to the occurrence of severely adverse events in studies that offered no potential clinical benefits for participants – such as the death of Ellen Roche, a healthy volunteer in a study investigating the pathophysiology of asthma or the drastic immune response of several healthy subjects in the Phase 1 TeGenero trial (Steinbrook 2002; Suntharalingam et al. 2006) – suggests that many people endorse absolute upper limits of acceptable research risk. (One needs to consider, however, that these judgments may be distorted by hindsight bias). It also seems that no morally serious person would think it permissible to kill someone purely for research purposes, even if the investigator had obtained highly scrutinized voluntary and informed consent and the research had tremendous public health value. All this suggests that there are upper limits on acceptable research risk, even in the context of informed and voluntary consent. Yet, what defines these risk limits remains an open question.

The only academic paper dedicated to this issue argues that the uncertainty of producing potential social benefit from any particular research study calls for prudence in exposing individual participants to substantial research risks (Miller and Joffe 2009). Yet, this line of argument does not exclude exposing participants to very high risks if the social value of a given study is substantial and almost certain to materialize. However, this view goes against the widespread intuition that societal gains in health and well-being should not be won at the cost of exposing individual participants to excessive risks, even when they give highly scrutinized informed consent.

The integrative approach (London 2006, 2007) also sets upper risk limits in research with competent, consenting participants, although it does not explore the matter in detail. As discussed above, the approach requires that the risks of “nontherapeutic” research interventions be no greater than the risks of activities that are socially sanctioned and relevantly similar to research. Another example from the literature is live kidney donation (Miller and Joffe 2009). Although risk limits in research with competent, consenting participants remain an underexplored topic, a common thread from the debate surrounding minimal risk emerges in the attempt to define and delineate risk limits in comparison to the risks posed by other activities. This finding presses the need to develop criteria for identifying appropriate comparator activities for research.

## Further Research

### What Fundamentally Justifies Exposing Research Participants to Risks?

The current, general framework for risk-benefit evaluations puts great emphasis on consent as a condition of acceptable research risk. Only minimal risk research is permitted with participants who *cannot* consent, and it remains controversial whether even this research is justified (for a good overview in the context of pediatric research, see Wendler 2010). Conversely, there is no explicit upper limit of risk in research with participants who *can* consent, as long as the risks to participants are reasonable in relation to the potential benefits of the research (Miller and Joffe 2009). But is it the consent of participants that fundamentally justifies exposing participants to research risks? It is telling that commentators have addressed this question primarily in the context of research that involves participants who cannot themselves consent, such as children (McCormick 1976; Ackerman 1980; Freedman et al. 1993; Brock 1994; Ross 1998; Wendler 2010). There is no corresponding literature on research with competent, consenting participants; this seems to suggest that exposing participants to research risks is not – or significantly less – worrying when consent can be obtained. Moreover, those commentators who argue that research without consent is justified often invoke some approximation of consent. For example, advance consent (Ellis 1993), hypothetical consent (Maio 2002), presumed consent (Manning 2000), retrospective consent (Abramson et al. 1986), proxy consent (World Medical Association 2008), parental consent (Ross 1998), the obligation to consent (McCormick 1974), and hypothetical consent to the institution of clinical research (Brock 1994) have all been proposed to justify research with participants who are unable to make their own decisions.

Consent clearly has an important role to play. After all, most research interventions involve some level of intrusion into participants' privacy and/or bodily domain, which typically requires permission. But, unlike current approaches suggest, it appears that consent does not fundamentally justify research risks. If consent were fundamental, it would be either a sufficient or a necessary condition for acceptable research risk. Yet, as outlined above, most people would probably not think it permissible for an investigator to put study participants at a very high risk of death purely for research purposes, even if he or she obtains valid informed consent and the study has tremendous social value. Conversely, nearly everyone agrees that it may be permissible to conduct important research without consent, such as research on childhood vaccinations, when the risks are sufficiently low. This suggests that consent, while important, is neither sufficient nor necessary for acceptable risk in research.

Instead, it would seem that the relationship between risks to participants and the potential social value of research is fundamental for determining the acceptability of research risks. Without social value, investigators would not be justified in exposing participants to any research risks (Emanuel et al. 2000). This suggests that risk-benefit evaluations should fundamentally revolve around the relationship between the risks that individuals incur for purely research purposes and the potential social benefits of the research, with consent becoming a necessary, but not a sufficient condition for exposing participants to *substantial* risks of harm. This perspective seems promising because it would capture our intuitions both that consent is not sufficient to justify any level of research risk, and that consent is not always necessary in low risk research. However, to scrutinize these intuitions, and to develop a sound normative foundation for risk-benefit evaluations in research, we need more analysis of what

fundamentally justifies exposing study participants to research risks – those who cannot themselves consent as well as participants who can consent.

## When Does Research Have Social Value?

---

It is widely – although not universally – agreed that research must have social value for research risks to be acceptable (for authors who question that social value is a necessary condition for acceptable research risk, see Rajczi 2004; Sachs 2010; Wertheimer 2010). Despite this, there is no clear concept of what makes research socially valuable. According to some, scientific value is sufficient for social value (Freedman 1987b). To others, research is socially valuable when it has the potential to improve health and well-being (Levine 1986; Emanuel et al. 2000). However, if the potential for health improvements is unlikely and/or temporally distant – for example, in cellular pathology – this concept collapses into the concept of social value as scientific value. Moreover, it is not clear how the potential to improve health and well-being should be evaluated. Cost-effectiveness analysis, the dominant approach for evaluating social benefits in the allocation of scarce health-care resources, is notoriously blind to distributive concerns (Brock 2004). Moreover, traditional cost-effectiveness analysis has no means of factoring in the likelihood that a research study might lead to the successful development of a new intervention. The literature on research priority-setting has developed criteria to guide decisions about research funding that comprise social value judgments (Institute of Medicine 1998; Kaplan and Laing 2004; Council on Health Research for Development 2006; Hollis and Pogge 2008). Yet, it is unclear to what extent these criteria should be transferred to the context of evaluating the risks and potential benefits of research studies. For example, funding criteria might deliberately aim to encourage women to pursue a career in science. But although promoting gender equality in science is a socially valuable goal, gender equality is arguably not the type of social value that should offset risks to participants. More conceptual work on the social value of research is needed.

## What Level or Type of Social Value Is Necessary to Justify Increasing Risks to Research Participants?

---

Another unresolved question relates to the constrained or limited proportionality of individual risk and potential social benefit. There is widespread agreement that greater social value is necessary to justify higher research risks to participants until the absolute upper limit of acceptable research risk in the given population is reached. But when does one study have greater social value than another? Greater social value can be generated through more value of the same type (e.g., greater health improvement for more people as opposed to less improvement for fewer) or through social value of a different, more “valuable” type (e.g., research into an HIV vaccine of a foot fungus medication). One could imagine various ways in which different types or magnitudes of social value might be seen as justifying higher risks to participants, such as, clinical as opposed to “merely” scientific research, research aimed to address catastrophic threats rather than “ordinary” health issues, research that might benefit the worst-off instead of the well-off, “professional” research as opposed to research that is conducted as part of scientific training,

research to settle truly scientific rather than policy debates (or perhaps the other way around), and so forth. There is essentially no literature on what makes research more socially valuable such that the social value justifies exposing participants to increasing levels of research risk.

## What Types of Potential Benefit for Participants Should Be Considered in Risk-Benefit Evaluations?

---

Standard approaches to risk-benefit evaluations span all types of risk to participants, but they typically exclude certain types of potential benefits. Financial benefits – in particular, payment for participating in a research study – are usually excluded because they can turn an otherwise unfavorable risk-benefit ratio into a favorable ratio. The concern is that any study could have a favorable risk-benefit ratio for the individual participant as long as the payment is high enough (Macklin 1989). Although this is never stated clearly, the same line of argument would exclude other potential benefits for subjects from entering the risk-benefit calculus, for instance, gaining psychological satisfaction from contributing to progress in clinical care and science, accruing social esteem for one's contribution, and enjoying the interaction with investigators and other subjects. As mentioned above, the exclusive focus on the potential *clinical* benefits for participants is probably explained by the fact that risk-benefit evaluations in research have traditionally been conceived of as an extension of risk-benefit assessments in clinical care. However, this position has been questioned as part of the general move away from a clinical orientation in risk-benefit evaluations (Jansen 2009; Sachs 2010; Wertheimer 2010). In particular, commentators have argued that RECs should incorporate reasonable judgments about the financial payment when evaluating the risk-benefit profile of a study (Wertheimer 2010).

The argument for incorporating payment is typically based on two assumptions (Wertheimer 2010). First, people are paid in many other areas of life – in particular, the occupational sector – to incur risks they would otherwise not incur. There is no reason why research participants should not be treated the same. Second, research is special in that it is complicated and prospective participants suffer from widespread decisional impairments regarding their enrollment decisions. This pertains not only to the risks and potential clinical benefits of the research, but also to the level of payment necessary to fairly compensate for those risks: When one misjudges the risk or risk-benefit profile of a study, it is difficult to evaluate whether the level of compensation is appropriate. If one assumes that risk-benefit evaluations are justified on paternalistic grounds – as a way of protecting people from their own misjudgment (Miller and Wertheimer 2007) – it follows that payment should be incorporated into risk-benefit evaluations. Thus, the question of which types of potential benefits should be considered is closely linked to another unsolved problem – namely, what fundamentally justifies risk-benefit evaluations in research. Is it the need to protect participants' interests? Or are there reasons beyond paternalism, such as the need to protect the professional integrity of physician-investigators, to maintain public confidence in the research endeavor (Miller and Joffe 2009) and ensure that societal gains in health and well-being are not won at the cost of exposing even competent, consenting participants to excessive risks?

## How Should We Define and Delineate Upper Limits of Acceptable Research Risk?

---

As discussed above, one of the unsolved challenges in risk-benefit evaluations is the definition and delineation of upper limits of acceptable research risk. Perhaps the most dominant approach is to define upper risk limits in comparison to the risks of other activities. Commentators have invoked the risks of routine clinical or psychological examinations (Kopelman 2004; Resnik 2005), daily life activities (Freedman et al. 1993), and charitable activities (Wendler 2005) to define the minimal risk threshold in research without informed consent. Others have used volunteer firefighting, emergency assistance (London 2006, 2007), and live kidney donation (Miller and Joffe 2009) as possible comparator activities to delineate upper risk limits in research with competent, consenting participants. Given the absence of a general theory of acceptable risk – or more specifically, a general theory of acceptable research risk – it makes sense to set upper risk limits in comparison to the risks posed by non-research activities (see ➤ [Critical Appraisal of the Integrative Approach](#)). Although this approach is ultimately circular, it has important advantages. Risk comparisons provide a context for delineating risk limits, they promote consistent risk judgments across activities in different realms of life, and they allow policy makers and RECs to appeal to considered risk judgments made outside the research context (Rid et al. 2010). However, for risk comparisons to be valid, one must choose comparator activities that are relevantly similar to research and widely considered to be acceptable for the given population. Future research needs to specify both requirements.

## Is the Current System of Research Oversight Sufficiently Sensitive to the Risks Posed by the Research?

---

Recently, there has been increasing dissatisfaction and concern that the current ethical and regulatory framework for research does not adequately calibrate the level of safeguards for participants to the level of risk posed by a study. REC members complain that they spend too much time reviewing low-risk research, which diverts time and resources from the review of research that poses greater risks (Fost and Levine 2007; Kim et al. 2009). Investigators complain about the bureaucratic burden associated with REC review when the risks of the research are low which seems to have little to do with the protection of participants (O'Herrin et al. 2004; Gunsalus et al. 2006; Fost and Levine 2007; van Teijlingen et al. 2008). On the other hand, there is significant concern – often after the serious injury or death of research participants – that the current system of research oversight fails to protect participants from excessive risks (Savulescu et al. 1996; Savulescu 2002). Many therefore call for a “risk-based” system of research oversight that matches various safeguards for participants – including independent ethical review and safety monitoring – to the level of risk posed by the research (European Commission and Health and Consumers Directorate-General 2011; The Academy of Medical Sciences 2011). The idea of a “risk-based” system of research oversight makes intuitive normative sense. If the goal is to protect research participants from excessive risks of harm, more safeguards are necessary if the risks of the research are high, and less if the risks are low. However, it remains unclear what such a system would or should look like. Future research should therefore develop a normative framework for risk-based approaches to research oversight.

Readers will note that the listed questions for future research remain within the traditional focus of risk-benefit evaluations, which concentrates on weighing the risks of a study to participants against the potential benefits to them and/or society. However, when adopting a broader perspective on risk-benefit evaluations, further unresolved questions emerge. What should be done when research results risk being abused (e.g., research on bioterrorism) or the research has the potential to produce “negative” social value (e.g., research on the relation between intelligence and race; for a discussion of such “dual use” research, see Green 2006b; Selgelid 2007, 2009)? When the conduct of research exposes third parties to risks? For example, in challenge studies with infectious diseases, how should we address the risks to individuals who do not participate in the research (Kimmelman 2005; Resnik and Sharp 2006; Hausman 2007)? Risk-benefit evaluations in biomedical research raise a multitude of interesting and important questions for future research to address.

## Acknowledgments

This chapter is based to a significant extent on two papers that I coauthored with David Wendler, Ph.D., from the Department of Bioethics in the Clinical Center of the National Institutes of Health (Rid and Wendler 2010, 2011). My work on this paper was supported by the Swiss National Science Foundation.

Many thanks to Frank Miller for critical comments on an earlier draft of this chapter, and to Greer Donley for editing the manuscript.

**Abstract:** Increase in the use and development of computational tools to govern public health risks invites us to study their benefits and limitations. To analyze how risk is perceived and expressed through these tools is relevant to risk theory. This chapter clarifies the different concepts of risk, contrasting especially the mathematically expressed ones with culturally informed notions, which address a broader view on risk. I will suggest that a fruitful way to contextualize computational tools, such mathematical models in risk assessment is “analytics of risk,” which ties together the technological, epistemological, and political dimensions of the process of governance of risk. I will clarify the development of mathematical modeling techniques through their use in infectious disease epidemiology. Epidemiological modeling functions as a form of “risk calculation,” which provides predictions of the infectious outbreak in question. These calculations help direct and design preventive actions toward the health outcomes of populations. This chapter analyzes two cases in which modeling methods are used for explanation-based and scenario-building predictions in order to anticipate the risks of infections caused by *Haemophilus influenzae* type b bacteria and A(H1N1) pandemic influenza virus. I will address an interesting tension that arises when model-based estimates exemplify the population-level reasoning of public health risks but has restricted capacity to address risks on individual level. Analyzing this tension will lead to a fuller account to understand the benefits and limitations of computational tools in the governance of public health risks.

## Introduction: Governing Public Health Risks

---

- ▶ Nothing is a risk in itself; there is no risk in reality. But on the other hand, anything can be a risk; it all depends on how one analyses the danger, considers the event (Ewald 1991, p. 199).

In June 2009, we faced a risk of a global pandemic caused by A(H1N1) “swine flu” virus. At the moment WHO defined the outbreak a *pandemic*, a viral flu infection turned into a global risk. Two years later the risk assessment process that led to the global call is questioned. Was the “swine flu” a global risk after all? “Nothing is a risk in itself” shows that what is identified as a risk depends on the way in which “danger is analyzed” or how risks are identified.

What, then, is a risk? Risk research answers to that question through three main paradigms: the statistical-probabilistic, the epidemiological, and the sociological. Initially developed for insurance industry, the statistical-probabilistic approach applies various estimates of personal benefits, effectiveness of treatments, and use “risk calculations.” This means translating “successful calculations of risk” into an objective measure. Estimates of how various health-related factors influence the probability of falling ill is a typical example of epidemiological paradigm. It comprises of psychometric studies, which focus on understanding public risk preferences and applies mental modeling to analyze rational decision making. When cultural and individual perception and responses to risk are interlinked, sociological approach is in use. Within this sociocultural paradigm, risk is regarded as a “socially constructed phenomenon although it has some roots in nature.” Furthermore, we can identify governmentality approach, which is based on Foucault’s analysis of societal governance and includes into the analysis broader issues of power as a part of the sociological approaches to risk. This form of analysis includes “construction of realities through practice and sense-making, encompassing the multitude of societal organizations and institutions producing social reality” (Taylor-Gooby and Zinn 2006, p. 43).

In the public health domain, the idea of what counts as a risk has a dynamic nature. Risk from the public health policy point of view may not be a risk for an individual. Dean argues that epidemiological risk forms a “long-standing and pervasive form of risk rationality.” In his words, “epidemiological risk is concerned with the rates of morbidity and mortality among populations.” When talking about epidemiological risk, “the health outcomes of populations are subject of risk calculation” (Dean 2010, p. 218). In regard to public health risks, we can talk about risk rationality as a form of rationality, a way of thinking about and representing events, which happens through calculations (Dean 2010, p. 213). Castell (1991) shows how mental health problems shifted in their classification as dangerous to risk as a part of historical, theoretical, and practical shift toward *risk rationality*. Underneath the emphasis of population as a subject of risk calculation is the historical shift from a family to population as a re-centering concept of economy. Michel Foucault argues that “[...] population has its own regularities, its won rate of deaths and diseases. [...] [S]tatistics shows also that the domain of population involves a range of intrinsic, aggregate effects, phenomena that are irreducible to those of the family, such as epidemics. Population comes to appear above all else as the ultimate end of government” (Foucault 1978/1991, pp. 99–100). Population becomes the object of governance. The attitude or mentality of governance is known as governmentality in Foucault’s work. It refers to the forms of thought, expertise, and knowledge that direct and guide the acts of governance (Dean 2010). How the risk rationality that shifts “dangerousness” of disease outbreaks into risks manifest in epidemiology?

New risks “violate many assumptions of risk calculation,” as Taylor-Gooby and Zinn (2006, p. 25) argue. They are global, complex, and entangled with different areas. They share characteristics of catastrophes. These new risks are “mainly invisible and inaccessible by direct means.” They challenge the statistical-probabilistic approach to risk. How do we encounter these new risks? One way of coming into terms with them is suggested in Smith’s analysis of SARS (Sudden Acute Respiratory Syndrome) epidemic (Smith 2006, p. 3114). He proposes a mediatory approach in order to overcome the dichotomy between the realist and constructivist accounts to risk. According to his “material-discursive” position, “risk is both a materially measurable probability of an event and a socially constructed element of how that probability is perceived by the individual and society.” This mediatory approach is useful when explaining the ways in which risk is represented, anticipated, and processed in models. The mediatory approach does not solely lean on realist interpretation, which sees risk as an objective threat or danger that can be measured independently of the social context within which it occurs. Nor does it reduce risk to culturally or socially constructed threat, which cannot be demonstrated independently of those processes. Close to the realist interpretation is Schlich and Tröchler’s (2006) definition of risk and uncertainty. He says that “one can speak of risk when the probability estimates of an event are known or at least knowable, while uncertainty, by contrast, implies that these probabilities are inestimable or unknown.” Riesch (2011) provides a classification of uncertainties that problematizes the clear-cut division between probability estimates and unknown events. I suggest that new risks, such as emerging infectious outbreaks, can be encountered by accommodating statistical-probabilistic approach of risk calculation (in the form of mathematical modeling) with the questions of governance. In this chapter, I will apply the Foucauldian notion of governmentality and address risk calculation as a *technical rationality*. How could we see public health risks through this lens?

The heterogeneity of the definitions of risk suggests that understanding risk encompasses the following aspects: dangerousness of an event, unpredictability of its occurrence and course,

and severity of its consequences. Infectious disease outbreaks, therefore, form a source of “danger” that affects the public. This means that public health risks are anticipated through surveillance and monitoring procedures, which are carried out by the national public health institutes. Surveillance and monitoring procedures comprise of keeping records of notifiable diseases or participating in international collaboration to govern outbreaks of emerging infections. Surveillance activities are carried out on various levels: on national level by public health institutes (e.g., Health Protection Agency in the UK) and on international and intergovernmental level (e.g., by WHO, ECDC, the European Disease Control Centre). However, risks from infectious outbreaks create a challenge for public health decision makers, who aim at identifying the risks through preparedness planning and revising protective interventions, such as vaccinations. Their interest is to employ predictions of the course of the outbreak. In order to do that, decision makers search for alternative ways to process the information flow. Evidence for developing the required preventive and protective measures for decision-making processes is produced by computer-based modeling techniques. Hence, modeling techniques can be utilized in the encounters with public health risks from infectious diseases. These *modeled encounters* provide predictions that facilitate risk assessment processes. This chapter shows how two modes of prediction: explanation-based and scenario-building provide strategies, not only to produce evidence for the decision-making, but also to translate the potential threat to a quantifiable, measurable risk. By doing so, modeled encounters with risks allow us to follow the social processes that try to control and minimize public health risk in society. In his commentary on climate models, Hulme et al. (2009, p. 127) highlights an important aspect of models, which is highly applicable to predictions from epidemiological models: “Scientists and decision-makers should treat climate models not as truth machines, but instead as one of a range of tools to explore future possibilities.” Through the analysis of the two types of predictions, I will address how epidemiological models function as *technologies* when encountering public health risks.

How is understanding of public health risks formed, estimated, and communicated through modeling? How does public health risk prevention use technical understanding gained by model-based predictions? These are the main questions addressed in the analysis of *modeled encounters* with infectious risks, which arise from *Haemophilus influenzae* type b bacteria and from A(H1N1) pandemic influenzae (“Swine flu” outbreak in 2009). By analyzing these two cases, I will show how modeling provides a way to *encounter* risks, which means that modeling itself forms a base for risk calculation and estimation that allows rendering the available information into predictions (cf. Mansnerus 2009a, 2011).

## About the Case Study

The case study analyzed in this chapter was conducted during 2002–2004 at the University of Helsinki. I observed modeling practices in 22 work meetings (recorded and transcribed, duration of a meeting app. 2 h) at the National Public Health Institute (currently the Institute for Health and Welfare) and conducted 28 thematic, semi-structured interviews (transcribed for analysis) with mathematical modelers, epidemiologists, and computer scientists working as members of the interdisciplinary team (published in Mattila 2006a, b). The models were published in Auranen 1999, 2000; Auranen et al. 1996, 1999, 2000 and Auranen et al. 2004; Leino et al. 2000, 2002, 2004 and Mäkelä et al. 2003. The study analyzes how an integrated simulation

model on Hib transmission in the Finnish population produces *explanation-based* predictions. In this chapter, I will keep the focus on a single, integrated model in order to allow a detailed description of the ways in which the model predicts. The findings from the Hib case will be discussed in relation to microsimulation model on mitigating an *influenzae* pandemic. This example will show how microsimulations produce *scenario-building* predictions. The analysis focuses on detailed micro-level observations and interpretations of the predictive capacities of microsimulations. Both models are chosen, because they provide clear examples of the predictive capacities of simulations. I have chosen not to explore the vast literature on *pandemic influenzae* models, but to concentrate on a detailed level on a single model. The analysis is informed by a practical course “Introduction to Infectious Disease Modeling,” organized by the London School for Hygiene and Tropical Medicine, 2006, which gave me ability to read the models and understand their core structure. As a part of the coursework, we analyzed the published pandemic simulation models and prepared a group exercise on national preparedness planning. I have chosen one of these as an example of scenario-building modeling exercise.

The structure of this chapter is as follows: section [● Toward Modeled Encounters with Public Health Risks](#) discusses the development of modeled encounters in epidemiology. Section [● Predicting Infectious Risks Through Modeling](#) shows how this development takes place when mathematical models are used in public health decision making. I will use two cases as examples to show how public health risks can be governed through modeling. Section [● Further Research: Toward the Analytics of Risk](#) discusses how the tension between individual level risk perception and population-level risk assessment could be reconciled analyzing public health risks suggests further research within the analytics of government approach.

## Toward Modeled Encounters with Public Health Risks

---

Technologies form an integral part of the procedures through which organizations and individuals try to control risks they encounter. These technologies range from software systems to visualizations and representations, from advanced technological structures (e.g., air traffic control) to models (Hutter and Power 2005). Models, or broadly speaking computer-based tools and techniques have become commonly used in various scientific and policy-making contexts. Yet, they have the potential to “legitimate a range of possible social futures,” as Evans (2000) frames the capacity of economic models. Den Butter and Morgan (2000) seem to suggest that models, which are engaged with policy-making processes in economics, actually build a bridge between research and policies or between “positive theory and normative practice.” In their account, these models form a part of the “value chain” through which knowledge is created, stored, and transmitted in organizations.

One of the main reasons to develop modeling techniques is to overcome uncertainties related to complex phenomena, such as climate, economy, or infectious diseases. Establishing modeling practices also helps forming a network that integrates available knowledge and communicates it further. Paul Edwards (1999, p. 439) argues that “Uncertainties exist not only because quantifiable, reducible empirical and computational limits, but also because of unquantifiable, irreducible epistemological limits related to inductive reasoning and modeling”(cf. also Hillerbrand 2010). His argument seems to suggest that due to the very nature of the modeled phenomenon itself, uncertainties remain as a part of the process. As Shackley and Wynne (1996, p. 276) emphasize, scientific knowledge, or the “authority” of

it, is limited in policy making, since it prevents decisions to be made or actions taken. Van den Bogaard (1999, p. 323) shows, on the contrary, that the first macroeconomic model, developed by Tinbergen in the 1930s for the Dutch Central Planning Bureau, was a “liberation both from the uncertainties caused by the whimsical nature of the economy and the woolly theories of the economists.” One form of uncertainties remains within the models, as MacKenzie’s (2005, p. 186) study on financial economics shows, “models affect the reality they analyze.” According to him, this “reflexive connection serves to increase the veracity of finance theory’s assumptions and the accuracy of its models’ predictions,” but it may also function in a counterproductive way (as in his case, the exploitation of arbitrage opportunities by using mathematical models leads to instability of the system). It seems to me that when modeling complex, open systems, such as climate (cf. Gramelsberger 2010) or ecological systems, there will remain uncertainties, because of limited computational capacity, biased reflection of the reality, or unpredictable nature of the phenomena themselves.

Encounters with risk, as Hutter and Power (2005, p. 11) clarify, are events of problematization that “place in question existing attention to risk and its modes of identification, recognition and definition.” “Risk identification,” they continue, “is socially organized by a wide variety of institutions which support prediction and related forms of intervention around the possibility of future events.” When we encounter risks and uncertainties, or predict a possible course of events, we develop and utilize various measurement devices, such as statistical methods, surveys, and models. From a historical perspective, we can identify a shift away from “informal expert judgment toward a greater reliance in *quantifiable objects*,” as Porter (2000, p. 226) argues in his case study of the use of mortality statistics in life insurance industry. The tendencies underlying this shift are addressed by a growing interest in sociology of quantification – i.e., in the “production and communication of numbers.” How do we “do things with numbers?” Espeland and Stevens elaborate J.L. Austin’s idea of speech acts (doing things with words) to the domain of quantification and they call it “doing things with numbers.” They argue that as with words, “numbers often change as they travel across time and social space” (Espeland and Stevens 2008, pp. 402–406). The “change in numbers” could be seen as a parallel process to the one that characterizes how public health risks become quantified through its historical development. This historical development can be aligned with two processes: First, the development and application of mathematical methods in order to understand the dynamics of disease transmission (Mansnerus 2009a), and second, the shift within biopolitics (politics that is concerned with governance of living conditions in a population) toward risk politics (Rose 2001).

The first process, gaining understanding of disease transmission and developing tools to express and represent that process in mathematical terms arose when germ theory of disease located the cause of infections to their microbiological origins, germs. What initiated the move toward mathematical formulations were population-level observations of infectious cycles, such as influenza outbreaks in households in London 1890–1905, as Hamer documented (Hamer 1906). Later on, Kermack and McKendrick (1927) divided the population into specific subgroups, *compartments* of susceptible, infected and immune, which represented different phases observed during an epidemic outbreak. These developments in mathematical epidemiology aimed at identifying various factors that caused transmission of germs and spread of the infectious outbreak.

The second process, which developed toward risk politics, was grounded on the developments on the microbiological level, but emphasizes the ways in which concern for the health of

the population adopted preventive measures. In his analysis of the birth of social medicine, Foucault looks into the organization of the Health Service and the Health Office in England at the end of the nineteenth century. He shows how three functions developed:

- “Control of vaccination, obliging the different elements of the populations to be immunized.
- Organizing the record of epidemics and diseases capable of turning into an epidemic, making the reporting of dangerous illnesses mandatory.
- Localization of unhealthy places and, if necessary, destruction of those seedbeds of insalubrity” (Rabinow and Rose 1994, 335).

The first two aspects in the development of health services show how public health measures take the form of governance. These forms, namely “control of vaccination,” especially if understood as a process of assessing and revising vaccination schemes, and “organizing the record of epidemics” are present when modeling techniques are applied to public health risks. “Control of vaccination” is one component in modeling process; it is applied as a preventive measure, as an estimate in terms of “herd immunity,” immunity cover for the whole of population when only a significant portion of it is vaccinated. This can be obtained as an indirect observation from the models and it allows estimating the vaccination coverage needed to protect the whole population. Organizing the record of epidemics could be extended to cover the predictive functions, as the following case studies will show. So mathematical methods in epidemiology developed initially in conjunction with the early observations of infectious cycles and outbreaks that gave rise to develop preventive actions against these risks.

Even though these aspects are to some extent present in the preventive public health work, the intention behind infection prevention has changed. Rose (2001) argues that the shift toward risk politics happened when public health programs and preventive medicine were transformed and health became “economized,” meaning that individuals were expected to become active in maintaining their well-being and health. Whereas the earlier programs understood health as fitness and were hence framed to tackle the “unfitness of populations,” the current emphasis is on costs of ill health for the economy (Rose 2001, pp. 5–7). This shift results in various strategies for the government of risk. Rose says that risk denotes in this context “a family of ways of thinking and acting, involving calculations about probable futures in the present followed by interventions into the present in order to control that potential future.” And, he continues, demand for these collective measures increases. As we will learn from the detailed study of how modeled encounters with public health risks happen, I would argue that the shift toward risk governance is still partially embedded in the preventive ideals of public health risk perception. The predictions from the models I will study are not estimates of the economic costs of a pandemic, although those have been taken into account through different analyses. Model-based predictions seem to function as a way to estimate the need to vaccinate and to assess the spread of the infection. On the basis of these predictions, protective measures toward the public can be initiated. But how do we actually build models to predict public health risks?

## Current Modeling Techniques

Modeling techniques provide a way to produce predictions, or in broader terms evidence for decision-making processes and, as such, they are a new way to encounter public health risks.

Modeled encounters with public health risks are approached in terms of studying the nature of model-based predictions. These predictions form the core of our attempts to control public health concerns, prepare for sudden outbreaks, or estimate population-wide effects of bacterial or viral transmissions. Modeled encounters with risk introduce two modes of predictions, those based on explanations and those building scenarios for future events or developments. Scenario in this context means an outline of an imagined, possible situation that has been quantified through modeling. By locating modeling into the context of measurement, we will learn the different ways in which trust, credibility, and usability of the modeled predictions emerge and are communicated from research domain to decision-making processes (cf. Morgan and Morrison 1999; Boumans 1999; van den Bogaard 1999).

What do we then understand by modeling? Generally speaking, computer-based models (including simulation techniques) in infectious disease epidemiology share the following characteristics: First, they have a three-part elementary structure, which comprises of data element, mathematical method and computational techniques, and element of substantial knowledge, or epidemiological component. Secondly, they are “tailor-made,” usually addressing specified research question, which to some extent limits their applicability. Thirdly, majority of these models rely on currently available data. And it is precisely the need to reuse and reanalyze the data that partially motivate the model-building exercise. Fourthly, micro-practices that are independent the context of application, say the pathogen studied, can be identified within modeling process. A detailed analysis of the eight consecutive steps in modeling process is documented in Habbema et al. (1996, p. 167):

- Identification of questions to be addressed
- Investigation of existing knowledge
- Model design
- Model quantification
- Model validation
- Prediction and optimization
- Decision making
- Transfer of simulation program

The importance of setting the question follows the idea of *tailoring* a model to address particular interests. Investigation of existing knowledge is a process in which existing literature, laboratory results, experiences of existing models, and data from surveillance programs are integrated as a part of model assumptions. Morgan (2002) aligns model building with similar steps to those mentioned by Habbema et al. (1996), although her focus is on economic models. The main difference is that in her account the model is first to build to represent the world, then subjected to questions and manipulation in order to receive the answers to the questions, then relating the answer to real-world phenomena.

Model design follows the existing understanding of how the phenomenon of interest behaves and is often represented through a compartmental structure. Compartmental structure means that the population is divided into subgroups according to the impact on immunity, susceptibility, and potential recovery from the modeled infection.

Model quantification is the process of estimating the optimal parameter values and setting the algorithms to run the simulations. In Habbema's et al. (1996) account, model validation means checking the model against data from control program. The particular interest in this

chapter is to analyze how the step from prediction and optimization to decision making is taken in regard to public health risks.

By transfer of simulation program, Habbema et al. refer to the generalizability of the computer program in other infectious diseases. This step-wise characterization of the micro-practices of modeling highlight that modeling is an *iterative* practice, which builds upon and checks back with previous steps throughout the process. Importantly, these models are not only scientific exercises to develop better computational algorithms, they are built first and foremost to explain, understand, and predict the infectious disease outbreaks or transmission processes. The major application of this group of models (including also simulations) is to design, for example, reliable and cost-effective vaccination strategies or to predict the course of influenza pandemic (Mattila 2006a, b, c). Morgan (2001) characterizes this process as “storytelling,” in which a model is a narrative device. I suggest that scenario-building predictions could be related to this aspect of model building, or “storytelling” through processes of manipulation, as we will learn through pandemic modeling.

Following Espeland’s and Steven’s account on quantification practices, modeling as a measuring practice aims at controlling and predicting risks through quantification. The modeled encounters with risk, after all, are encounters to minimize the risk, to predict, and to prepare in front of the uncertain course of events. In broader terms, both types of prediction, explanation-based and scenario building, are *technologies of governance* that allow different interest groups to act at a distance (cf. Miller and Rose 2008). In explanation-based predictions, the underlying uncertainties are smaller, perhaps more manageable, whereas in scenario-building predictions the distance between what is known and what remains unknown is greater. Scenario-building predictions share some similarities with audit process, as discussed in Power (1997, p. 40):

- ▶ The audit process shrouds itself in a network of procedural routines and chains of unverified assurance, which express certain rituals of evidence gathering, but which leave the basic epistemic problem intact.

But are these similarities actually showing us what may result from overreliance on regulatory processes of governance? As we will learn through the case study of scenario-building predictions, their capacity to explain the phenomenon may manifest as a limitation or restriction, and yet they operate as useful tools to shed light on unknown future state of an anticipated public health risk. In the following, I will study in detail the modes of prediction provided by models. Through the analysis, I will show how useful models are in encountering and governing public health risks.

## Predicting Infectious Risks Through Modeling

In public health decision making, predicting is one of the key motivations to develop modeling techniques. What kinds of model-based predictions we are able to identify in infectious disease studies? Two cases analyzed in this chapter allow us to compare different types of model-based predictions (cf. Mansnerus 2011b). First, as an example of predictions that facilitate the renewal of vaccination strategies, a case of population-level transmission models of *Haemophilus influenzae* type b bacteria is analyzed. This case introduces us to *explanation-based* predictions that produce “what would happen if” scenarios. These scenarios derive their predictive capabilities from the available datasets and reach out to short-term predictions

beneficial to predict outbreaks within a particular area. So, the development of preventive measures in public health can be informed by *explanation-based* predictions.

Secondly, by analyzing a microsimulation model on mitigation strategies for a pandemic influenza, we will learn about *scenario-building* predictions. Typical for these predictions is that the data utilized in them are derived from past pandemics. Hence, these predictions are not capable to explain a possible future pandemic, but to produce reliable scenarios of its potential development, and thus facilitate the distribution of protective measures. So, in order to assess reliability and usability of model-based predictions, it is beneficial to increase transparency of evidence throughout the production and utilization process. This allows the different groups, who are involved in the decision-making processes, to evaluate the predictive scenarios and make well-informed decisions.

However, within infectious disease studies, one of the major public health concerns is the limited capability to predict emergence of outbreaks and people's behavior in such an event. Outbreaks could be regarded either as "small," when they occur, say in closed populations, such as army units, or "large," such as the anticipated pandemic outbreak. Small outbreaks, say transmission of bacterial meningitis, caused by Hib, in a military garrison may not receive broad media coverage, but are nevertheless important for the core tasks of public health officials. After all, it presents a life-threatening risk. To protect public health asks to be prepared for or capable of controlling and managing these outbreaks. Dynamic transmission models provide a rather flexible tool in order to do that – they form a ground to address anticipatory "what would happen if"-type questions. Larger, unexpected outbreaks that are capable to cause wider devastation gain easily significant attention. Preparedness plans are conducted both on national and international level. Large-scale simulation models that utilize data from past pandemics, on travel patterns and population density, produce a part of the scientific evidence base. One example of these models focuses on mitigation strategies and provides estimates of their effectiveness. So, these two cases analyzed in this study inform us of the two distinct modes of prediction represented in the models.

## Explanation-Based Predictions

---

Infections that affect mainly children's health are a mundane public health concern. One of the main threats is considered to be bacterial meningitis, because of its life-threatening nature. However, most of these infections are vaccine preventable, as in our example case, *Haemophilus influenzae* type b bacterial transmission. The main effort remains to reduce the risk of these severe disease forms in a population. So, the need to predict potential public health risks is answered by developing sophisticated transmission models. Evidence of potential outbreaks, indirect effects of vaccinations, and estimates of herd immunity are assessed by models. What kinds of predictions are useful to form the evidence base for vaccine-preventable infections? Amy Dahan Dalmenico (2007) argues that there is a continuous tension between the explanatory and predictive functions of models. According to her, this tension is seen as a source of conflict and compromise:

- ▶ Modeling practices [...] should they be first and foremost predictive and operational or cognitive and explanatory. Tension between explanatory and predictive capacities, between understanding and forecasting is a source of conflict and compromise in modeling (Dahan Dalmenico 2007, p. 126).

From a philosophical point of view, the distinction between explanations and predictions is considered separate or even in a conflict with each other as Dahan Dalmenico suggests. However, my analysis of the short-term, *explanation-based* predictions in the case of Hib transmission models, will argue that the tension could be set aside. Model-based predictions can be grounded on explanatory mechanisms, as the case of Hib transmission models, or they can provide desirable qualitative tools in a form of *scenario-building* prediction, as we will see. This is an interesting outcome, and useful when we are looking at how predictions help in public health risk assessment. The main benefit from models is that they allow us to “do things with numbers,” to build the platform upon which one can develop understanding of the infectious risk itself and experiment with the various mitigation strategies. Through these quantifiable tools, the evidence base for risk governance is widened. In the following, I will present a detailed case study how *explanation-based predictions* work in the case of modeling Hib transmission.

## Case of an Integrated Simulation Model of *Haemophilus influenzae* Type B (Hib) Transmission

Hib colonizes the human nasopharynx and is transmitted in droplets of saliva. The public health risk is related to its severe disease forms (Ladhani et al. 2009). Hib is capable of causing severe and often life-threatening diseases, such as meningitis and pneumonia in young children (an estimated three million cases of serious illness and 400,000 deaths each year in children under 5 years of age worldwide). A part of the incentive to produce model-based predictions lies in the cost of vaccines. Hib vaccine is not yet a part of national vaccination strategies in the developing countries, mainly in Africa and Asia. Polysaccharide vaccines were on market in the 1970s and conjugates in the 1980s. The main difference is that the polysaccharides protect against the disease forms, whereas the conjugates are capable of reducing the carriage of the bacteria and hence have effect on population level circulation of the bacteria. If considered from the economic point of view, polysaccharide vaccines are older and somewhat cheaper to produce, and the conjugates are more expensive. As clarified by Hib Initiative, Hib infections are difficult to treat in the developing countries, due to the lack of access to antibiotics, which are proven to be effective when treating the severe disease forms ([www.hibaction.org](http://www.hibaction.org), accessed 25.3.2009). Because of this, the Hib Initiative presents an estimate that 20% of children in developing countries with meningitis caused by Hib will die and 15–20% of children suffering from it will develop lifelong disabilities. As an epidemiologist from the Helsinki modeling group argues:

- ▶ WHO and GAVI (the Global Alliance of Vaccinations and Inoculations) advocate Hib conjugate vaccines, the major question remains whether universal vaccination will be at all feasible in the poorest economies. Will it be cost-effective, and will it be an appropriate use of resources among other possible health interventions? Schedules optimizing the age of vaccination and the number of doses are crucial for the acceptance of the expensive vaccines (Leino 2003).

These general concerns are translated into an integrated simulation model in order to produce qualitative, anticipatory predictions of the potential vaccination effects on the population level. The translation process meant that the modelers needed to study particular

mechanisms that were responsible for the behavior of the bacteria. In order to address these mechanisms in the integrated model, they studied them separately.

The global concern to implement conjugate vaccines is based on data from the UK and Finland. Both countries tell their own “success stories” that support the initiative to include Hib conjugate vaccines in the vaccination programs.

## “What Would Happen If” Questions as a Key to Explanation-Based Predictions

---

Seeking answers to “why”-questions means *explaining* a particular phenomenon, say a cause of an infection. When “why”-questions are addressed in models, they search for a particular mechanism that is responsible for the phenomenon. In other words, models capture epidemiological mechanisms and extrapolate explanations on the basis of that. But what are mechanisms and how are they addressed in models?

In order to develop the notion of explanation-based predictions as anticipatory techniques to address public health risks, I will discuss how the mechanism of natural immunity was expressed in a population-simulation model in order to gain short-term predictions to assess the efficacy of Hib-vaccines. So, the short-term predictions that answer “what would happen if” questions, even though studied in the Finnish context provide a potentially broader application context when extended or applied to address the benefits of implementing Hib vaccines in the developing countries.

In general terms, *explanation-based* predictions are predictions that explain the causal mechanism(s) responsible for a particular phenomenon and extrapolate on the basis of that short-term predictions, i.e., answers to “what would happen if”-type questions. In order to unpack this, I will elaborate the role of mechanisms and their relation to explanation-based predictions. *Mechanisms* form the basis or *anchor* the explanations to the available datasets, the epidemiological ground of the phenomena. Bechtel and Abrahamsen (2005, p. 423) define a mechanism as follows:

- ▶ A mechanism is a structure performing a function in virtue of its component parts, component operations, and their organization. The orchestrated functioning of the mechanism is responsible for one or more phenomena.

This definition clearly underlines that mechanism is involved with orchestrated functioning, which I interpret as being capable of bringing together specific properties, parts or operations of the phenomena. Mechanisms are responsible for a phenomenon, mobilizing its cause, occurrence, or development. In this sense, mechanisms contain the generalizable properties of the phenomena.

Disease transmission is a multiplex phenomenon, which is dependent, for example, on the frequency of contacts within a population group, infectivity of the pathogen, and the existing immunity within the population. These aspects of the transmission were taken into account, when a mechanism was explained in a model. In other words, studying research questions in the family of Hib-models helped clarifying the disease transmission mechanism and uncovered the connection between a mechanism and the research questions addressed in modeling. These models were built during 1994–2003 within the research collaboration between the National Public Health Institute and the University of Helsinki.

Let us study more closely how *explanation-based* predictions were established in a population-simulation model.

The leading question motivating the building of the population-simulation model was: What would happen if a 5-year-old child  $x$  acquires a Hib infection and how likely she is to infect the members of her family? This question is by its nature a “what would happen if” question that has a predictive emphasis. To see how this question was manipulated in the model, we need to unpack the structure of the model itself. The population-simulation model, published in 2004, has a three-part structure: a demographic model (covering the age-structure of a Finnish population), a Hib-transmission model (including the contact-site structure), and an immunity model (including the immunization program and its effects). Yet, this simulation model resulted after a 10-year period of modeling work, which was dominated by integrating practices that brought together the three parts, built earlier in the project (see Mattila 2006c). So, all three parts, especially the transmission model and immunity model, were partially studied prior to the accomplishment of the population-simulation model (2004) in terms of following questions (the year after the question refers to the published model):

- How long does the immunity [against Hib] persist? (1999)
- How do we estimate the interaction between the force of infection and the duration of immunity? (2000)
- What is the effect of vaccinations? (2001)

These questions address particular aspects that affect the transmission dynamics in a population: length of immunity, estimate related to the force of infection, and effect of vaccinations. In particular, two mechanisms were detected in these models: the mechanism of immunity and mechanism of transmission. Mechanism of immunity was defined as:

- ▶ Natural immunity is believed to depend on repeated exposure to Hib bacteria resulting in the production of functional antibody (Leino et al. 2000).

This mechanism is primarily about how to sustain natural immunity in a population. In the simulation model, it was used for explaining what would happen to the natural immunity, when vaccinations were introduced on a population level. This was an important aspect, since the epidemiological studies of the chosen vaccine confirmed that the vaccine itself is capable of reducing carriage. The reduction of carriage in a population could potentially lead to the waning of the natural immunity that had protective impact on a population level. In other words, *herd immunity* (the population level protection against an infection) could be affected (cf. Fine 1993). This indirect effect was documented in the model studying the dynamics of natural immunity. This mechanism and its numerical estimates, which were defined in terms of Hib antibody dynamics, show the descending trend in serum antibody concentration. Later, this mechanism was integrated in the population-simulation model, in particular into its immunity model part. Hence, the mechanism of natural immunity, when manipulated in the simulation model, showed that if the bacterial circulation is diminished, the natural immunity is likely to weaken and a potential increase in the risk of serious infections may affect those who are not vaccinated.

Explanation-based predictions hence allow us to both explain the phenomenon of interest and predict in a short-term its development, i.e., the course of Hib transmission in a population and the underlying epidemiological mechanisms that maintain circulation of the bacteria. An interesting parallel can be drawn to den Butter and Morgan (2000, p. 296):

- ▶ More general empirical models provide a consistent and quantitative indication of the net outcome of the various principle mechanisms thought to be at work based on the particular case (not stylized facts) and which might be affected by the policies proposed.

As den Butter and Morgan show, empirical economic models are linked with mechanisms as well. These models provide a base to work on a particular case and examine what kinds of effects suggested policies have. In a similar way, explanation-based predictions in public health policies allow estimations of risks by showing the short-term development of the infections, explicating the optimal immunity levels within the community, and sometimes even providing unexpected results of the optimal vaccination coverage. This was discussed in a lecture by Auranen and Leino (Lecture given at the London School of Economics, Workshop organised by the Economic History Department, March 2008), when they showed that Hib conjugate vaccine minimizes the carriage of the bacteria and allows optimization of vaccine coverage to be as low as 10%.

## Building Pandemic Scenarios

---

*Explanation-based predictions*, as discussed above, provide the ideal ground for short-term anticipation of public health risks, or low-impact, high-frequency events, as referred in the risk literature (cf. Hutter and Power 2005). However, most of the media attention is given to high-impact, low-frequency events, which in the public health context are pandemics. How do we respond to these events? Following International Health Regulations (IHR were revised by the WHO in 2005), each country is responsible for notifying WHO of “any events that may constitute a public health emergency of international concern.” In a way, these internationally coordinated activities are an early warning, but they may not be able to anticipate or predict the occurrence of a pandemic. According to WHO, we are currently living in a pandemic period, which means that preparedness plans are in use on national and international level and predictive models are tinkered with new daily estimates of the course of the pandemic.

How do *scenario-building* predictions form a part of the scientific evidence base for decision-making? *Scenario-building* predictions are predictions that “sketch, outline or describe an imagined situation or sequence of events, and outline any possible sequence of future events” (OED). In other words, *scenario-building* predictions are primarily tools to *produce qualitative scenarios* based on the available, past data, and as such they provide model-based encounters with future risks. These scenarios are not necessarily grounded directly on data of the future event (which does not exist), but build upon available sources of past data in order to anticipate the “unknown,” the risk.

## Predicting the Pandemic

---

Humankind has faced cycles of pandemics, one of the most famous being 1918 Spanish flu that killed, according to older estimates approximately 50 million people worldwide. The pandemic spread all around the world and lasted about 2 years (1918–1920). Its oddities were that it infected and killed young and healthy, and it spread during the spring months. The most recent cycle of a pandemic began in the end of April 2009, when human cases of a novel influenza type A virus were confirmed. These cases were identified in the USA and in Mexico. The virus, according to epidemiological evidence, had been circulating in Mexico since February 2009

and may have emerged already earlier that year. It was also confirmed that the new human strain was identical to a strain of virus that had been circulating in pigs in North America. Flu survey reports that the A(H1N1) strain has a complicated history: “some of its genes moved to birds to pigs in 1918, other genes from birds to pigs at the end of the 20th century, some got into pigs in the 1960s having first passed through humans.”

The strain spread rapidly, the first infections happened through contacts with those who were or traveled from Mexico. WHO reacted to the public health emergency by raising the Pandemic Alert Level from 4 to 5 (sustained community outbreaks in a limited number of countries) at the end of April. On June 11, 2009, WHO declared a pandemic and raised the Alert Level to phase 6, which means wide geographical spread, but does not indicate the severity of the infection.

According to ECDC Situation Report (27.7.2009), within the EU/EFTA countries, there are 20,512 confirmed cases and 35 deaths among those cases. Outside EU/EFTA countries, the corresponding numbers are 139,526 confirmed cases and 956 deaths. So far, critical voices have questioned the rationale of the pandemic alertness, since the cases seem to be somewhat mild and responding to the antiviral treatments. The major concern, however, was that there is very little natural prior immunity to the new strain and the infection it causes. This was already seen in the fact that the main group of infected is children. Due to the uncertainty of how serious the new type of virus was, the information campaigns for increased hygiene, advice for general audience and risks groups were available. In July 2009, vaccine production was underway, first vaccines were available for risk groups in September 2009, and, for example, the UK bought 90 million doses of vaccine in order to vaccinate the whole of population.

Uncertainties of the severity and spread of a pandemic raise questions of how to develop mitigation strategies to protect populations. Simulation models provide a way to predict the possible future course of the pandemic flu and hence function as a tool for planning and testing intervention strategies. When the simulation techniques are used in the preparedness planning, the data are grounded on observations from the past pandemics (1918 and 1957). These predictive simulation models allow studying various mitigation strategies.

## What Kinds of Models Are Used as Scientific Evidence Base for Preparedness Planning?

One of the major public health concerns in infectious disease studies is the limited capability to predict emergence of outbreaks and people’s behavior in such an event. To mitigate this problem, several studies have developed large-scale simulation models that utilize data from past pandemics, on travel patterns and population density. In the following, I will focus on one rather recent pandemic flu model and discuss its predictive capabilities. The model in question is an individual-based simulation model of pandemic influenza transmission for Great Britain and the United States (Ferguson et al. 2006). It represents transmission in households, schools and workplaces, and the wider community. The main aim of the model is to study strategies for mitigation of influenza pandemic. Mitigation means all actions that aim at reducing the impact of a pandemic (Nicoll and Coulombier 2009). I will focus on two model-based assumptions that affect the transmission: estimate for the reproductive rate and behavior. On the basis of a closer analysis of these assumptions, I will discuss the nature of *scenario-building* predictions and especially reflect on the suggested policy outcomes of this model.

## Fingerprint of the Pathogen, and of the Population

---

Transmission is quantified in epidemiological models as a basic reproductive rate, which is the rate that is used for estimating the spread of infection in a susceptible population. It is defined as  $R_0$ , which is the average number of individuals directly infected by an infectious case during her entire infectious period, when she enters a totally susceptible population. In infections that are transmitted from person-to-person, the potential of the spread is called the reproductive rate that depends on the risk of transmission in a contact and also on how common the contacts are. The reproductive rate is determined by the following four factors (Giesecke 2002):

- The probability of transmission in a contact between an infected individual and a susceptible one
- The frequency of contacts in the population
- How long an infected person is infectious
- The proportion of the population that is already immune

All these characteristics can be expressed in mathematical equations to provide numerical estimates of the transmission dynamics in a population. This rate is usually determined by empirical data, i.e., by deriving the estimate from previous epidemiological studies. However, it is a rate that carries a “fingerprint” of the pathogen. By this I mean that the reproductive rate is sensitive to particular strain of the pathogen in question. This sensitivity brings in a question of uncertainty in the model-based predictions. What if the strain is not so virulent? Alternatives are taken into account by modeling different possible scenarios based on different approximates of the reproductive rate. But what do the models do to the reproductive rate? In pandemic flu modeling, a future strain is unknown and therefore the models actually use data from the past strains. This relies, of course, on the assumption that the future pandemic is as virulent and contagious as the past one. If we look more closely to the reproductive rate and its variation, we can see how it manifests itself as a fingerprint of the pathogen. This idea means that population density affects the estimate since  $R_0$  tends to be higher in crowded populations. Nicoll and Coulombier (2009, Table 4) provide following estimates for  $R_0$ :

- In seasonal influenza:  $R$  around 1.1–1.2
- In pandemic influenza:  $R = 1.5–2.5$
- In current pandemic (H1N1):  $R = 1.5–2$
- In measles:  $R_0 > 10$

The variance in  $R_0$  leaves uncertainty into the predictions. This uncertainty is decreased once the pandemic begins to spread, and the pathogen is isolated and its virulence within a population (e.g., who are encountering the infection) is known.

## Behavioral Assumptions and Their Alternatives

---

The simulation model studying strategies for mitigating influenza pandemic makes assumptions concerning the effectiveness of behavioral interventions. These are movement restrictions, travel restrictions, quarantine, and school closure. The question is: What kinds of behavioral assumptions are made in order to predict the spread and transmission of the outbreak?

In Ferguson et al. (2006), a rather clear behavioral assumption is claimed when reporting the model design:

- We do not assume any spontaneous change in behavior of uninfected individuals as the pandemic progresses, but note that behavioral changes that increased social distance together with some school and workplace closure occurred in past pandemics.

Furthermore, the underlying assumption is to consider that individuals will behave according to the guidelines, rules, and restrictions given by the health authorities. In a way, the effectiveness of behavioral restrictions is based on the assumption of rational agents. But how reliable this assumption is? In a recent discussion on the novel ways to study real-world epidemics, Eric Lofgren and Nina Fefferman (2007) suggest that virtual game worlds might provide a different perspective. According to their analysis of an outbreak in an Internet playground, World of Warcraft, they observed that individuals did not follow the rules of movement restrictions and some voluntarily spread the disease. The question is: If the scientific simulation models are used for preparedness planning, how do we find reliable assumptions concerning the behavior, which is, after all a key to prevent the spread of pandemics?

## Scenario-Building Predictions

---

What is, then, the policy outcome of the model? What kind of scenarios the model suggested? Both epidemiological and behavioral assumptions have their limitations. On the epidemiological level, the assumptions represent the *fingerprint* of the pathogen, hence leaving some level of uncertainty when drawn to the predictive scenarios. On the behavioral level, the assumption that individuals' behavior remains unchanged during the pandemic period opens the questions of credibility of these scenarios. Yet, it was clearly stated that the models allowed to explore “number of scenarios” regarding the transmissibility of the pathogen, movement, and travel restrictions. One could easily think that if *scenario-building* predictions are relying on particularly uncertain assumptions, they are mere fantasies, no better than “fortune-telling.” However, this is not the case. As documented already with the Helsinki models on Hib, models provide a useful “playground,” a platform to examine and explore particular features of the infection and its transmission (cf. Keating and Cambrosio 2000, 2003; Mattila 2006c).

*Scenarios* which allow us to “access the inaccessible” provide qualitative tools and produce evidence of the unpredicted for decision making. The challenge remains how to communicate this particular mode of evidence – its changing and mutable nature (cf. Mansnerus 2011a). As Ferguson et al. (2006, p. 451) state: “The transmissibility of a future pandemic virus is uncertain, so we explored a number of *scenarios* here.” They argue that these scenarios depend on “model validation and parameter estimation,” which should be given a priority in future research. Transmissibility, which is based on the estimate of the reproductive rate, is considered to be on the level of 1918, if it actually follows the levels seen in 1968 or 1957 pandemics, “global spread will be slower and all the non-travel-related control policies examined here will have substantially greater impact.” Ferguson et al. emphasize the importance to collect the “most detailed data on the clinical and epidemiological characteristics of a new virus.” In other words, he is calling for research that allows us to base the scenario-building into a detailed understanding of the explanatory mechanisms of phenomena. The “fingerprint” of the pathogen is important, as pandemic simulations show.

What kind of scenario was built around the behavioral assumption? Interestingly, the outcome of the simulation model suggests that travel restrictions, which include both border controls and within-country restrictions, “achieve little” in delaying the peak of the epidemic. This was taken into account when WHO gave recommendations and guidance on traveling during the current A(H1N1)v pandemic:

- ▶ Scientific research based on mathematical modeling shows that restricting travel would be of limited or no benefit in stopping the spread of disease (7.5.2009, WHO, GAR, Travel: Is it safe to travel?).

The social functions of simulation models are also worth emphasizing. Scenario-building helps allocate resources, agree on, for example, preordering and manufacturing the vaccines, and stocking the antiviral. As we observed in the two examples, the scientific models have “uncertainty” built-in: the assumptions made on the basis of past facts may not provide accurate predictions of the scale of the outbreak. Nor are they capable of capturing the changing behavioral patterns of individuals. Testing out both assumptions and exploring them as part of various scenarios was “doable” only by modeling. This is an indication of the usefulness of *scenario-building* predictions; they are qualitative tools that “fill the gaps” in existing knowledge, allow reasoning to touch upon the “known unknowns” and perhaps “unknown unknowns.” A good example of “unknown unknowns” was the origin of outbreak of A(H1N1) pandemic in 2009. The main focus was on avian (H5N1) influenza that is currently circulating in South-East Asia. However, the pandemic emerged from pig farming industry in Mexico (cf. Mansnerus 2010).

## Beneficial Encounters with Infectious Risks

---

How modeling provides useful tools for risk assessment? As we learned through the case studies, predictive capacities of models encompass the ambition to “access the inaccessible,” as Oreskes (2007) shows in her analysis of scale models in geology. She refers to models “whose predictions are temporally or physically in accessible.” But this ambition is not merely epistemic. Models, either physical or numerical, seemed not to adjust to the changes in epistemic values shared in scientific communities, but also reflect aspirations of scientific patrons, as Oreskes discusses. Models seem to do more than epistemological work: in the attempts to predict the future, models generate predictions to inform policy decisions. This is what Oreskes argues to be the primarily social role of predictions. In a way, *scenario-building* capacities of models express the social role by providing “access to the inaccessible,” even though scenarios may not satisfy the epistemic quest of explaining the viral mechanisms of a pandemic.

In scenario-building predictions, the epistemic, for example, the precise rate of transmissibility plays a secondary role. The main importance is to explore and evaluate various outcomes. On the contrary, explanation-based predictions, when they successfully encompass epidemiological mechanisms, accommodate both the epistemic and social functions.

What kinds of modeled encounters with public health risks do the two types of predictions provide? How reliable are they? The analysis supports Boumans’s (2004) notion of instrumental reliability, which incorporates both the “instrument” and expertise required. In other words, reliable predictions, in both cases, result as the quality of the model and the expertise of the modelers. This means that calibration of the model is not indifferent to the other factors,

expertise of building the model and practice of using the model when addressing instrumental reliability. Oreskes and Belitz (2001) make a similar point by arguing that all models are approximations, and they suggest that it is more useful to “think of models as tools to be modified in response to knowledge gained through continued observation of the natural systems being represented.” In other words, when estimating public health risks through model-based predictions, instrumental reliability refers to the fact that these predictions are not valid descriptions of reality, but best available approximations of the risk. They are not static either, but as more data are cumulated during the outbreak, they gain greater accuracy. Both types of predictions show that modeled encounters with public health risks depend on the complex chain of interactions between experts and technologies, and between users and producers of these predictions.

*Explanation-based* predictions that are utilized in assessing low-impact, high-frequency infectious risks function in two ways. First, they explain the phenomenon by allowing researchers or policy-makers manipulate the model by questions. As we learned, the broader policy-driven questions are translated during the modeling process into smaller and more targeted questions that reveal the details of the transmission dynamics in a population and explain how the disease mechanism affects the possible infectious outbreak. Second, the explanation-based predictions are able to address “what would happen if”-type questions that arise when infectious outbreaks are encountered within a small group of population, such as a nursery group or military garrison. The prediction as an answer to “what would happen if” question is beneficial for assessing risk and further mitigation strategies, such as containment of the outbreak.

*Scenario-building* predictions should not be regarded as “nonsense” despite my choice to refer to the modeling platform that gives rise to them as a “playground.” As Oreskes pointed out, they function as “access to the inaccessible,” in that role they allow risk assessment to stretch itself beyond the “accessible”: Beyond the available data from surveillance or monitoring processes by simulating the outbreak on the basis of data from previous pandemics, or beyond the actual situation, i.e., ongoing outbreak by simulating variations of the spread of the infection and the effectiveness of mitigating strategies already during the pre-pandemic phase for preparedness planning. It seems that both these predictions provide beneficial tools to encounter public health risks from infections. However, their limitations are worth discussing in the context of analytics of governance.

## Further Research: Toward the Analytics of Risk

Modeled encounters with public health risks are proven highly beneficial, as we have learned. A challenge, however, remains to be tackled with, namely, the tension between population-level estimates of risk and individuals’ behavior. I will suggest this tension can be accommodated within the governmentality approach by showing how the analytics of risk benefits from the integration of technical and ethical rationalities along with the deepened understanding of risk rationality. This will be discussed as a direction for further research.

What are then the possible limitations of “modeled encounters” with risks? As the case of predictive scenarios of pandemics shows, availability of data may be limited or as in this case, nonexistent in regard to an actual outbreak when scenarios were built in pre-pandemic phase. Explanation-based predictions were also modeled on the basis of limited data, for in that case,

the data were collected for other purposes (as a part of pre-Hib vaccine studies) and therefore they did not accommodate all the relevant information for model parameterization. This meant that during the modeling, some parameter estimates were acquired on the basis of comparative datasets from collaborating research groups. Along with the limits of availability of data, computational capacity may present limits to modeled encounters with risks. The modelers may not be able to access the highest-level of computing power (such as supercomputers in national computing centers), which was the case with Hib-models. These technical limitations have an effect on the way in which models are built, how fluently a model-based prediction is gained, and how reliable the instrument, (i.e., the model) itself is. Limited access to high-level computational capacity restricted the number of simulation runs for the population-simulation model that estimated Hib transmission, for example. Although these restrictions may weaken the reliability of the model-based prediction, it is worth bearing in mind how Oreskes and Belitz (2001) described models as approximations.

Along with the technical limitations of modeled encounters with risks, there are social and epistemic limitations as well. As we learned through the analysis of the two types of models, the modeling process itself is not highly transparent. Specialized expertise is required to build the models, and even those who work with modelers may not be able to assess the choice of mathematical algorithms during the process. Interdisciplinary modeling teams develop a division of labor (see Mattila 2006a). This lack of transparency may be limiting when model-based predictions are communicated to audiences who have not been involved in the primary model building process or who are not familiar with modeling techniques. This is the point when models may turn into “truth-machines,” to gain their authority, as Hulme et al. (2009) suggests in the case of climate models. The assumptions made in the model may remain unknown due to the lack of communication of the modeling process and the choices made within it.

Furthermore, as I described that these models are typically *tailored* to address specific policy-driven questions, one could consider this characteristic a limitation. How applicable are the outcomes? If the simulation model particularly addresses a question like “what would happen if a child x in a day care unit y encounters a Hib infection?”, can the prediction be applied to estimate the risk of infection among adult men in military garrison? Or if the predictive scenario of a pandemic spread examines mitigation strategies, such as school closures or travel restrictions in a particular geographical location, can the estimates be extended to cover other areas as well? These questions address the inevitable limitations of modeled encounters with public health risks, which should not be read as a recommendation not to use modeling techniques or to advocate them. After all, model-based predictions, as these two cases show, are highly beneficial as a one source of evidence for the broader base of risk assessment. The limitations are discussed in order to balance the view.

As we learned, model-based predictions operate on population level. They provide information of risks that affect the whole population, hence being interested in the “welfare of the flock as a whole,” as Rose (2001) phrases Foucault’s terms. The “pastoral” attitude that is concerned of the welfare of the whole population, Rose continues, is a form of “collectivizing power.” This leads to a tension that arises when a public health risk manifests on a population level and appropriate health interventions are introduced, but at the same time, individuals consider their risk from a different angle and refuse or ignore to participate in the interventions. In other words, when an epidemic outbreak that causes a severe risk to the population (or to a part of it) happens, its further spread is prevented, for example, by vaccinations.

Yet, individuals may think that the side effects from the vaccination are more severe than the infection itself and refuse to follow the public health recommendations. But what lies behind this tension? I will reassess this tension from three perspectives: as a narrative, as a case of difference between individual's risk perception and that of a group, and as a challenge that needs a broader context to address it. The concept of narratives, as I already mentioned, is helpful when applied to modeling. Morgan talks about modeling as storytelling and I will follow the most recent work by Dry and Leach (2010) to discuss how to broaden out the modeled encounters with public health risks by acknowledging the narratives told through modeling. I will address the lack of focus on individuals' risk behavior, which was highlighted in the studies by Lofgren and Fefferman (2007). I will argue that a satisfying way to contextualize modeled encounters is by regarding them as *technical rationalities* within the governmentality approach to risk.

The fairly monolithic view of a population, as represented in the models, may lead to a biased interpretation of the model-based predictions or, more broadly, the model-outcomes and estimates. The population is seen as the "ultimate end of governance," as Rabinow and Rose (1994) claims. When governance seeks the form of modeling, we may use the metaphor of storytelling (Morgan 2001), which allows manipulation of the world through representing it in a model and addressing questions to it. But whose story is told and whose is ignored? Who remain silent? Dry and Leach (2010) raise this issue when they argue that narratives about infectious diseases are deeply rooted in questions of power and social justice. In order to address these questions, Dry and Leach suggest analyzing the different narratives that construct disease and epidemics. Narratives for them are not just stories, but stories with purposes and consequences. In a recent study on avian influenza surveillance, Scoones (2010) identifies three "outbreak narratives": A narrative that links veterinary risk with agriculture, a human public health narrative, and a narrative focusing on pandemic preparedness. His analysis shows that a single narrative is perhaps not enough to create the evidence base in order to understand the multiplicity of an infectious risk from pandemic. We could see the benefits of model-based predictions in a similar way. At best they give us a single narrative, and perhaps our task is to look for other complementary ones for well-grounded risk assessment.

One could take yet another step further and say that narratives, despite introducing more heterogeneity to the fairly fixed perspective on population, are still focused on groups rather than individuals. Neither *explanation-based* nor *scenario-building* predictions address individuals' perceptions of risks and the various factors that affect them. What is left aside in these modeled encounters with risks is the ways in which individuals perceive risk and how they behave. A typical bias in individuals' response to risk is known as *optimism bias*, which means that individuals underestimate risks to themselves (Costa-Font et al. 2009). Joffe (2003) argues that individuals construct risks through group attachment or on the basis of their experiences in groups. She continues that response to risk is therefore "a highly social, emotive and symbolic entity." Roeser's (2007) study on ethical intuitions about risks point to the same direction by acknowledging that individuals' intuitive risk judgments express ethical concerns that should be taken into account in methodologies for risk analysis or risk policy. None of these observations are accommodated on the population level analyses of public health risks.

How could we, then, satisfactorily accommodate the "unbearable tension" between individuals' perceptions of risks and the population-level assessment we gain through modeling? I will argue that we will benefit from a broader context to understand infectious risks in public health. By this broader context, I refer to the literature on governmentality that brings together

the technical rationalities of governance with ethical and epistemological aspects that are present in the process and manifest through the dynamics of power.

In Michel Foucault's work, the analytics of government covers three aspects that help contextualizing risk. These aspects focus on how we come to know about and act upon different conceptions of risk. How these different forms of risk rationality become a particular set of calculatory practices and technologies. How social and political identities emerge from these technologies (Dean 2010, p. 217). In this chapter, modeling techniques have been regarded as a form of technical rationality or *techne* in the governance of risk, which Dean defines as: "[...] a search for analytical clarity concerning the techniques and instruments of government, the arts, skills and means by which rule is accomplished" (Dean 1995, p. 560). As I have shown, model-based predictions are "instruments of government"; they are tools to anticipate risks, build predictive scenarios, and test mitigation strategies. At the same time, these techniques have their limitations. They easily enforce the purely probabilistic interpretation of risk, and the evidence produced by models assesses population-level risks but cannot include estimates for individual-level or address individuals' perception of risk simultaneously. This limitation can be addressed through the analytics of risk within the context of governance.

The analytics of risk is formed through four successive and overlapping stages, as Dean claims. In the beginning, one explores different forms of risk rationality, which Dean calls *episteme* of risk. Then, one seeks to find out how such conceptions are limited to particular technologies and practices that form the *techne* of risk. And finally, one studies how such technologies and practices give rise to new forms of social and political identity, and finally, how these identities are merged into political programs, which give them a particular *ethos* (Dean 2010, p. 217).

If we follow how Dean characterizes *episteme* within the analytics of government, we will notice a set of questions that are useful to map risk rationalities. "What forms of thought, knowledge, expertise, strategies, means of calculation, or rationality are employed in practices of governing?" (Dean 2010, 42). It seems to me that *episteme* and *techne* of risk rationality indicate a different direction or different dynamics of governing risks. Especially in the case of the pandemic, the risk considered to threaten the whole of population seemed to remain relatively small. Individuals made their own estimations for risk disregard to the recommendations or guidelines given by the public health officials. Those who were at risk did not consider the risk to be severe enough for them to follow the guidelines. As we can see, *episteme* and *techne* of risk rationality are pointing to the "care of oneself and of others," to the ethical dimension that is present when encountering public health risks. This forms the *ethos* of risk rationality or the social and political identities, which emerge out of *episteme* and *techne*, out of the rationalities of governance.

"Knowing an object is a process that shapes rationalities of governance by forming our understanding of how a risk of an infection is established and the ways in which all this was turned into a form of calculation," as Miller and Rose (2008, p. 30) define. For them, "knowing an object" involves "procedures of inscription," which are ways of collecting and presenting statistics, for example. It is not a process of speculative activity, but a way in which "governmentality" is made up. In my reading of governance of public health risks in the two cases, risk became a "knowable object." But the actors may not have reached a point what could be called "accountability of one's own actions." This is an important aspect of the *ethos* and its formation through rationalities of governance. Dean emphasizes that "if morality is understood as the attempt to make oneself accountable for one's own actions, or as a practice in

which human beings take their own conduct to be subject to self-regulation, then government is an intensely moral activity” (Dean 2010, p. 19). To recognize government as “an intensely moral activity” leads Dean to suggest that “techniques and rationalities of government needs to be complemented by a fuller clarification and elaboration around third axis, that for want of a better term, we might call ‘axis of self-formation’” (Dean 1995, p. 560). So, in order to complement risk rationality and to enhance successful governance of risk, I would suggest to include all “three axes of governmentality” into the process. This could lead to a balanced view which, according to Castell, seem to be threatened by modern ideologies.

- ▶ The modern ideologies of prevention are overarched by a grandiose technocratic rationalizing dream of absolute control of the accidental, understood as the irruption of the unpredictable. In the name of this myth of absolute eradication of risk, they construct a mass of new risks, which constitute so many new targets for preventive intervention (Castell 1991, p. 289).

Are the expiring stocks of pandemic vaccines a sign of “grandiose technocratic rationalizing of dream of absolute control?” This question asks for further research that potentially engages with critical assessment of risk governance and addresses the various tensions that may prevent good governance from reaching its purpose.

## Acknowledgments

---

I thank the British Academy for funding my research through Post Doctoral Fellowship at LSE Health, London School of Economics and Political Science. My research on risk and regulation was supported by an ESRC Post Doctoral Fellowship at the Centre for Analysis of Risk and Regulation (CARR), 2009. I was affiliated with Mellon Sawyer Seminar on Modelling Futures: Understanding Risk and Uncertainties at the Centre for Research in Arts, Social Sciences and Humanities, CRASSH, University of Cambridge, and a Visiting Fellow at Wolfson College, 2009–2010. I thank CRASSH for providing a dynamic research environment for me and Wolfson for hosting me.

**Abstract:** What does a transport safety regulator have in common with a shaman conducting a rain dance? They both have an inflated opinion of the effectiveness of their interventions in the functioning of the complex systems they purport to influence or control. There is however a significant difference. The clouds are indifferent to the antics of the shaman and his followers. But people react to the edicts of a regulator and frequently not in the way the regulator intends. There are two different kinds of managers involved in the management of transport risks: there are the “official,” institutional, risk managers who strive incessantly to make the systems for which they are responsible safer, and there are the billions of individual fallible human users of the systems, each balancing the rewards of risk against the potential accident risks associated with their behavior. Conventional road safety measures rest on a model of human behavior that assumes that road users are stupid, obedient automatons who are unresponsive to perceived changes in risk and who need protecting, by law, from their own and others’ stupidity. The idea of risk compensation underpins an alternative model of human behavior that road users are intelligent, vigilant, and responsive to evidence of safety and danger and, given the right signals and incentives, considerate.

## **Introduction: “We Know What Works”**

---

In March 2010, the United Nations proclaimed 2011–2020 the Decade of Action for Road Safety (UN announcement [2010](#)). It aspired to promote road safety everywhere, but especially in countries in the early stages of motorization with the highest accident rates.

Credit for this proclamation has been claimed by the Make Roads Safe campaign of the FIA Foundation ([Make Roads Safe 2010](#)). On the campaign’s Web site a “TAKE ACTION” tab offers a selection of Make-Roads-Safe T-shirts, banners, publications, and wristbands, but no suggestions for what might actually be done to make roads safer. Former UK defense secretary Lord Robertson, who is chairman of the campaign, is a bit more specific. He claims “We know what works: making vehicles safer and designing roads to be safe for all road users; tackling inappropriate speed and drink driving; promoting seat belt use and helmet wearing; improving driver training and police enforcement.”

The spearheading of the campaign by the FIA (Fédération Internationale de l’Automobile) the organization that glamorizes “inappropriate speed” through its promotion of Formula 1 racing, is an incongruity that seems thus far to have escaped comment elsewhere. At the time of writing (November 2010) the Make Roads Safe campaign is the most prominent feature on the FIA home page ([www.fia.com](http://www.fia.com)) – competing for attention with pictures of racing cars doing exciting things at inappropriate speeds.

At the launch ceremony for the campaign John Sammis, representing the United States, drew attention to the “6,000 of his fellow citizens killed and the more than half a million injured in 2009 due to distracted driving, particularly text messaging” (UN announcement [2010](#)). This contribution highlights a significant problem for those who claim to know what works.

In the United States, laws banning text messaging while driving are a matter of state jurisdiction; some states have passed laws others have not. This has created a natural experiment in which the accident experience of states with laws can be compared with the experience of those that have not. In 2010, the Highway Loss Data Institute published a report on the effect of the laws. It concluded:

- ▶ The results of this study seem clear. In none of the four states where texting bans could be studied was there a reduction in crashes. It is important to remember that the public safety issue in distracted driving is the crashes resulting from cell-phone conversations and texting, not the use of these devices, *per se*. If the goal of texting and cell phone bans is the reduction of crash risk, then the bans have so far been ineffective. Bans on handheld cell-phone use by drivers have had no effect on crashes (HLDI 2009), as measured by collision claim frequencies, and texting bans may actually have increased crashes (HLDI 2010).

The texting study concludes with a plausible speculation to explain the increase in crashes in *states that passed laws banning texting while driving*:

- ▶ This unexpected consequence of banning texting suggests that texting drivers have responded to the law, perhaps by attempting to avoid fines by hiding their phones from view. If this causes them to take their eyes off the road more than before the ban, then the bans may make texting more dangerous rather than eliminating it.

The perverse effect of texting bans created a difficulty for the US Department of Transportation Secretary Ray LaHood, a strong advocate of texting bans. He dealt with the difficulty by simply denouncing the study as “ridiculous” ([www.textkills.com/?p=1418](http://www.textkills.com/?p=1418)) and by issuing an angry, hand-waving dismissal of the method of assessment used by the HLDI, stating that the same method would have cast doubt on the efficacy of seatbelt and drink-drive legislation (USDOT 2010). As we shall see below this is a less than convincing argument. Like Lord Robertson, and numerous other road safety campaigners, LaHood knows what works and is exasperated by evidence that contradicts this “knowledge.”

The American experience with texting bans is but the most recent installment of a long-running saga. In 1985, the late Frank Haight, the long-term editor of *Accident Analysis and Prevention*, one of the most highly regarded scientific journals in the field, observed:

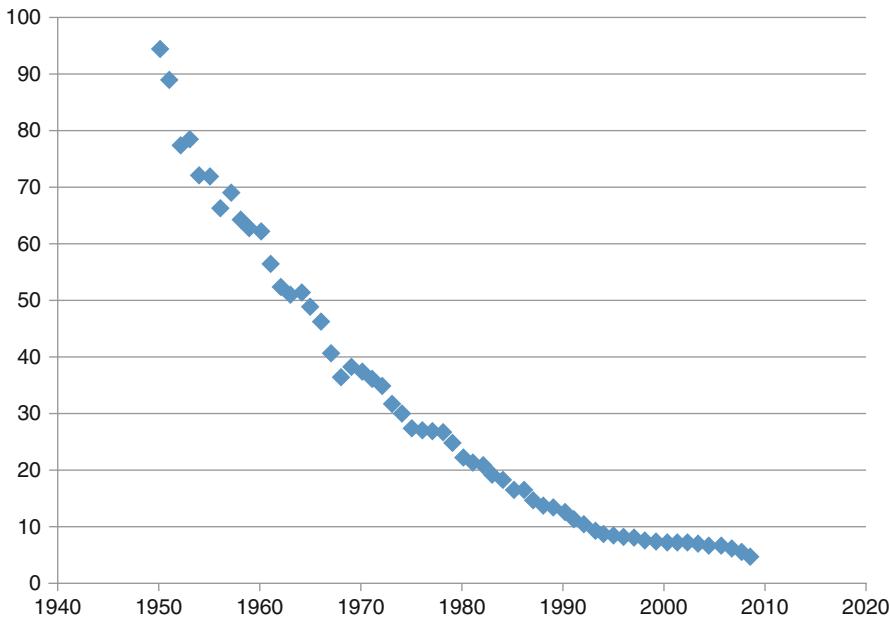

- ▶ One sees time and again large sums of money spent [on road safety] in industrialized countries, the effect of which is so difficult to detect that further sums must be spent in highly sophisticated evaluation techniques if one is to obtain even a clue as to the effectiveness of the intervention (Haight 1985).

## History: What Works?

Since the earliest days of mechanized transport there have been efforts to manage the risks that accompany it. In Britain the famous Red Flag Act (the Locomotive Act of 1865) required traction engines to be preceded by a man walking 60 yards ahead, at no more than 4 mph, carrying a red flag. This requirement was not repealed until 1896 – coincidentally the same year in which the first pedestrian was killed by a car in Britain.

Since then countless road safety measures have been implemented, in many jurisdictions: speed limits, accident black spot treatments, vehicle construction regulations, drink-drive laws, road signage, traffic lights, and seatbelt laws, to name but a few.

Concerns about the risks attached to transport have deep roots. The *Dublin Police Act* of 1842 created the offense of “driving furiously” – the same style of driving attributed to Jehu in the Old Testament (2 Kings, 20). As recently as November 2008, the Irish Law Commission

**Fig. 10.1**

Deaths per billion vehicle kilometers – GB

(Law Commission 2008) was consulting on whether this offense should be abolished. Whether it has now been abolished I am afraid that, at the time of writing, Google does not relate.

Intriguingly, despite decades if not millennia of interest in the problem of managing transport safety, there is remarkably little agreement about what works. Consider **Fig. 10.1**. Since 1950, road accident fatalities per kilometer traveled in Britain have dropped dramatically.

**Figure 10.2**, with the vertical axis transformed into logarithms, shows that the trend between 1950 and 2008 can be approximated by a straight line whose slope reveals that over this period deaths *per vehicle kilometer* decreased at a rate of 5.2% per year. The risk of death per kilometer traveled at the end of the period was 1/20th of the risk at the start of the period. Clearly something was working to make travel safer. But what?

The downward trend illustrated by **Fig. 10.2** does not mean that the number of road accident fatalities decreased every year. **Fig. 10.3** shows that in years when traffic grew a rate higher than 5.2% the number of fatalities tended to increase, and when it grew more slowly they tended to decrease.

The arrows on **Fig. 10.3** indicate (with the exception of the 1991 arrow) the introduction of significant road safety measures – government interventions intended to make the roads safer. Each should have produced, according to the prior claims of their promoters, a sharp downward step in the graph displayed in **Fig. 10.2**. But the steps are not there.

The first, the 1962 *Traffic Act*, imposed new speed limits, increased the maximum fines for speeding and careless driving by 150%, and introduced the “totting-up” procedure whereby

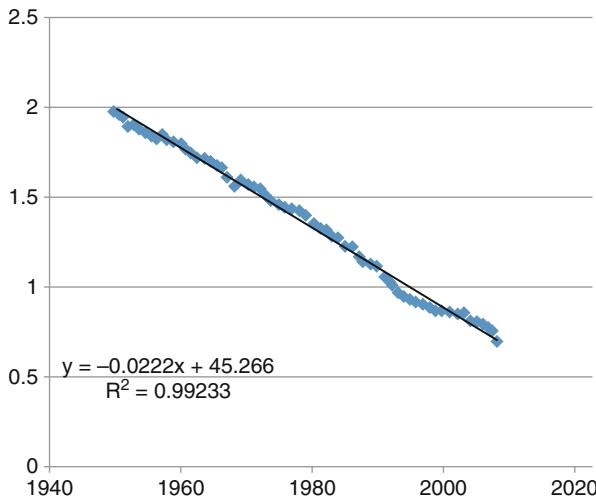

Fig. 10.2  
Log deaths per billion vehicle kilometers – GB

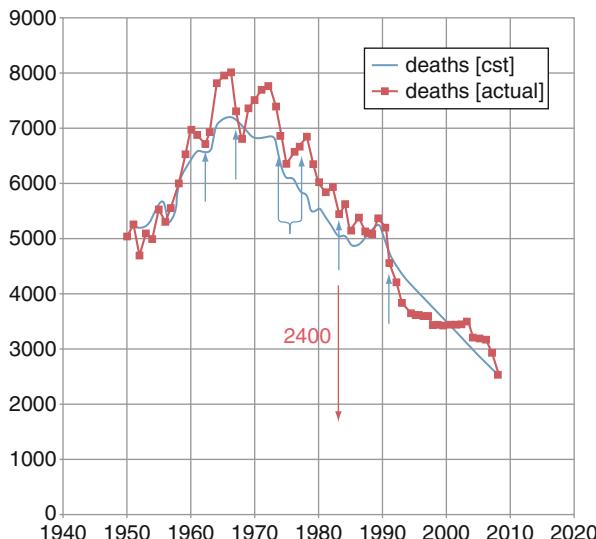

Fig. 10.3  
Road accident deaths in Great Britain: 1950–2008

drivers could be disqualified for three offenses. The second, the *Road Safety Act of 1967*, made it an offense to drive with over 80 mg of alcohol per 100 ml of blood. The third pair of arrows brackets the “energy crisis” speed limits. Between December 1973 and April 1977, various speed limits were imposed in response to the energy crisis and then repealed; they were introduced as

a fuel conservation measure, but were warmly welcomed by safety experts as a safety measure. The fourth, *the seat belt law* took effect in January 1983; it made the wearing of seatbelts in the front seats of cars and vans obligatory and was introduced with the claim that it would save 1,000 lives a year. The fifth arrow we shall come to shortly.

## The 1962 Traffic Act

---

The penalties provided by law for motoring offenses are intended to act as incentives to safer driving – disincentives to law-breaking being equated with disincentives to unsafe behavior. The objective of the new speed limits, larger maximum fines, and the totting-up procedure (whereby 12 penalty points led to disqualification) was to increase the severity of the punishment for the most persistent offenders. However, changing the law did not necessarily lead to a change in practice; although the maximum permitted fines for speeding and careless driving had been increased by 150%, the average fine handed out by the courts did not increase at all (Plowden 1971). Following the implementation of the measures contained in the 1962 Traffic Act, the number of road accident deaths, which had fallen over the previous 2 years, climbed more steeply than the trend identified in Fig. 10.3 until reaching a post-war peak in 1966. Perhaps the increase would have been even greater without the 1962 Act. Perhaps not.

## 1967: The Breathalyzer

---

The introduction of blood alcohol limits in October 1967 and a new method of testing coincided with a sharp drop in road accident fatalities. It appears likely that the new limits and the Breathalyzer deserve credit for a substantial part of this decrease. The number of over-the-limit dead drivers dropped from 25% to 15%. The number of deaths between 2200 and 0400 h (the period in which most drink-drive offenses are committed) dropped by 31%. However the effect was temporary. By 1969, the percentage of drivers killed in accidents while over the legal limit was back above its prelaw level. It is difficult to see a clear correlation between drinking and driving and total road accident deaths. By 1983, the number of over-the-limit dead drivers had risen to 31% while total road accident fatalities had dropped from 6,810 in 1968 to 5,445.

In 1983, *Accident Analysis and Prevention* devoted an entire issue to the problem of impaired driving. The guest editor summarized his long experience of drunken driving countermeasures in a despairing introduction:

- ▶ Once again, drinking and driving has come to the fore as a public concern. The beginning of every decade over the past 30 years has seen a surge of interest in, and concern over, drinking and driving. This concern has led to millions being spent throughout the world on countermeasures, with little measurable success in reducing the problem (Vinglis 1983).

It is frequently argued that the temporary success achieved by some drink-drive “blitzes” proves that the problem could be solved by some combination of more draconian penalties and more vigorous enforcement. Scandinavia, with its low permitted alcohol levels, rigorous enforcement, and draconian penalties for over-the-limit driving is frequently held up to the rest of the world as an exemplar. But Ross in a 1976 article entitled “The Scandinavian Myth”

(Ross 1976) cast doubt on this hypothesis. His interrupted time-series analyses revealed no effect of the Scandinavian drink-drive laws on the relevant accident statistics.

His analysis suggested that tough drink-drive legislation is only likely to work where it accords with prevailing public opinion. He noted the existence of a politically powerful temperance tradition in Scandinavia. Many people considered drinking and driving a serious offense (if not a sin) before it was officially designated as such by legislators. The absence of a detectable effect of Scandinavian drink-drive laws on accident statistics at the time the laws came into effect suggested, according to Ross, that the laws were symptomatic of a widespread concern about the problem, and that most people likely to obey such laws were already obeying them before they were passed. The laws, in effect, simply ratified established public opinion.

Where laws are passed that run ahead of public opinion there appears to be a conspiracy involving motorists, the police, judges, and juries to settle for a level of compliance and enforcement that accords with public opinion. In Britain after 1983, there was an impressive decrease in the number of dead drivers over the legal limit. The cause appears not to have been any specific intervention by the government, but a change in social attitudes.

### 1973–1977: The Energy Crisis Speed Limits

---

In December 1973, a blanket speed limit of 50 mph was applied to all roads in Britain not already subject to a lower limit. At the same time petrol prices were increased by 20%, followed by another increase of 20% in February 1974, and a further increase in April; between December 1973 and April 1974 petrol prices increased by about 57%. The motorway speed limit was restored to 70 mph at the end of March, and in May the 70 mph limit was restored to other all-purpose roads previously subject to that limit. In November 1974, the limit on some all-purpose roads was reduced to 50 mph and on others to 60 mph. Finally, in April 1977 Parliament agreed that the 50 and 60 mph limits on all-purpose roads should be raised again to 60 and 70 mph – in the face of protest and dire predictions by safety experts.

In 1974 and 1975, the total number of road deaths decreased. In 1976, 1977, and 1978 they increased. However the contribution of the different modes of travel to the changes in the total numbers of deaths in these years varied considerably. One response to the large increase in the price of petrol that accompanied the energy crisis was a large increase in the use of more energy efficient, but also more dangerous, motorcycles. Between 1975 and 1978, there was an increase of 465 in the total number of road deaths per year, but most of this increase (325) was accounted for by motorcyclists. In 1977, after the last of the energy crisis speed limits was repealed, the total number killed – excluding motorcyclists – decreased. After 1978, deaths for all modes, despite the dire predictions of road safety campaigners advocating lower speed limits, decreased markedly.

### 1983: The Seatbelt Law

---

The effect of the 1983 seatbelt law remains the subject of extraordinary myth making. On January 31, 2008, Britain's Department of Transport celebrated the 25th anniversary of the laws coming into effect with a press release in the name of the Road Safety Minister claiming:

- ▶ Twenty five years of seatbelt wearing laws have helped save 60,000 lives (Department for Transport 2008).

Others were quick to claim a share of the credit. The Web site of the Royal Society for the Prevention of Accidents claims:

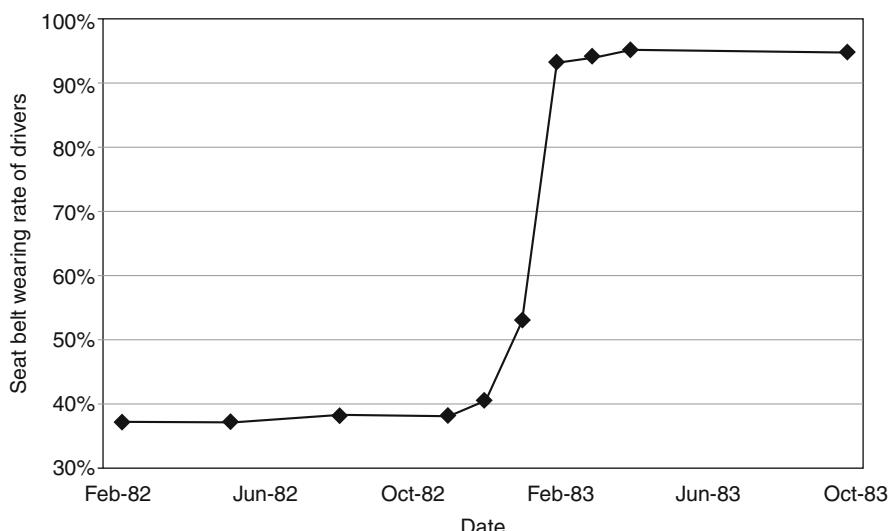

- ▶ 1982 – RoSPA's president, Lord Nugent, secured compulsory wearing of seatbelts with a late amendment to a Transport Bill. The law is estimated to have saved 60,000 lives to date (RoSPA 2010).

While the Parliamentary advisory Council on Transport Safety explained their role as follows:

- ▶ On the 31st January 2008, the 25th anniversary of the law change which made front seatbelt wearing compulsory was celebrated. PACTS itself was set up by Barry Sheerman MP as part of the fight to get mandatory seatbelt wearing turned into legislation. Eight years later it became compulsory for all backseat passengers to use seatbelts and it is estimated that since the introduction of the first law change in 1983, seatbelts have prevented 60,000 deaths and over 670,000 serious injuries (PACTS 2010).

The 60,000 claim has been endlessly recycled in the national and local press, radio, and television by the police and on Web sites including those of the National Health Service, insurance companies, law firms, and numerous others rather marginally connected to road safety concerns such as the Yorkshire Dales National Park. Such is the mesmerizing power of large numbers that the claim even escaped the usually sharp editorial eyes of a large team of highly experienced transport researchers who maintained in a report for the Department for Transport that “Over the past 25 years the compulsory wearing of seatbelts has been estimated to have saved at least 60,000 lives” (Erel Avineri et al. 2009).

Sixty thousand lives saved over a 25-year period averages 2,400 per year (shown on Fig. 10.3). The increase in wearing rates at the time the law came into effect was large and abrupt (see Fig. 10.4). The claimed effect of the law should have been evident in Fig. 10.3 as

**Fig. 10.4**  
Seatbelt-wearing rate of drivers

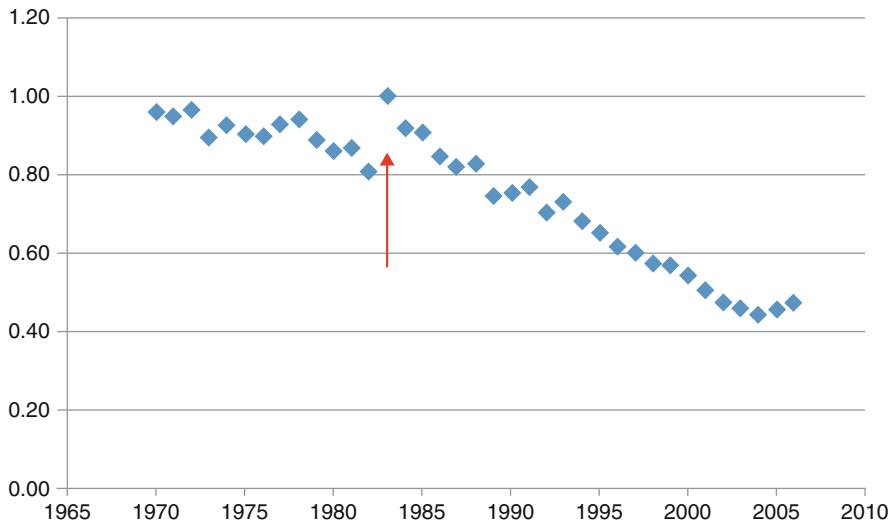

Fig. 10.5

Ratio of pedestrian and cyclist fatalities to car occupant fatalities 1970–2006

a sharp downward step in the established downward trend. Instead the trend leveled off, not resuming until after 1990.

There is however a sharp step effect to be seen in the road accident data. The ratio of pedestrian and cyclist fatalities to car occupant fatalities had been declining for many decades as the numbers traveling in cars increased and the amount of walking and cycling decreased. In 1935, the ratio was 6 to 1; by 1982 it was down to 0.8 to 1 (see Fig. 10.5). In 1983, it jumped 25% to 1.0 and it was another 7 years before it fell below 0.8. Consistent with the result in other jurisdictions with seat belt laws there was a shift in the burden of risk from those best protected in cars to more vulnerable road users on foot or bicycle (Adams 1995, 2010, Chap. 7).

In 1991, the total road accident fatalities decreased by 12.5%. This was the largest annual decrease since the war years when fuel shortages removed large numbers of vehicles from the roads. Frustratingly for road safety campaigners, it is not possible to attribute the decrease in 1991 to any of the safety measures introduced in that year. Indeed, 1991 was a quiet year on the road safety front in terms of the implementation of new safety measures. The following list presents the most significant new safety interventions in 1991 listed in *Road Accidents Great Britain 1991*, and the associated casualty effects, where available, from published sources.

#### Road safety measures implemented in 1991

- Twelve 20 mph zones introduced – *the decrease in casualties in built-up areas was less than the overall decrease*
- Thirty-one million pounds allocated for local safety schemes – *a sum equal to the value of 41 fatal accidents in a DoT cost-benefit analysis*
- Chevron markings tried out on the M1

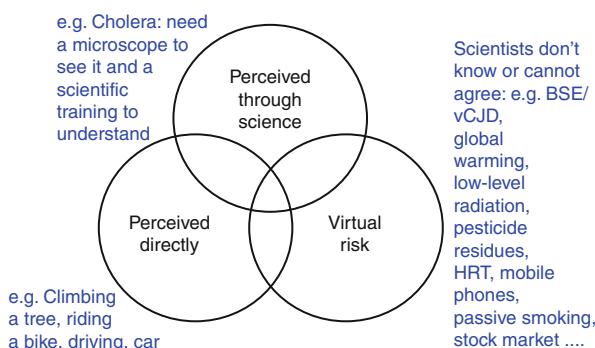

- Trials of nearside pedestrian signals at junctions
- Launch of “The Older Road User” campaign – *the decrease in casualties for those over age 65 was less than the overall decrease*
- Campaign to encourage wearing of cycle helmets by children – *decrease in cycling casualties ages 0–15 was less than overall decrease*  
Change in law requiring adults in rear seats to wear belts in cars where belts are fitted and available – *comparable statistics not available, but decrease in total rear seat casualties less than overall decrease*
- Campaign to encourage drivers to slow down in areas where children are likely to be about – *decrease in casualties suffered by pedestrians and cyclists age 0–15 was less than overall decrease*

A more plausible explanation for the record decrease in road deaths in 1991 than any actions on the part of the Department of Transport or other safety organizations is that the decrease coincided with the most severe recession since the war. There is clear evidence that road accident casualties go up and down with the economy (Adams 1985, Chap. 7).

## Further Research – Explaining the Paradox

► Figures 10.1–10.3 represent what for most transport risk managers is a paradox. They display an enormous decrease in the death rate per volume of traffic with no significant connection to road safety measures introduced by legislators or regulators. None of the measures listed in Lord Robertson’s list of “we know what works” have been proven to work (Adams 1985, 1995).

In seeking an explanation for this paradox it will be helpful to place it in a wider risk management context. ► Figure 10.6 presents a risk typology that is germane to most discussions of a wide variety of risks and their management. Presented as a Venn diagram it suggests that it can be useful to distinguish three different, but not mutually exclusive, types of risk. Typing the single word “risk” into Google produces hundreds of millions of hits. One need sample only a small fraction in order to discover unnecessary and often acrimonious arguments caused by people using the same word to refer to different things and shouting past each

► Fig. 10.6  
Different kinds of risk

other. The typology offered in  Fig. 10.6 can help to dispose of some unnecessary arguments and civilize others.

Risks in the *perceived directly* circle are managed using judgment. We do not undertake a formal, probabilistic risk assessment before crossing the road; some combination of instinct, intuition, and experience usually sees us safely to the other side.

The second, *risk-perceived-through-science*, circle dominates the risk management literature. In this circle we find books, reports, and articles with verifiable numbers, cause-and-effect reasoning, probability, and inference. This is the domain of, amongst others, biologists with microscopes searching for microbial pathogens and astronomers with telescopes plotting the courses of incoming asteroids. This circle contains contributions from the whole range of science, technology, and the social sciences – from physics and chemistry to epidemiology and criminology. But the central science is statistics – the discipline that has probability at its core. This is the circle in which most of the published work on road safety can be found.

The circle labeled *virtual risk* contains contested hypotheses, ignorance, uncertainty, and unknown unknowns. If an issue cannot be settled by science and numbers we rely, as with directly perceptible risks, on *judgment*. Some find this enormously liberating; all interested parties feel free to argue from their beliefs, prejudices, or superstitions.

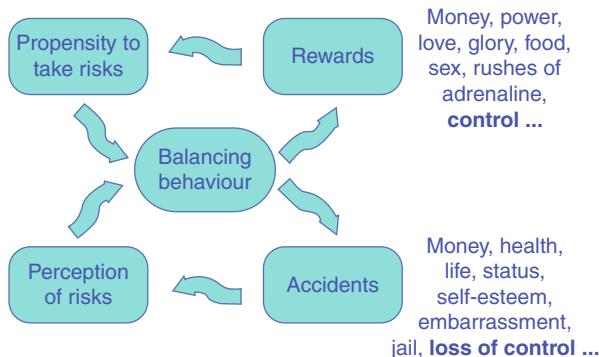

For students of risk this is by far the most challenging circle. The rules of mathematics and probability break down or there is insufficient data to invoke them. Although focused primarily on financial rather than physical risk, a provocative guide to behavior in this circle is Nassim Nicholas Taleb, author of *Fooled by Randomness* (2004) and *The Black Swan* (2007). On the road, as on the financial trading floor, all the participants react to the behavior of all the other participants. Risk behavior is reflexive and not well predicted by any known mathematical systems. It is in this circle that we find the longest-running and most acrimonious arguments. Virtual risks may or may not be real, but beliefs about them have real consequences.

Road safety is an intensively studied subject. It is awash with numbers, numbers adduced in support of the efficacy of existing road safety measures or in support of new ones proposed. And yet, despite all these numbers, we have the paradox described above. This suggests that most of the debate about road safety should be consigned to the third circle – virtual risk. After decades of road safety interventions we still appear to be unclear about what works.

Why should there remain any uncertainty about “what works”? Surely we know about the crash-protection benefits of seatbelts, air bags, and crumple zones. So why should the contribution of such benefits be so difficult to find in the aggregate statistical outcome?

## Different Risk Managers

A major part of the explanation lies in the fact that there are two very different sets of risk managers at work and their work tends to be found in different circles of  Fig. 10.6. One set might be called “institutional risk managers.” These are the legislators and regulators who make and enforce the rules governing transport safety, and the highway and vehicle engineers concerned with making roads and vehicles safer. Their quantitatively embellished work can be found mostly in the *perceived through science* circle. Their endeavors are routinely frustrated by the behavior of a second much larger set of risk managers consisting, worldwide, of billions of road users managing directly perceived risks guided by individual judgment.

**Fig. 10.7**  
The risk thermostat

Figure 10.7, the “risk thermostat,” presents a model of the risk management process that can help to demystify the paradox described above.

The model postulates that

- Everyone has a propensity to take risks – the setting of the thermostat.
- This propensity varies from one individual to another.
- This propensity is influenced by the potential rewards of risk taking.
- Perceptions of risk are influenced by experience of accident losses – one’s own and others’.
- Individual risk-taking decisions represent a balancing act in which perceptions of risk are weighed against propensity to take risks.
- Accident losses are, *by definition*, a consequence of taking risks (to take a risk is to do something that carries with it a probability of an adverse outcome); the more risks an individual takes, the greater, on average, will be both the rewards and the losses he or she incurs.

Credit for discovering this phenomenon is shared between a University of Chicago economist, Sam Peltzman (1975) after whom it is labeled by economists as the “Peltzman effect,” and a Canadian psychologist Gerald Wilde who dubbed it “risk compensation” and later “risk homeostasis.” Wilde’s most recent elaboration of the effect can be found in *Target Risk* (Wilde 1994, 2001).

The risk compensation model might also be called cost-benefit analysis without the £ or \$ signs. It describes a phenomenon known to the insurance industry as “moral hazard” – they have discovered that their customers are less careful about locking up if they have contents insurance. It is a conceptual model, not one into which you can plug numbers and from which you can extract decisions; the Rewards and Accidents boxes contain too many incommensurable variables. Our reasons for taking risks are many and diverse, and vary from culture to culture and person to person.

Most institutional risk managers work with a different model. “Reducing Risks, Protecting People” is the mantra of Britain’s Health and Safety Executive, the country’s foremost risk manager. It is also the title of the publication in which it explains its decision-making process (HSE 2001). In terms of Fig. 10.7, this process is confined to the bottom loop. It exemplifies the thought processes of most institutional risk managers, including those working on the

management of transport risks. Outside the offices of investment banks and hedge funds most institutional risk managers have only a bottom loop. Often their job specification precludes contemplation of the rewards of risk taking. Their job is to prevent accidents. The rewards loop is someone else's business – perhaps the marketing department.

But road users, whether pedestrians, cyclists, or motorists, have top loops. While trying to avoid accidents they are also in pursuit of the rewards of risk. These can range from getting from A to B on time, to the adrenaline rush of the boy racer or making contact with the person calling or texting one's mobile phone.

The model proposes that safety interventions that do not reduce the setting of the thermostat (propensity to take risks) will be offset by behavior that seeks to restore the balance of risk.

Antilock braking systems (ABS) provide a good example. When introduced, their superiority persuaded many insurance companies to offer discounts for cars with antilock brakes. Most of these discounts have now been withdrawn. The ABS cars were not having fewer accidents, they were having different accidents. Or perhaps they were having fewer accidents, but no fewer fatal accidents; the evidence from various studies is less than conclusive – leaving antilock brakes still in the disputed *virtual risk* category of Fig. 10.6.

The opening sentences of the Executive Summary of a recent US Department of Transport study on the long-term effect of ABS in passenger cars and LTVs states:

- ▶ Antilock brake systems (ABS) have close to a zero net effect on fatal crash involvements. Runoff-road crashes significantly increase, offset by significant reductions in collisions with pedestrians and collisions with other vehicles on wet roads. But ABS is quite effective in nonfatal crashes, reducing the overall crash-involvement rate by 6% in passenger cars and by 8% in LTVs (light trucks – including pickup trucks and SUVs – and vans) (NHTSA 2009).

The report notes that early studies of the initial effectiveness of ABS produced results that were “counterintuitive”:

- ▶ The overall effect of ABS on fatal crash involvements was close to zero.

Vehicles with four-wheel ABS had significantly higher rates of fatal run-off-road crashes than vehicles without ABS. In fact, the overall effect netted out to zero only because this increase was offset by a reduction in collisions with other vehicles on wet roads. These fairly strong statistical results did not square with intuition. The behavior of ABS on the test track did not provide any obvious reason that run-off-road crashes should increase; if anything, they suggested there ought to be a benefit.

In listing hypotheses to explain these perverse findings it is clear that the NHTSA's intuition was not informed by the risk compensation hypothesis. Still puzzled by their statistical findings, and seeking reassurance that antilock brakes are an effective safety measure, the report announces a 2008–2012 evaluation plan (Allen et al. 2008) that will seek to answer the following questions:

- What is the overall effect of ABS on nonfatal crashes?
- Even if the net effect of ABS on fatal crashes is close to zero, does ABS prevent enough nonfatal injuries and property damage to endorse ABS technology for its safety benefits? (p. 16)

It is sometimes argued that a risk compensation effect should only be found in cases where there is a clearly perceptible change in a vehicle's performance (IIHS 2007). It might help, it is accepted by some, to explain the statistical outcome associated with antilock brakes, but not

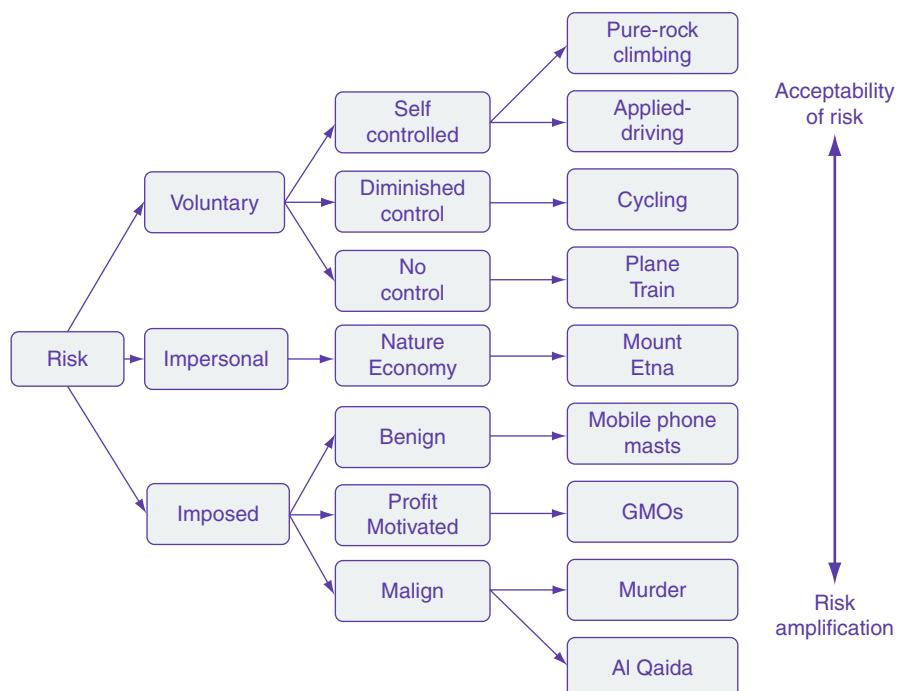

with seatbelts; that is, its effect should be confined to risks falling in the *directly perceptible* circle of the Venn diagram in [Fig. 10.6](#). But most people will admit to feeling safer when belted or, if habitual wearers of seatbelts, to feeling exposed and vulnerable without it. This feeling is surely amplified by highly publicized (and grossly exaggerated) claims for their effectiveness.

## What Kills You Matters

In listing some of the contents of the *Rewards* and *Accidents* boxes in [Fig. 10.7](#) control and loss of control were highlighted. [Figure 10.8](#) sets out the significance of this factor.

Acceptance of a given actuarial level of risk varies widely with the perceived level of control an individual can exercise over it and, in the case of imposed risks, with the perceived motives of the imposer.

- With “pure” voluntary risks, the risk itself, with its associated challenge and rush of adrenaline, is the reward. Most climbers on Mount Everest and K2 know that it is dangerous and willingly take the risk. Similarly thrill-seeking young men driving recklessly are aware that what they are doing is dangerous; that is the point.
- With a voluntary, self-controlled, applied risk, such as driving, the reward is getting expeditiously from A to B. But the sense of control that drivers have over their fates appears to encourage a high level of tolerance of the risks involved.

**Fig. 10.8**  
What kills you matters

- Cycling from A to B (I write as a London cyclist) is done with a diminished sense of control over one's fate. This sense is supported by statistics that show that per kilometer traveled a cyclist is much more likely to die than someone in a car. This is a good example of the importance of distinguishing between relative and absolute risk. Although much greater, the absolute risk of cycling is still small – 1 fatality in 25 million kilometers cycled; not even Lance Armstrong can begin to cover that distance in a lifetime of cycling. Numerous studies have demonstrated that the extra relative risk is more than offset by the health benefits of regular cycling; regular cyclists live longer.
- While people may voluntarily board planes, buses, and trains, the popular reaction to crashes in which passengers are passive victims suggests that the public demands a higher standard of safety in circumstances in which people voluntarily hand over control of their safety to pilots, or bus or train drivers.
- Risks imposed by nature – such as those endured by people living on the San Andreas Fault or the slopes of Mount Etna – or by impersonal economic forces – such as the vicissitudes of the global economy – are placed in the middle of the scale. Reactions vary widely. Such risks are usually seen as motiveless and are responded to fatalistically – unless or until the risk can be connected to base human motives. The damage caused by Hurricane Katrina to New Orleans is now attributed more to willful bureaucratic neglect than to nature. And the search for the causes of the economic devastation attributed to the “credit crunch” is now focusing on the enormous bonuses paid to the bankers who profited from the subprime debacle.
- Risks imposed by one's fellow humans are less tolerated. Consider mobile phones. The risk associated with the handsets is either nonexistent or very small. The risk associated with the base stations, measured by radiation dose, unless one is up the mast with an ear to the transmitter, is orders of magnitude less. Yet all around the world billions of people are queuing up to take the voluntary risk, and almost all the opposition is focused on the base stations, which are seen by objectors as impositions. Because the radiation dose received from the handset increases with distance from the base station, to the extent that campaigns against the base stations are successful, they will increase the distance from the base station to the average handset, and thus the radiation dose. The base station risk, if it exists, might be labeled a benignly imposed risk; no one supposes that the phone company wishes to murder all those in the neighborhood. The extent to which traffic is seen as an imposed risk varies widely. Parents of young children and cyclists are much more likely to feel it as an imposition than drivers of SUVs and big cars.
- Even less tolerated are risks whose imposers are perceived to be motivated by profit or greed. In Europe, big biotech companies such as Monsanto are routinely denounced by environmentalist opponents for being more concerned with profit than the welfare of the environment or the consumers of its products. Manufacturers of high-performance cars are assigned by some campaigners to the same category, their arguments sometimes adding damage to the environment to the danger posed to vulnerable road users.
- Less tolerated still are malignly imposed risks – crimes ranging from mugging to rape and murder. In most countries the number of deaths on the road far exceeds the numbers of murders, but far more people are sent to jail for murder than for causing death by dangerous driving. In the United States in 2002, 16,000 people were murdered – a statistic that evoked far more popular concern than the 42,000 killed on the road – but far less concern than that inspired by the zero killed by terrorists.

- This brings us to Al-Qaida and its associates. How do we account for the massive scale, worldwide, of the outpourings of grief and anger attaching to its victims, whose numbers are dwarfed by victims of other causes of violent death? In London, 52 people were killed by terrorist bombs on July 7, 2005, about 6 days worth of death on the road. But thousands of people do not gather in Trafalgar Square every Sunday to mark, with a 3-min silence, their grief for the previous week's road accident victims.

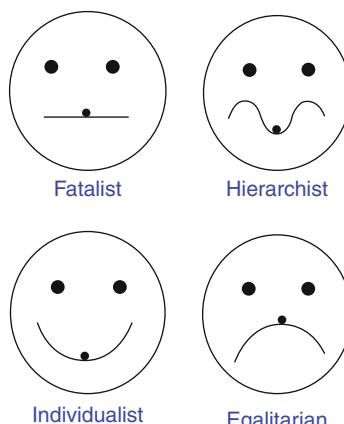

The dangers that can be tracked to the malign intent of terrorists are amplified by governments who see it as a threat to their ability to govern – to their ability to control events. To justify forms of surveillance and restrictions on liberty previously associated with tyrannies, “democratic” governments now characterize any risk to life posed by terrorists as a threat to *Our Way of Life*.

## Our Way of Life

How “we” manage risk to safeguard our way of life depends on who “we” are. ➤ [Figure 10.9](#) presents in cartoon form a typology of cultural biases commonly met in debates about risk (for the pre-cartoon version see Adams 1995).

These are caricatures, but nevertheless recognizable types that one encounters in debates about threats to safety and the environment. They have their origin in the work of anthropologist Mary Douglas on *cultural theory* (see Douglas and Wildavsky 1983; Douglas 1986). With a little imagination you can begin to see them as proponents and defenders of different ways of life. In a report for Britain’s Health and Safety Executive (Adams and Thompson 2002) they are described as follows:

- Individualists* are enterprising “self-made” people, relatively free from control by others, and who strive to exert control over their environment and the people in it. Their success is

■ **Fig. 10.9**  
A typology of cultural biases

often measured by their wealth and the number of followers they command. They are enthusiasts for equality of opportunity and, should they feel the need for moral justification of their activities, they appeal to Adam Smith's Invisible Hand that ensures that selfish behavior in a free market operates to the benefit of all. The self-made Victorian mill owner or present-day venture capitalist would make good representatives of this category. They oppose regulation and favor free markets. Nature, according to this perspective, is to be *commanded* for human benefit.

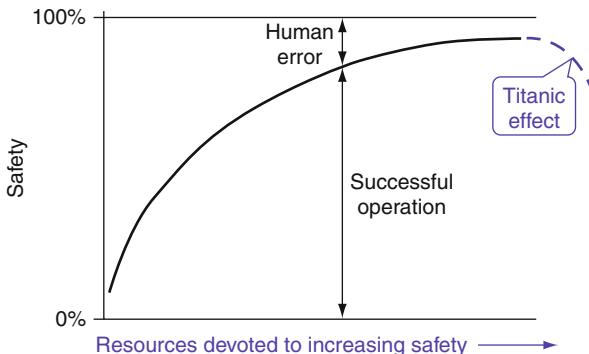

- *Egalitarians* have strong group loyalties but little respect for externally imposed rules, other than those imposed by nature. Human nature is – or should be – cooperative, caring, and sharing. Trust and fairness are guiding precepts and equality of outcome is an important objective. Group decisions are arrived at by direct participation of all members, and leaders rule by the force of their arguments. The solution to the world's environmental problems is to be found in voluntary simplicity. Members of religious sects, communards, and environmental pressure groups all belong to this category. Nature is to be *respected and obeyed*.
- *Hierarchists* inhabit a world with strong group boundaries and binding prescriptions. Social relationships in this world are hierarchical with everyone knowing his or her place. Members of caste-bound Hindu society, soldiers of all ranks, and civil servants are exemplars of this category. The hierarchy certifies and employs the scientists whose intellectual authority is used to justify its actions. Nature is to be *managed*.
- *Fatalists* have minimal control over their own lives. They belong to no groups responsible for the decisions that rule their lives. They are nonunionized employees, outcasts, refugees, untouchables. They are resigned to their fate and see no point in attempting to change it. Nature is to be *endured* and, when it is your lucky day, *enjoyed*. Their risk management strategy is to buy lottery tickets and duck if they see something about to hit them.

Transport risk managers, in the terms of this typology are statuary Hierarchists who make the rules and enforce the rules. For the foreseeable future they can expect to be attacked from the Egalitarian quadrant for not doing enough to protect us, and from the Individualist quadrant for over regulating and suffocating freedom and enterprise.

During the public debate that preceded the passage of Britain's seatbelt law the principal participants could be readily assigned to quadrants of this typology. The proponents of the law were Hierarchists, otherwise labeled "the Nanny State" by Individualists in the lower left-hand quadrant who were, in turn, labeled "loony Libertarians" by the law's supporters. The Egalitarian quadrant was divided. It contained traditional safety campaigners such as the Royal Society for the Prevention of Accidents and the Parliamentary Advisory Council on Transport Safety who supported the law. But it also contained campaigners for pedestrian and cycling safety who had bought into what was then the radical new idea of risk compensation and saw the seatbelt law as a threat to their constituents.

## What Sort of Risk?

- *Figure 10.10* below, borrowed (and amended) from the risk management manual of a major airline, presents yet another way of looking at the different types of risk set out in *Fig. 10.6*.

**Fig. 10.10**  
The human reliability curve

On the steep part of the curve risks, whether up Mount Everest or down a Victorian (or Chinese) coal mine, are usually obvious (directly perceptible), but the responses are diverse and often contentious. Certainly traditional Everest mountaineers are resentful of bureaucratic interference in their risk taking. But their traditions are being compromised by commercial tour companies who, at great expense, offer to guide people to the top and back *safely*. A fatality in 1999 led to a claim of negligence and an out-of-court settlement for £70,000 (Mountain Clients 2007). Britain's oxymoronic Adventure Activities Licensing Authority, instituted to ensure safe adventure, is also seen, by Individualists, as a threat to traditional risk-taking freedoms.

Large risks associated with employment are commonly viewed as imposed risks, imposed by economic necessity especially when the employees are poor (as in the case of Victorian, or Chinese, coal miners). Here interventions in the form of regulation and inspection are more readily accepted – but not always with the expected result. The Davy Lamp (named after its inventor Sir Humphry Davy), which most histories of science and safety credit with saving thousands of lives, is usually described as one of the most significant safety improvements in the history of mining. But it appears to have been a classic example of a potential safety benefit consumed as a performance benefit. Because the lamp operated at a temperature below the ignition point of methane, it permitted the extension of mining into methane-rich atmospheres; the introduction of the “safety lamp” was followed by an increase in explosions and fatalities (Albury and Schwarz 1982).

But when all the obvious measures are in place accidents will still, occasionally, happen. Hundred percent safety is a utopian goal. Indeed it is possible to have too many safety measures. So long as there is a residual dependence on the vigilance of fallible humans, their level of vigilance will depend on the strength of their belief that something can go wrong. The impressive safety record of civil aviation, and all the safety redundancy built into modern aircraft and their operating systems have created a problem of keeping pilots awake on long flights across time zones. Why should they stay alert for the whole of their working lives in anticipation of something they believe will never happen? When you are on the flat part of the curve you do not have a clue whether further safety precautions will have any beneficial effect. The area above the flat part of the *human reliability curve* might be

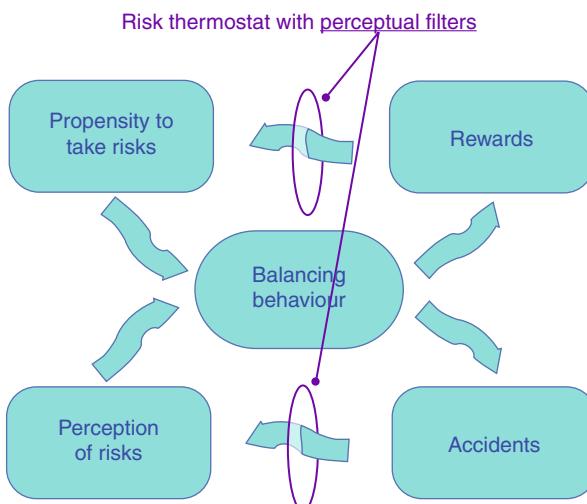

thought of as a zone of *virtual risk*. There are circumstances within this zone where further safety measures can have a perverse effect – where the belief in such measures can induce complacency – the *Titanic Effect*.

## Filters

The variety to be found in the risks and rewards boxes of the *risk thermostat* and the variable responses to them illustrated in [Fig. 10.8](#) (what kills you matters) by the different actors presented in [Fig. 10.9](#) suggest that the *risk thermostat* should be fitted with perceptual filters. The same objective facts can have an enormously varied influence on risk-taking behavior.

[Figure 10.11](#) can serve as a description of the behavior of the driver of a single car going around a bend in the road. His speed will be influenced by his perception of the rewards of risk; these might range from getting to the church on time to impressing his friends with his skill or courage. His speed will also be influenced by his perception of the danger; his fears might range from death, through the cost of repairs and loss of his license, to mere embarrassment. His speed will also depend on his judgment about the road conditions – Is there ice or oil on the road? How sharp is the bend and how high the camber? – and the capability of his car – How good are the brakes, suspension, steering, and tires?

Overestimating the capability of the car or the speed at which the bend can be safely negotiated can lead to an accident. Underestimating those things will reduce the rewards gained. The consequences, in either direction, can range from the trivial to the catastrophic. The balancing act described by this illustration is analogous to the behavior of a thermostatically controlled system. The setting of the thermostat varies from one individual to another, from one group to another, from one culture to another, and for all of these, over time. Some like it

**Fig. 10.11**  
Perceptual Filters

hot – a Hell's Angel or a Grand Prix racing driver, for example – others like it cool – a Casper Milquetoast or a little old lady named Prudence. But no one wants absolute zero.

## Risk: An Interactive Phenomenon

Figure 10.12 introduces a second road user to make the point that risk is usually an interactive phenomenon. One person's balancing behavior has consequences for others. On the road one motorist can impinge on another's "rewards" by getting in their way and slowing them down, or help them by giving way. One is also concerned to avoid hitting other motorists or being hit by them. Driving in traffic involves monitoring the behavior of other motorists, speculating about their intentions, and estimating the consequences of a misjudgment. Drivers who see a car approaching at high speed and wandering from one side of the road to the other are likely to take evasive action, unless perhaps they place a very high value on their dignity and rights as a road user and fear a loss of esteem if they are seen giving way. During this interaction enormous amounts of information are processed. Moment by moment each motorist acts upon information received, thereby creating a new situation to which the other responds.

On the road and in life generally, risky interaction frequently takes place on terms of gross inequality. The damage that a heavy truck can inflict on a cyclist or pedestrian is great; the physical damage that a cyclist or pedestrian might inflict on the truck is small. The truck driver in this illustration can represent the controllers of large risks of all sorts. Those who make the decisions that determine the safety of consumer goods, working conditions, or large construction projects are, like the truck driver, usually personally well insulated from the consequences of their decisions. The consumers, workers, or users of their constructions, like the cyclist, are in a position to suffer great harm, but not inflict it.

The world, at the time of writing, contains about 6.5 billion risk thermostats, and they interact. Figure 10.13, the *Dance of the Risk Thermostats*, provides a tiny window on a few of these interactions. Some of the thermostats are large – presidents with fingers on buttons – most are tiny – shepherds in Afghanistan or children chasing balls across streets. In a rapidly globalizing world the lines of interaction are growing longer and more numerous.

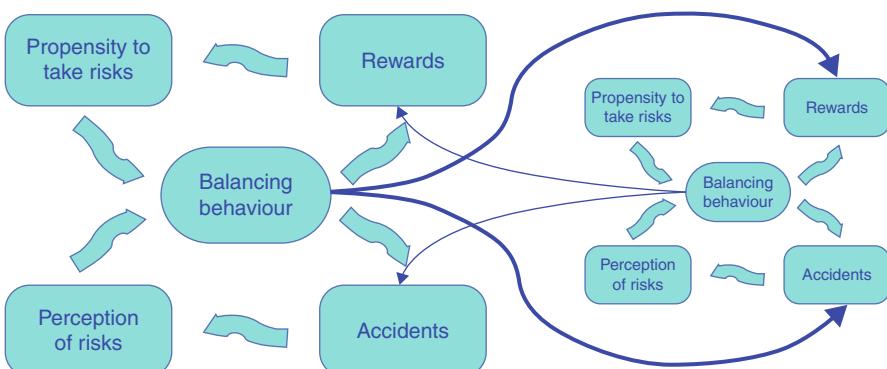

Fig. 10.12  
The truck driver and the cyclist

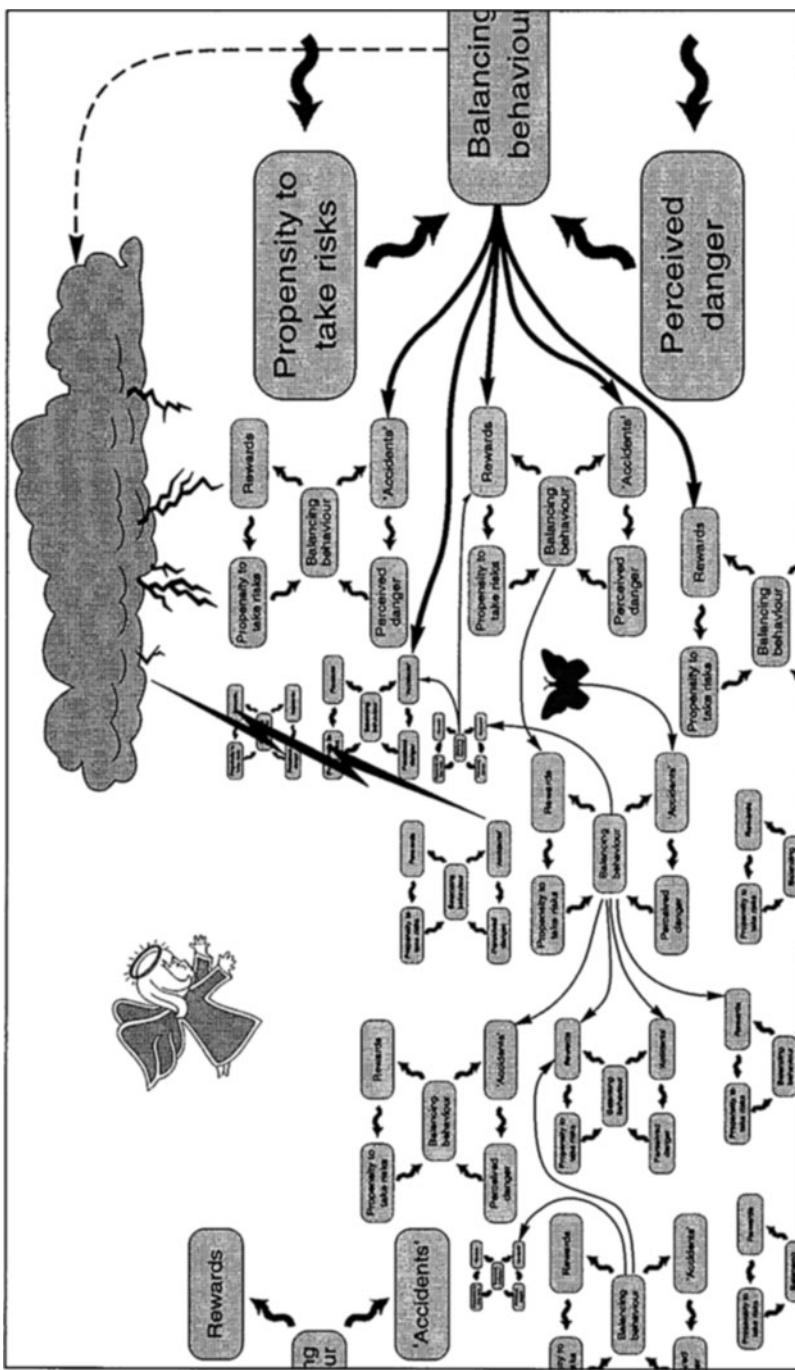

Fig. 10.13  
Dance of the risk thermostats

Overhanging everything are the sometimes destructive forces of nature – droughts, floods, earthquakes, hurricanes, and plagues. The broken line symbolizes the uncertain impact of human behavior on nature. Lurking below are those seeking to control or influence them, from would-be climate engineers to shamans conducting rain dances. Fluttering about the dance floor are the Beijing butterflies beloved of chaos theorists: They ensure that the best laid plans of mice and men “gang aft agley.”

The winged creature at the top left was added in response to a survey that revealed that 69% of Americans believe in angels and 46% believe they have their own guardian angel. The “angel factor” must influence many risk-taking decisions – from those of suicide bombers to those of risk-taking motorists; Deus é Brasileiro (God is Brazilian) is an expression invoked by Brazilian motorists whose wild driving under purported divine protection has terrified me (Adams 2009, Preface).

❸ [Figure 10.13](#) shows but an infinitesimal fraction of the possible interactions between all the world’s risk thermostats; there is not the remotest possibility of ever devising a model or building a computer that could predict accurately all the consequences of intervention in this system.

In the mix are jihadists and CIA operatives, financial regulators and subprime mortgage brokers, occupational health and safety regulators, employers and employees, doctors, no-win-no-fee lawyers, police judges, and juries. And in the realm of transport risks one finds engineers, regulators, and the regulated.

## Conclusion

---

Most transport risks are likely to remain in the contested *virtual risk* circle of ❸ [Fig. 10.6](#). Many will doubtless continue to insist that they know what works. However the United Nations Decade of Action for Road Safety and the Make Roads Safe campaign referred to at the beginning of this essay would appear doomed to disappointment in the developing countries on which their efforts are focused. Wherever one looks one finds the tendency illustrated by ❸ [Figs. 10.1–10.3](#) repeated. As the number of cars in a country increases, the death rate per car decreases. In countries in the early stages of motorization each vehicle is incredibly lethal. Poor countries with a small number of modern cars, with 100 years of safety technology built into them, are achieving kill-rates per vehicle as high or higher than those at the time of Model-Ts. This phenomenon has become known as Smeed’s Law, after Reuben Smeed who established the relationship over 50 years ago (Adams 1985, 1987).

The confidence of some institutional transport safety managers that they “know what works” is undermined all round the world by the behavior of billions of individual risk managers who *react* to the impositions of the official risk managers, but also to the behavior of everyone else on the road. It is known that seatbelts provide significant protection in crashes, that helmets reduce injury caused by a knock on the head, that antilock brakes are superior brakes, that alcohol increases the likelihood of accidents, and speed their severity. But whenever safety measures attempting to put this knowledge to effective use are imposed from on high by institutional risk managers, the result is at best disappointing.

So what did cause the declining death rates described by the Smeed Law? Here we must speculate; the myriad interactions involved in the dance of the risk thermostats defy capture by any known computer. If one accepts ❸ [Fig. 10.7](#) as a plausible description of the process of risk

management, one looks to changes in the setting of the thermostat for an explanation. As we get richer we become more risk averse.

Car ownership correlates strongly and positively with income. As nations become richer they can afford, *and demand*, higher levels of safety and security. The setting of the collective thermostat is turned down. Reference was made above to the risks experienced in Victorian (or Chinese) coalmines. In poor countries life is cheaper and safety standards of all sorts are lower; life expectancy at birth is much lower and road accident rates much higher.

In the most affluent countries of the world there is a trend toward increasing institutional risk aversion and growth in the numbers of institutional risk managers. Their job is to reduce accidents, and then get them lower still. For them, one accident is one too many. As noted above their risk thermostats have no top loop. But despite the increase in the activity of institutional risk managers it is often difficult to discern the effect of their work. As in the case of “The Scandinavian Myth” discussed above, their growing activity appears to be symptomatic of increasing societal risk aversion rather than the cause of a decrease in accidents.

Growing concern for the safety of children on the road might serve as another indicator of an increase in societal risk aversion in affluent countries, and an explanation for a significant part of the plummeting death rate illustrated in [Figs. 10.1](#) and [10.2](#). Today in Britain, per 100,000 children, the road accident death rate is less than a quarter of what it was in 1922 when there was hardly any motorized traffic and the country had a nationwide 20 mph speed limit. This is not because the streets have become safer for children to play in; there is now much more metal in motion. It is because few children are allowed out on their own anymore. In 1971, 80% of 7- and 8-year-old children got to school unaccompanied by an adult. By 1990, this had dropped to 9% (Hillman et al. [1990](#)), and by 2010 it had become a child protection issue (in England in 2010, two controversies appeared in the press in which parents were threatened with child protection orders for allowing their children what used to be the widely accepted freedom to get to school unaccompanied: <http://www.telegraph.co.uk/family/7872970/Should-the-Schonrock-children-be-allowed-to-cycle-to-school-alone.html> and <http://www.bbc.co.uk/news/uk-england-lincolnshire-11288967>). The decrease in child road accidents appears to be overwhelmingly attributable to a decrease in exposure, and the decrease in exposure attributable not to institutional edict but to a growing fear on the part of parents of the threat posed to their children by traffic.

At present the two countries with the best road safety records in the world are pursuing diametrically opposed philosophies of road safety. The Swedish “Vision Zero” policy assigns ultimate responsibility for road safety to the institutional risk manager in the form of the state. The responsibility of users of the system is to obey the rules. It asserts that the rules for the system are that:

1. The designers of the system are always ultimately responsible for the design, operation, and use of the road transport system and thereby responsible for the level of safety within the entire system.
2. Road users are responsible for following the rules for using the road transport system set by the system designers (e.g., wearing seat belts and obeying speed limits).
3. If road users fail to obey these rules due to lack of knowledge, acceptance, or ability, or if injuries occur, the system designers are required to take necessary further steps to counteract people being killed or seriously injured (Hill [2008](#)).

In the Netherlands, a country with an even (slightly) better road safety record, there is a growing enthusiasm for “shared space.” This is an intriguing idea pioneered by the late Hans Monderman, a highway engineer in Friesland. He removed almost all the traffic lights, pedestrian barriers, stop signs, and other road markings that had been assumed to be essential for the safe movement of traffic.

For traditional highway engineers his idea was anathema. Since the advent of the car they have planned on the assumption that car drivers are selfish, stupid, but obedient automatons who had to be protected from their own stupidity, and that pedestrians and cyclists were vulnerable, stupid, obedient automatons who had to be protected from cars – and their own stupidity. Hence the ideal street was one in which the selfish-stupid were completely segregated from the vulnerable-stupid, as on the American freeway or European motorway where pedestrians and cyclists and pedestrians are forbidden. Where segregation was not possible, in residential suburbs and older urban areas, their compromise solution was the ugly jumble of electronic signals, stop signs, barriers, and road markings that now characterize most urban environments.

Monderman observed those using the streets for which he was responsible and concluded that they were not stupid, but neither did they obey all the rules and barriers that assumed that they were nor, on the whole, did they behave selfishly. Pedestrians, he noticed, were nature’s Pythagoreans – always preferring the hypotenuse to the other two sides of the triangle. Given half a chance they did not march to the designated crossing point and cross at right angles to the traffic; if they spotted a gap in the traffic they opted for the diagonal route of least effort.

And motorists did not selfishly insist on their right of way at the cost of mowing down lots of pedestrians. Monderman decided that those for whom he was planning were vigilant, responsive, and responsible. He deliberately injected uncertainty into the street environment about who had the right of way. The results were transformative. Traditional highway engineers have never been concerned with aesthetics. Their job was to move traffic safely and efficiently. They dealt not with people but PCUs (passenger car units). The removal of the signals, signs, and barriers that were the tools of their trade not only greatly improved the appearance of the streetscape but, by elevating the status of the pedestrian and cyclist relative to that of the motorist, made them more convivial as well. Monderman was a practitioner, and so far as I am aware published nothing in the peer-reviewed literature, but his practice has been enormously influential (see Wikipedia – [http://en.wikipedia.org/wiki/Hans\\_Monderman](http://en.wikipedia.org/wiki/Hans_Monderman) – and numerous other online references).

Claes Tingvall, who is credited with being the architect of Sweden’s Vision Zero, said in an interview “Vision Zero . . . is a shift in philosophy. Normal traffic policy is a balancing act between mobility benefits and safety problems. The Vision Zero policy refuses to use human life and health as part of that balancing act; they are non negotiable. . . . Part of the Vision Zero strategy is to improve the demand for safety” (Tingvall 2009).

## A Concluding Speculation

---

Tingvall’s characterization of “normal traffic policy” as “a balancing act between benefits and safety” is a fair approximation of the risk management behavior described by the risk thermostat in Fig. 10.7. But who decides that the thermostat should be set to zero? If it were truly set to zero for all road users no one would move.

In both Sweden and the Netherlands, one senses a high and still growing demand for safety. This is perhaps the ultimate explanation of the good accident records of both. This increasing demand might be characterized as a progressive reduction of the setting of both the Dutch and the Swedish societal risk thermostats.

Every pedestrian, cyclist, and motorist is also a risk manager, performing “a balancing act between benefits and safety.” Anyone with direct experience of how this act is performed in countries at the early stages of motorization (as well as those studying their accident statistics) will know that the performance in such countries is very different from that in highly motorized countries.

The UN’s Decade of Action for Road Safety seeks to promote road safety everywhere but is focused primarily on the least motorized countries with the highest accident rates. The claim quoted at the beginning of this essay that “we know what works,” in the light of the evidence reviewed here, appears hubristic. Unless and until ways are devised to lower the settings of the collective risk thermostats of these countries, the slaughter on their roads looks destined to increase in the early rapid-growth stage of their motorization. The policy maker’s choice of setting of the thermostat is of marginal relevance; it is the average setting of the thermostats of *all* the participants in complex interactive systems that determines the accident outcomes.

The challenge for those trying to make roads safer is to change attitudes – to promote greater risk aversion on the road. There are encouraging precedents. The stigmatizing of smoking and drunken driving has greatly reduced the practice of both; but the change took many years. Perhaps the widespread distribution of Make-Roads-Safe T-shirts, banners, publications, and wristbands by the Make Roads Safe campaign is not a bad way to start. Recruitment of the endorsement of the campaign by superstars of Formula 1, the most spectacular possible exemplars of high-risk driving, is a less obvious method of promoting risk aversion on the road.

Safety as a Spatial Value: Siting Risks as a Matter of Distributive Justice .....	286
Concluding Remarks: Toward a Moral Understanding of the Relation Between Risks and Space .....	290
<b>Further Research .....</b>	<b>291</b>

**Abstract:** Proponents of site-specific hazardous technologies and members of involved communities are often in conflicting positions regarding the most appropriate location for their siting. Because of the component of uncertainty that characterizes the assessment of the potential consequences of these technologies and the different perception of risks by the side of individuals, the “where of risks” is rarely uncontroversial.

This chapter discusses the relation between “risks” and “space” and argues, in particular, on its moral implications. Such implications regard the land use planning evaluations related to the risks (e.g., of the release of hazardous substances or radioactive emissions) arising from these technologies. These risks constitute the main locational criteria. This chapter reflects on the moral legitimacy of the development and outcomes of locational assessments by arguing on possible forms of synergy between spatial planning theories and ethical theories.

In the first part of this chapter, a concrete example of a European chemical safety regulation (namely, Directive 96/82/EC on Hazardous Substances, the so-called Seveso Directive) is discussed. Article 12 of the Directive, that is, the “Control of Urbanization” requirement, requires member states to assess and maintain opportune safety distances from Seveso establishments according to the risk of major accidents. This requirement is of particular interest in the context of this chapter as it offers the opportunity to investigate different methods used to perform the assessment of safety distances that are “spatially relevant” safety measures. Such methods are implemented in selected European countries. Their differences relate not only to considerations of technical nature but also to different cultural attitudes toward risk. Somehow there are also non-explicit, although identifiable different ethical assumptions at their basis. These assumptions and their implications will be therefore discussed.

The second part of this chapter focuses on the matter of framing the “siting risks” issue correctly. The matter of overcoming the predominant tendency of interpreting all siting controversies as “not-in-my-backyard” (in the following: NIMBY) situations will be discussed in detail. It is proposed that controversies that do evidently lose, along their development, identifiable spatial and temporal dimensions may signal a general social opposition to a given technological development rather than a merely local rejection of a technological installation. This distinction between site-specific and “a-site” controversies is particularly important for both the planning theory and practice. Spatial planning processes are the appropriate framework for addressing and solving NIMBY cases; however, they become merely instrumental in those cases in which it is not the “where” but the “if” of the technology to be object of discussion. As it will be discussed the moral implications to be considered in the two different circumstances are of remarkably different nature. Arguing on the distinctive elements of NIMBY versus non-NIMBY cases does therefore occupy this part.

Having presented some examples of European national approaches to the siting of hazardous installations and having provided the distinctive elements of the cases to be framed within a spatial planning discourse, the final part of this chapter concentrates on the possible integration of ethical and spatial planning theories. By referring to the Rawlsian theory of justice (1971) as applied to spatial planning theories by Moroni (1997), a conception of “spatial safety” as primary spatial good is proposed. By taking this perspective aim of the spatial planning practice in a fair society becomes distributing spatial safety equally up to the lowest societal level. As it will be argued this theoretical approach to the distribution of spatial safety in society has important, and promising, implications particularly for the planning practice. First, it implies an evaluative shift from the single siting case to the higher regional or national scale; second, next to spatial and risk tolerability criteria it provides the planner with a *moral*

criterion (i.e., the fair distribution of risks in society) for justifying the outcomes of locational assessments. Indications for the further research needed to strengthen this fruitful integration of risk, spatial planning, and ethical theories in the context of hazardous facility siting are provided in the conclusive part of this chapter.

## Introduction

---

Driving on a highway in Northern Europe, contemplating the countryside and being suddenly adjacent to a large industrial site is a rather different experience in comparison to entering the historical city of Venice through the Liberty Bridge and looking toward the lagoon across the fumes of the petrochemical harbor. However, these experiences have something in common: the evident background of technology and the invisible presence of risks.

If also these risks could be visualized they would appear as potential areas of impacts within which our life and health, together with those of those around us, are under threat. The threats consist of the possible release of hazardous substances, of noxious radiations, or of the sudden wave of overpressure caused by an explosion. If these scenarios could be visualized while we experience the living environment, what we would see is that, simply, we are daily *at risk*.

Among the hazardous technologies coloring the geographical maps designed by risk analysts to visualize potential areas of impacts there are nuclear power plants, LPG storages, chemical establishments, hydrogen-fuel stations, and generally all installations that, while providing sometimes vital benefits to society, have the potential to harm. Despite they do not involve any form of industrial processing and are underground, emerging technologies such as carbon dioxide disposals (in the following: CO<sub>2</sub> disposals) could be also accounted. The common feature among these technologies is being site-specific and posing risks to the man and the environment because of a specific hazardous factor. To prevent and minimize the consequences of the deriving risks, these technologies must therefore be object of a careful locational assessment.

It is rather banal stating that a chemical factory should not be placed within a residential district or a nuclear power plant in a highly instable hydrogeological area. Nevertheless, locational assessments are much more complex than what common sense would lead one to conclude. Finding the most appropriate site to risks consists of a difficult search of balance among land scarcity, an unachievable risk-free living environment, and the many material and immaterial benefits contemporary society opted to rely upon. That is why hazardous facilities siting processes are rarely uncontroversial. Risky installations stigmatize localities and affect the identity of places as well as individuals in a sometimes irreversible way (Boholm and Löfstedt 2004). Loss of property values, phenomena of industrial encroachments, spoiled place-, and self-perception are recurrently documented implications of living nearby hazardous facilities (Boholm and Löfstedt 2004; Lesbirel and Shaw 2005). As periodically reported by the media policy-makers, proponents of such installations and the public are often polarized when decisions about their siting have to be taken.

This problem is well known in literature and in the past two decades it has been object of increasing attention by the side of a variety of scholarly fields. “Siting risks” implies accounting a large number of factors, which are mirrored by the many disciplinary fields that provided their contributions to what has, in time, become an established literature. Considering the

multidimensionality of the concept of risk and its technology-specific and site-specific implications, the siting of risk-bearing installations can be considered a problem of “irreducible complexity” (Renn 2006). Despite the acknowledged difficulty of approaching such complexity through a generally applicable theoretical framework, recent research explored the cross-technology, cross-boundaries, and common ethical questions that characterize facility siting processes beyond their more specific implications. In particular, in her editorial on the new perspectives on siting controversies Boholm (2004) identifies three main areas of investigations that, she suggests, may help in overcoming exploited interpretational shortcuts and framing facility siting conflicts correctly. One of these shortcuts is interpreting all siting controversies as not-in-my-backyard (in the following: NIMBY) situations. “NIMBY” is the popular label attached to those siting controversies in which more or less fierce oppositions polarize risk posers and risk runners. In the majority of cases, the NIMBY perspective sees the former as the promoters of the general good and the latter as the selfish defenders of local interests. Under this light siting controversies are reduced to oppositions not only between polarized actors, but also between a technocratic and neutral versus an irrational and biased appraisal of the risks at issue. Somehow, the NIMBY dispute becomes a confrontation between rationality and irrationality.

The underlying assumption of this predominant interpretation of siting controversies is that a motivated collective interest finds an obstacle in a selfish local resistance. The limitedness of this interpretation is quite evident; by reducing all siting controversies to these minimal terms, the overall desirability of the technology under consideration, its effective compatibility with the chosen context, and the legitimacy of the decision-making process promoting its installation are not the real focus of the discussion. What it is so is rather preventing the supposed collective benefits from finding an obstacle in narrow-minded forms of rejections. Empowering planning procedures to enforce siting processes regardless of these rejections while limiting their duration in time becomes, consequently, the real focus of decisional processes and furthermore policy making (Owens 2004). Privileged instruments in this respect are risk communication strategies that delegitimize subjective and emotional appraisals of risks and the introduction of forms of compensation for at-risk communities.

Inevitably, the legitimacy of such “enforcing instruments” has been put under severe discussion by risk scholars. Both metaethical studies on their assumptions (Roeser 2006, 2010) and interdisciplinary studies on their ethical implications (Linnerooth-Bayer, in Lesbirel and Shaw 2005) denounced their possible fallacies. There is growing consensus that throughout their development, siting processes require a rigorous consideration of their moral implications and that the interests and perceptions of involved parties should be simultaneously accounted. On the one hand, “there are no universal *norms* on which to base a siting strategy” (Linnerooth-Bayer 2005, in Lesbirel and Shaw 2005, at 59), as the perceptions and interests of involved parties do strongly depend on their (both collective and individual) cultural backgrounds. However on the other hand, there are precise universal moral obligations which should be observed prior to legitimize the outcomes of siting processes (Peterson and Hansson 2004). Identifying rigorous and consistent ethical *principles* through which justifying the legitimacy of siting processes beyond any contextual specificity remains, therefore, a needed research effort.

Deciding about technological risks entails deciding about how, in order to (supposedly) advantage the whole, a status and feeling of uncertainty can be (concretely) imposed to what will become disadvantaged ones. A status of risk inequality among members of society is

indeed a common implication of the siting of risky facilities. Notably in the case of site-specific installations, the created *risk* inequality is largely a form of *spatial* inequality. This is why the matter of risk inequality is the point of departure of the present discussion, whose most general question is: What is *concretely* at stake during risky facilities siting processes? When taking the predominant NIMBY outlook the immediate reply would be the trade-off between the collective benefits brought by the technology under consideration and the local risks imposed to those living nearby. Weighing such collective benefits against the local safety loss is therefore what ought to be done. The assumption is that both gained benefits and safety loss can be calculated and then used as the indicators for describing the “siting problem.” Is that the case?

The question may sound banal. The benefits brought by hazardous technologies are evidently not only quantitative entities of immediate appreciation; for example, somehow and someday nuclear power production could reveal to have been the greatest contributor to climate change abatement. By its side, although perhaps less evidently, safety is more than the antonym of risk (Moller et al. 2006). In a given spatial setting, *being safe* and *valuing* such feeling of safety are determinant factors of opposition to intruding technologies (Simmons and Walker 2004). Eradicated “space values” result from the intra-subjective meanings deposited by individuals on other individuals and, through them, projected on the shared living environment. In other words a community that shares a history and therefore a feeling of safety attaches a profound value to it, and through it attaches a value to the own living environment. In short, safety is not only a quantifiable status related to the major or minor exposure to risks; it is also, when not primarily a value at the very basis of the identity of places.

To conclude the unquantifiable and intangible value-component of safety that is cemented in the collective perception of the space shared by individuals is what is concretely the object of violation when a risky technology is proposed for siting. The siting of an ultrahazardous facility puts at risk not only people and things but also the value and identity that will be attached to the place in which they live. This seems to be the underlying idea also of the analysis of Boholm regarding the main areas of investigation to be further explored for shedding new light on siting controversies (Boholm 2004). These areas are listed below:

1. Identifying appropriate procedures for planning and decision making by accounting both the tangible and intangible “values at risk” of the localities intruded by controversial installations
2. Identifying the distinctive aspects of NIMBY cases in contrast with the overall lack of acceptance of controversial technological developments which may be signaled during conflicting siting processes
3. Promoting a broader understanding of the consequences of risks in terms of the threats to the space values that a community regards as nonnegotiable, and accounting them since the early stage of siting processes

This work discusses these three areas of investigation but will contribute mainly to the development of the third one. As mentioned above, the main scope of this study is proposing a perspective on risky facilities siting based on a synergy between risk, ethical, and spatial planning theories. The contributions which will be recalled along the text are therefore both of philosophers of risks (Hansson and Peterson 2001; Peterson 2001, 2003; Peterson and Hansson 2004; Ersdal and Aven 2008; Asveld and Roeser 2009; Roeser 2010) and of ethicists of spatial planning (Moroni 1993, 1994, 1997, 2004, 2006; Golany 1995; Hare 1999). Basic notions of risk

analysis will be also provided in support of the reading (Apostolakis 1990, 2004; Amendola et al. 1992; Christou and Amendola 1998; Amendola 2001; Christou 1998).

It is worth repeating that arguing on the siting of technological risks suffers from several limitations when done at a high level of generality. Procedures for planning and decision making vary depending on different legislative, political, and cultural frameworks (Cozzani et al. 2006; Basta et al. 2008; Basta 2009). Furthermore, the type of technology under consideration and the story line of the relevant siting process in its time and space pose extremely specific challenges. This chapter opts for investigating the distinctive elements of risky facility siting processes beyond such specificities and, to do so, it starts with providing a general outline of the “siting risks” issue.

## The “Siting Risks” Issue

---

In a highly simplified manner, a risky facility siting process consists of the building of an installation meant to deliver certain benefits in a specific geographic setting (Boholm 2004). To such benefits certain risks correspond. Generally, whereas the produced benefits are broadly collective the so-called unwanted consequences are mostly locally distributed. Such consequences consist, essentially, of health and environmental effects.

Although effective, this introduction does evidently neglect some not banal aspects of the problem. That the unwanted consequences of technological risks are locally distributed, for example, is a consideration that has been put under severe discussion in past literature. The risks posed by certain ultrahazardous installations (e.g., by nuclear waste disposals or by dangerous chemicals’ factories) are “no more tight to their place of origin” (Beck 1986:1992) as their effects may overcome geographical as well as generational horizons. The consequences of the sadly known nuclear accident of Chernobyl of 1986 cannot be reduced to the immediate and long-term effects on the citizens and the environment of the surrounding village. Equally the consequences of the chemical disaster which killed thousands in Bhopal in 1984 cannot be understood as merely “local” (see Shrivastava 1992 and 1996 in particular). Notably while this writing undergoes the final editorial work, the consequences of the Fukushima nuclear disaster that followed the earthquake in Japan of March 2011 occupies the world headlines; even here it would be hard defending that such consequences are merely “tight to Fukushima.”

These considerations serve to clarify from the outset that notwithstanding the acknowledged multidimensionality of the consequences of site-specific technological risks this chapter will refer mainly to *spatially relevant* consequences (Schmidt-Thomé 2006a, b, c). The latter are those rare, unwanted, and disruptive consequences that following accidents develop into scenarios that involve the surroundings of installations. Differently than the *ordinary* impacts related to the operational standard of the given technology (like emissions and nuisance), these scenarios may be also identified as its *extraordinary* impacts (Basta 2009). In simpler terms, they are the so-called major accidents which may occur due a failure of the technology and/or of the human–technology interaction.

The spatially relevant measures of prevention of the consequences of major accident scenarios include safety distances, emergency planning, geographical information systems, and additional technical measures (in the following: ATM) such as reinforced glasses and protective fences. Generally, they include all the material and organizational measures

dislocated in a given territorial setting that are designed according to the risks posed by the technology (Basta et al. 2006) and are meant to prevent the relevant consequences. Spatial planning instruments (particularly, local land use plans) are among the governance instruments through which such measures are regulated, designed, dislocated, and maintained in time.

Nevertheless these instruments can be unprepared to regulate such measures timely and effectively. New and emerging technologies pose new risks to which preexisting risk prevention regulation and land use planning procedures are often neither ready to respond, nor flexible to adapt to. Furthermore the hydrogeological, morphological, natural, and urban features of the areas where newly designed technologies can be appropriately located must respond to specific requirements, which are sometimes as diverse and complex as the social contexts in which these technologies are to be sited. These features of the territory, both in the West and in the East of the industrialized world, keep varying also in time and generally shortening the possible distance between risks and inhabited urban areas. “Regions of risks” kept changing their configuration and concentration, but generally they kept expanding in both European and extra-European countries (Hewitt 1997). During the 1960s and 1970s, the siting of hazardous installations was evidently less constrained by the proximity of urbanized areas than nowadays.

Because of their political and legislative implications, planning instruments and procedures have rarely anticipated the urging matter of this shortening distance. Planning instruments, risk regulation, and risky technologies do not simply evolve at the same rhythm (Arcuri 2005). Rather the former two adapt to the demands of the latter and, in most cases, once the latter needs to be sited. Sadly, planning instruments did often adapt to risks also when the latter manifested themselves in the form of tragic consequences. This is why current European national frameworks for spatial planning in at-risk areas are often seen as *lessons learned from accidents*, with the meaningful example of the thoroughly revised French regulation on the siting of dangerous establishments which followed the accident of Toulouse in 2001 (Salvi et al. 2005).

Analyzing the postaccidents development of national spatial planning regulations is particularly useful in the context of this chapter. Different methodological orientations adopted in Europe offer the opportunity to reflect on the specific as well as cross-boundaries aspects of the “siting risks” issue. Before developing the discussion in this direction, it is important to keep in mind some clarifications. First of all, the technologies under considerations in this work are site-specific hazardous technologies of known risky potential. In more simple words, their operation implies the presence of substances and/or risk-factors known to be harmful for the man and the environment. As mentioned above, chemical factories, nuclear facilities, fossil fuel, and non-fossil fuel storages together with their distribution networks and CO<sub>2</sub> underground disposals are examples of such technologies. A second clarification is that their overall desirability will not be object of discussion. This chapter does only discuss the ethical implications of their siting. This choice is motivated by the spirit of generality that animates the present collection and furthermore by the fact that the desirability, acceptability, and justifiability of risky technology relates, at least in part, to the specific context of their design and operation. Discussing whether and how given risky technologies are desirable without accounting these aspects is therefore not possible at this level of generality. This chapter does rather wish to provide critical instruments which may support a better understanding of the complexity of spatial planning processes in relation to technological risks and,

to do so, only their most common features can be considered. Possible routes to be followed to deviate from generality are provided through the bibliography.

## History

---

The matter of siting risky technologies became a prominent topic of investigation for increasingly heterogeneous scholarly fields starting, in particular, from the 1970s (Ale 2005a, b). At that time the increasing presence of chemical establishments, LPG storages, and networks of fuel distribution started to conflict with the risk of accidents within, equally expanding, urban areas. Periodically revamped by the occurrence of catastrophic accidents, the matter of “siting risks” remains one of the most controversial challenges posed by technological development to spatial planning practices. Considering the parallel growth of urban areas and industrial sites that characterized the last 60 years of European history, evidently the “space available to risks” has been decreasing (Hewitt 1997) while, at the same time, the catastrophic potential of hazardous technologies kept dramatically augmenting (Beck 1986;1992).

New technologies imply new risks whose modeling and quantification is a complex exercise of sometimes debatable outcomes. However also the *ex ante* assessment of the risky scenarios associated to established technologies (like LPG storages or chemical factories) is characterized by a degree of uncertainty and subjectivity (Amendola et al. 1992; Apostolakis 2004). Stochastic uncertainty (i.e., the variability of the variables in time; e.g., of predominant winds direction) and imperfect knowledge (i.e., the lack of information) limit the possibility of predicting the development of accident scenarios with precision (Christou 1998). Several studies have also demonstrated that on the basis of the same information experts called to perform a risk analysis exercise may arrive to different, although all well-grounded, conclusions (Amendola et al. 1992). These aspects of uncertainty and subjectivity do not limit the relevance of risk analysis to risk decision making, but do surely warn against an a-critical utilization of its outcomes.

The European Directive stating the land use planning requirements regarding the siting of establishments wherein hazardous substances are present (the before mentioned Directive 96/82/EC on Dangerous Substances) is named after the accident of Seveso occurred in 1976 in the Northern region of Lombardy (Italy). The accident consisted of a massive release of dioxin and involved the population living in the nearby rural area. Besides causing a number of injuries and precautionary abortions, the accident led to a long lasting pollution of the soil and, consequently, of the food chain. The emotional and political impacts of these dramatic consequences were proportional to the unpreparedness of the population of Seveso to cope with them. Citizens were unaware of the nature of the substances produced by the establishment. Meaningfully, because of the pleasant odors released during the processing of chemicals the plant was nicknamed “the fabric of perfumes” (Arcuri 2005). Information on the effects of dioxin on edible vegetables, animals, and above all humans was delivered by the plant management to authorities and the public with dramatic delay. The evacuation of the area surrounding the plant following the accident was consequently organized with substantial delay. Despite following accidents worldwide led to worse immediate consequences in terms of human lives and environmental impacts, the Seveso accident does therefore remain the epitome of everything; the spatial and emergency planning practices must be prepared to prevent and to cope with.

It is also by reflecting on the many implications of these tragic accidents that starting from the 1990s different scholarly fields started to contribute to the technological risks literature. The risk analysis literature (Apostolakis 1990; Christou and Mattarelli 2000; Amendola 2001; Cozzani et al. 2006 among others), the legal and sociological literature (Beck 1986:1992; Renn 1992; Arcuri 2005; Renn and Graham 2005), and the geographical and spatial planning literature (Walker 1991, 1995; Boholm and Löfstedt 2004; Lesbirel and Shaw 2005) started to have, in the matter of “siting risks,” a shared area of interest. Psychologists started to contribute to the understanding of (to paraphrase one of the most known authors among them) the interpretational distance between “risk as numbers” and “risk as feelings” (Slovic 1991, 1999, 2002). Thanks also to the empirical evidence provided by these studies that ethicists could start reflecting on the moral implications of such distance (Roeser 2006, 2010), while others kept arguing on the inherently ethical nature of the analytical assessment and decision-making processes whose objects are the most diverse risk-bearing technologies (Schrader-Frechette 1991; Peterson and Hansson 2004; Ersdal and Aven 2008; Asveld and Roeser 2009; Hillerbrand 2010).

Spatial planning started to contribute to this heterogeneous research area somehow later than the listed scholarly fields. One of the possible explanations of this delayed interest from the side of planning scholars in a matter that is increasingly affecting planning processes worldwide is the historical distance between spatial planning theory, spatial planning regulation, and the relevant professional practice. But for few exceptions (see Walker 1991, 1995) before the current decade spatial planning scholars had hardly considered the “siting risks” issue as an autonomous field of investigation. The relatively recent inclusion of land use planning requirements for areas at risk within European legislations might explain this otherwise moderate attention. Notably the land use planning requirement of the mentioned Seveso Directives (the already mentioned Article 12 on the Control of Urbanization) was added to the requirements of the Directives relatively recently, especially when thinking at the events that led to its formulation. Article 12 is dated 1996, hence two decades “older” than the Seveso disaster and a significant number of disastrous accidents worldwide (see Lees 1996 for a thorough account). Several national transpositions of Article 12 are also quite recent. The Italian Decree on land use planning in areas subject to major accidents risk was issued in 2001; the new French Law on natural and technological risk prevention in 2003 (see Basta 2009). The majority of contributions of spatial planning scholars followed but have rarely anticipated the methodological challenges posed by these new regulatory requirements. It could be said that as risk regulation is a lesson learned from accidents, spatial planning derives lessons from risk regulation.

A second possible explanation of the relatively scarce contributions of spatial planning scholars to the risky facilities siting literature is the historical “ownership” of the analytical assessment that informs siting processes by the side of risk analysts. Somehow when it comes to large-scale hazardous facilities, land use planning instruments become the “recipients” of (risk) assessments solely performed by technicians. The most impacting technological risks are still too often “implanted” within local land use plans without having preventively integrated the knowledge of risks with the knowledge of the territory. The latter is intended not only as the material configuration of the living environment but also as the immaterial dynamics at the basis of its identity and future developments. The knowledge and understanding of these dynamics would be fundamental to site hazardous installations compatibly with the surroundings and with their lines of development.

Next to the historical ownership of locational assessments by the side of risk analysts, there is also the problem of the different evaluative scales of risky facilities siting and local land uses. In the majority of European spatial planning frameworks, the central or regional governments hold the competence for licensing top-tier Seveso establishments and, generally, risky facilities of “general interest” like nuclear power plants and energy infrastructures. Differently, the elaboration of land use plans is usually assigned to municipalities with all the deriving problems of coordination of consistency. There is, in essence, a problem of “who does what” and “at what scale she does so.”

The lack of coordination between the technical assessment that guides the siting of a given risky technology and the procedures for allocating land uses and granting permits of construction in the same area resulted in the many situations of proximity between risks and residents which are visible in European cities. Installing technological risks within land use plans “from the top” while dealing with the development of industrial sites separately from the development of the surrounding areas equaled to a sort of technological colonization of localities or, as defined elsewhere, of industrial encroachment (Simmons and Walker 2004). Several spatial planning scholars have captured the unpreparedness of spatial planning instruments and of the professional practice behind them in preventing a process of siting from becoming, in time, a sort of uncontrolled industrial metastasis. In a somehow paradigmatic case study, Walker and Simmons (2004) documented how in the course of five decades a small industrial area in a village in the South of Great Britain kept expanding up to 17 ha. At the same time residential districts expanded, if not proportionally, equally considerably. The proximity between the boundary fences of the industrial site and nearby houses augmented especially during the 1970s, with the current result that the fences have little or no separation from gardens and footpaths. What this situation exemplifies is that the land use planning in the area had not foreseen the situation of conflict which would have resulted from the mutual expansion of the industrial area and of the residential districts; most probably because of the lack of coordination between the two respective licensing processes. On the one side the industrial management was allowed to acquire new land and expanding the works, while on the other side developers and privates were allowed to acquire new land and constructing residences. The current situation of proximity is therefore difficulty resolvable as it consists of the opposition between parties who have acquired, in time, equally legitimate property rights.

As any other case of industrial encroachment, the story line of this case is highly contextual. However, it is paradigmatic of the historical lack of a methodological and procedural bridge between risk prevention and land use planning. Furthermore, it is paradigmatic of the impacts on the self-identity of communities that end up with cohabiting with industrial establishments, and the associated risks, in an increasingly intruding and stigmatizing way. Hazardous industries may progressively stigmatize the perception of certain areas to the point that what in the collective memory was recalled as a (safe, relaxing, unpolluted) rural area does quickly become an (unsafe, threatening, polluted) industrial one. Somehow, different values and attributes start to be associated to the living environment once hazardous installations become a substantial part of it. How to incorporate the values that are attached to the living environment before its potential installation (e.g., the valued feeling of safety) when it comes to decide about their best location is therefore a crucial point of attention for the planning research in the field.

As anticipated, in order to develop this discussion, the main areas of investigation identified by Boholm (2004) helped in organizing this chapter in the following sections.

## Current Research

### Finding a Place to Risks: The Example of the European Regulatory Framework on Dangerous Substances

In order to discuss the *methods and procedures* for spatial planning in relation to site-specific hazardous establishments, this section refers to a European chemical safety regulation, that is, the already introduced Seveso Directives on Dangerous Substances (96/82/EC and following amendment). Article 12 of the Directive states the Control of Urbanization requirement. An overview of selected national implementations of the requirement will help to identify some specific aspects of national planning methods and procedures while highlighting the cross-boundaries aspects of the “siting risks” issue.

Article 12 calls Member States to “ensure that the objectives of preventing major accidents and limiting the consequences of such accidents are taken into account in their land-use policies and/or other relevant policies.” A major accident consists of the release, explosion, or fire involving dangerous substances whose impacts may extend outside the boundaries of establishments. The massive dioxin release in Seveso (Italy, 1976), the disastrous methyl-isocyanate release in Bhopal (India, 1984), the fireworks explosion in Enschede (The Netherlands, 2000), and the ammonia explosion in Toulouse (France, 2001) are all examples of major accidents. Considering their risks while elaborating land use planning instruments consists, essentially, of modeling possible accident scenarios and “overlapping” their visualization with the land use map of the area. To model major accident scenarios, risk analysts consider a great number of variables, including the stock of dangerous substances, the safety system in place, and the predominant meteorological conditions in the area. Visualizing the spatial extension of accidents on a geographical basis does therefore serve to identify whether the corresponding land uses (residential, service, or transportation routes) would lead to the involvement of residents and environmental goods. The following step is establishing the spatial measures which may prevent it. The most important spatial measures are safety distances and emergency plans. According to the Seveso Directives, safety distances in particular should restrict land uses and being maintained in the long term.

Following the entry into force of the Seveso Directives, in 2004 the Major Accidents Hazards Bureau of the Joint Research Centre of the European Commission launched the “Land Use Planning Including MAHB and NEDIES” investigation. The focus of the investigation was on the different approaches adopted by Member States for implementing Article 12 within their land use policies and instruments. The scope of the investigation was providing an up-to-date overview of national implementations of the requirement and supporting the elaboration of a European implementation guidance. The latter was adopted by the European Commission in 2006 (Christou et al. 2006).

Next to the implementation guidance, the MAHB investigation led to the elaboration of a second supporting instrument, published in the form of a JRC Technical Report, named *Roadmaps* (Basta et al. 2008). Based on a questionnaire survey, literature review, and direct interviews with the members of the European Working Group on Land Use Planning (EWGLUP), this JRC technical report collects the detailed description of the different methods and procedures for land use planning in Seveso areas developed by a selected group of Member States. The Dutch, British, German, French, and Italian implementations of Article 12 are here analyzed together with the procedures in place for their implementation within land use

planning instruments. Indications for interpreting the differences among these five member states' *roadmaps* from Article 12 to local land use plans are provided together with general recommendations to member states on how implementing the Article in accordance with the European regulatory framework.

These different European national implementations of Article 12 are particularly interesting in the context of this chapter as they allow to highlight fundamental differences in spatial planning frameworks across Europe and the way different risk prevention policies interrelate with them. As documented in a case study that was performed during the elaboration of the implementation Guidance, the "methodological bridge" between the two national regulatory frameworks (that are the spatial planning and the major accidents risk prevention frameworks) leads to remarkably different land use planning interventions (Cozzani et al. 2006). Understanding the underlying factors of such differences while identifying what does not vary across methodologies, boundaries, and cultures has therefore been the focus of this chapter. Before introducing some findings such differences are briefly described.

From a methodological perspective, major accidents risk assessment in relation to land use planning can be distinguished in probabilistic and deterministic approaches (Christou 1998; Cozzani et al. 2006; Basta et al. 2008; Basta 2009). The assumptions at the basis of the two approaches differ in relation, particularly, to the decisional relevance of the expected probabilities of accidents. The probabilistic approach considers the calculated probabilities of accident scenarios as an explicit decisional criterion of the assessment of safety distances from dangerous establishments and of the compatible land use destinations in their surroundings. Differently, the deterministic approach considers as explicit decisional criterion only the expected consequences of accident scenarios.

This difference is fundamental as, in principle, it implies that a very rare accident scenario (say with less than  $10^{-8}$  event/year probability of occurrence) with disastrous consequences (immediate death of stationary individuals within, say, 500 m of distance from the source of the accident) may be discarded when land use planning instruments are to be designed. On the basis of its extreme rarity, the probabilistic planner who has to "draw on the map" the safety distance which shall be restricted from construction may simply ignore it. Differently, the deterministic planner would not regard the rarity of the event as an explicit decisional element: Only its consequences would be considered as such; therefore, the distance within which the consequence of "immediate death" would occur, regardless of its expected probability, would become the reference for drawing safety distances on the map. The rationale of the deterministic approach is that an even poorly credible catastrophic event (that in technical jargon does usually correspond to the *worst-case scenario*; see Lees 1996) would be considered as the *reference-scenario* on the basis of which safety measures could be established. It is important to point out that the most adopted form of determinism in major accidents risk prevention is selecting, in place of the worst scenario, the worst *credible* one (accounting, in so doing, probabilities implicitly rather than explicitly). Nevertheless, the rationale of the probabilistic and deterministic approaches remains sharply different and as demonstrated leads to substantially different land use planning interventions (Cozzani et al. 2006).

The United Kingdom and the Netherlands have adopted and largely contributed to the development of the probabilistic orientation (Ale 2005a, b; Bottleberghs 2000; Jongejan 2008). Germany has historically maintained a deterministic orientation. France and Italy have recently reviewed and formulated their legislations respectively and have both opted for a mixed method. The latter method decays from the deterministic orientation as it privileges the

consideration of the severity of the consequences of reference-scenarios while accounting expected probabilities as a mitigating factor (for a detailed overview of these national methods see Basta et al. 2008).

A second significant difference among the analyzed national approaches to land use planning in Seveso areas is the target versus legally binding risk tolerability criteria which are indicated in legislations. Adhering to its common law tradition, the United Kingdom does not provide fixed criteria: The as-low-as-reasonably possible (in the following: ALARP) principle underlies the risk prevention policy of the country (Ale 2005a) and no legally binding, but only target criteria, are indicated in the relevant legislation. With the exception of the Dutch societal risk tolerability criteria, generally European national legislations provide a legally binding risk tolerability or “consequences acceptability” threshold that has to be respected when establishing the land use planning measures in the vicinity of hazardous establishments.

• *Table 11.1* summarizes the criteria used for major accidents risk assessment in relation to land use planning in the examined countries.

■ **Table 11.1**

Risk in land use planning: a summary of policy orientations in selected European countries

	MA risk prevention policy orientation	Criteria for risk assessment in land use planning	Status of the criteria
France	Traditionally deterministic; recently reviewed, it accounts severity levels and probability classes for determining safety distances	Individual risk and “severity” levels on the basis of the number of expected fatalities and damages	Legally binding
Italy	Semiquantitative: a deterministic assessment of accident scenarios and effects is followed by the consideration of probability classes as mitigating factor for defining safety distances	Individual risk and environmental risk	Legally binding
Germany	Traditionally deterministic	Individual risk	Legally binding
The Netherlands	Strictly quantitative: a full QRA is required in all cases risky establishments have to be installed and operated	Individual and societal risk	Individually binding for individual risk, target criteria for societal risk
Great Britain	Based on the application of the ALARP principle, the evaluation of safety distances is risk oriented in case of emissions and consequence oriented in the case of thermal radiation and explosions	Individual and societal risk	Target criteria: the advice of the safety authorities is not legally binding for planning agencies

The Table provides a general summary of the approaches adopted by the selected European countries for regulating land uses in the vicinity of the hazardous establishments falling under the requirements of the Seveso Directives. How to explain the adoption of different methods by the side of often neighbors Countries? Which are the most relevant spatial implications? Both questions are discussed in the following section.

## Deciding on Chances or Deciding on Consequences? European Answers and Their Ethical Basis

As discussed above, the first and most important difference between the approaches adopted in selected European countries for land planning in at-risk areas consists of the adoption of deterministic versus probabilistic approaches. The spatially relevant implications of the two approaches could be summarized as more conservative and sensitive to hazardous substances stock in the former case and less conservative and more focused on risk abatement at source in the latter case. Deterministic approaches do usually consider, as reference-scenario, worst-, or worst-credible scenarios. By doing so they lead to opt for larger safety distances, for decreasing the stocks of substances in order to shorten them or, at least theoretically, for (re)locating the establishment elsewhere in case both measures reveal insufficient to site the establishment compatibly with the surrounding land uses. Probabilistic approaches instead rely on quantitative risk assessment (QRA) for modeling the reference-scenarios which may *credibly* occur and select the reference-scenarios to be used for planning purposes on the basis of a given risk tolerability threshold. In the Netherlands for example, the risk of  $10^{-6}$  events/year probabilities for a stationary individual of dying due to the involvement in a major accident is the legally adopted risk acceptability threshold (Bottleberghs 2000; Ale 2005a, b). Above this threshold, accident scenarios are therefore not considered for planning purposes.

Even though the described divergences between the two approaches are more theoretical than practical, the range of considered accident scenarios does concretely differ. Whereas the probabilistic approach leads to restrict the set of reference-scenarios to those whose occurrence is credible from both a magnitude and probabilistic viewpoints, the deterministic approach considers the whole range of possible events, including the worst. As worst-scenarios are likely also the rarest and have the most extended area of impact it follows that the spatial measures in their relation include, among other measures, long safety distances and large restricted zones.

There are several possible explanations of this fundamental difference between the two described approaches. One relates to the national environmental and spatial frameworks in which they are adopted. In countries like Germany, wherein the Federal Constitution defines the precautionary principle as a fundamental environmental principle, justifying the adoption of a probabilistic orientation in risk prevention may be regarded as inconsistent (Boehmer-Christanses 1994, reported by Adams 2002). Differently in the Netherlands, “the government has committed to the concept of risk rather than to the false promise of safety” (Jongejan 2008). Here the combination of land scarcity and high population density represents an insuperable limitation to the adoption of a deterministic orientation: Restricting large areas around hazardous establishments from construction would conflict with the need of other primary land uses.

Next to policy and spatial issues also economic considerations matter. Current situations of proximity between hazardous establishments and urbanized areas consist of the opposition

between parties who have acquired, in time, legitimate property rights. Any measure of relocation and/or land use restriction would hence require a large investment of both public and private resources. For new siting processes, the problem is somehow similar: Imposing large clear areas around Seveso establishments may lead to a loss of constructible land plots and hence conflicting with other primary residential and infrastructural needs.

These considerations are, however, more of pragmatic than of theoretical nature. From a theoretical viewpoint, the rationale of the two approaches could be rather seen as the result of fundamentally different ethical assumptions. Opting or not opting for considering a threshold of probability of occurrence of unwanted scenarios as an explicit decisional element for selecting the reference-scenarios to be used for planning purposes relates to relying or not relying on quantitative risk assessments of known uncertainty. In other words, it relates to considering or not considering the whole range of consequences regardless of the investment needed to limit their possible, although extremely rare, occurrence. In conclusion, it relates to “taking the risk” of relying on quantitative risk analysis. As mentioned above, imperfect knowledge and the unpredictability of contour-conditions in time and space make the modeling of accident scenarios a necessary but not exclusive criterion on the basis of which spatially relevant risk prevention measures were established. Note that the engineering jargon in this field is full of qualitative attributes: the “credible,” “worst,” “poorly credible” labels stress the qualitative component of the *ex ante* assessments whose objects are events whose likelihood and development are not fully predictable.

From a theoretical perspective, it could therefore be said that deterministic and probabilistic approaches differ on the ground of their different attitude toward uncertainty. Determinism is bent toward the maximum avoidance of it. This could be interpreted as the prioritization of a moral principle, that is, the principle according to which what the planner ought to do in front of the *possibility* of unacceptable consequences cannot be mitigated because of their extreme rarity. What ought to be done is opting for their avoidance *tout court*. Probabilism instead moves from the assumption that the planner ought to consider the *probability* of unacceptable consequences in light of the sacrifice needed for their prevention. What ought to be done is therefore preventing (only) the set of credible consequences by considering the (calculated) rarity of events as an (explicit) decisional criterion.

The former assumption, that is that the whole set of *possible* scenarios must be object of prevention, is based on a categorical imperative. The latter assumption, which differently sees only the *credible* scenarios as the due object of prevention, underlies a balanced consideration of the relation between risks and the resources needed to prevent it. In other words, it considers the trade-offs between risks and benefits. On the basis of these remarks, it is proposed that the deterministic and probabilistic approaches for land use planning in at-risk areas may be linked to deontological and utilitarian theories respectively.

Several authors have investigated the implications of different ethical theories to risk decision making and only a dissatisfying selection can be cited here (Schrader-Frechette 1991; Peterson 2001, 2003; Peterson and Hansson 2004; Ersdal and Aven 2008). Ersdal and Aven (2008) for example give an account of the moral theories which can be retraced underneath the surface of the risk assessment criteria which are most commonly adopted by legislation and by professional practices. In their account, utilitarianism is defined as a theory of both the good and the right as it identifies both a nonmoral value (i.e., utility) and which principle shall justify the right actions (i.e., its maximization). Deontology by contrast is a theory solely concerned with establishing the principles following which actions would result

good or bad. Its most known formulation, that is the Kantian formulation, is based on the concept of categorical imperative, which is the universal normative guidance through which judging the “goodness” and “badness” of actions. A categorical imperative is universal in the sense that it applies to anyone, anywhere, and anytime: No breaches are possible under any circumstance. An interesting interpretation of deontology in contrast to utilitarianism is that categorical imperatives are in fact not established on the basis of what individuals ought to pursue and realize, but solely on what individuals ought to honor (Pettit 1991). Therefore, while in utilitarianism the goodness of badness of actions relates to their capacity of *realizing* individual and collective utility, in deontology the same statuses relate to their capacity of *honoring* given moral imperatives.

As known utilitarianism is based on consequentialism in the sense that what individuals ought to do among, for example, possible alternatives relates to their consequences. Deontology instead rejects the idea that a moral imperative (say, “individuals ought not to pose risks to others”) can be overruled because of the consequences the breach of the imperative could imply (e.g., individuals may pose risks to others to achieve a greater collective utility). In a strictly Kantian perspective this is not solely a matter of morality, but rather of rationality: Breaching the categorical imperative opens de facto to a rational contradiction. If one assumes, categorically and imperatively, that killing others is unjust but that “now and then” it should be possible because of the greater positive consequences, than one should also accept the unbearable contradiction that “killing someone is just.” This is an unacceptable contradiction from a rigorously Kantian deontological perspective.

When applied to the two approaches to land use planning in at-risk areas that are described above, the utilitarian and deontological theories reveal to constitute the assumptions of the probabilistic and deterministic orientations respectively. The probabilistic planner grounds her decision on the consideration of its consequences, which are, to avoid any confusion, not the consequences of the events under consideration but solely the consequences of considering or not considering extremely low probabilities of events as an explicit decisional criterion. One of these consequences, and perhaps in utilitarian terms the most important, is the high cost of referring to the worst and most unlike scenarios each time safety measures have to be established. In the specific case of hazardous facilities, siting this is particularly relevant as spatially relevant safety measures are extremely costly in terms of construction capacity loss. Is this capacity loss justifiable when considering the extreme rarity, if not poor credibility, of worst-case scenarios? The latter result from the combination of all worst conditions, for example the maximum amount of substances possibly present within the establishment, the worst meteorological conditions, the worst possible chain of technological failures, the highest possible number of contemporarily exposed individuals, etcetera. From a probabilistic point of view, the contemporary combination of all these conditions may indeed be so extremely rare to be unrealistic. At the same time, their disastrous nature would result in unduly high costs of prevention. These considerations lead the probabilistic planner to opt for a more realistic appraisal of the risks under consideration and thus to opt for credible scenarios in order to establish the safety distances to be maintained from establishments.

One of the moral implications of this line of reasoning is that by acting according to considerations of “credibility” and “utility” the planner, in case of occurrence of the “incredible” scenarios she has not considered, discharges the responsibility of their consequences. This is explicitly stated in a milestone of the British risk prevention policy that reads “[...] a computation must be made by the owner in which the quantum of risk is placed on one

scale and the sacrifice involved in the measures necessary for averting the risk (whether in money, time or trouble) is placed in the other, and that, if it be shown that there is a gross disproportion between them – the risk being insignificant in relation to the sacrifice – the defendants discharge the onus on them.” (British Court of Appeal in its judgment in Edwards vs National Coal Board, 1949, 1 All ER 743). In this sentence, arguably the “gross disproportion” between an “insignificant” risk in relation to the “sacrifice” needed to prevent its consequences has a clear normative relevance. According to it the planner would *not* be responsible for *not* taking action in all cases in which she can demonstrate the existence of such gross disproportion. This equals defending that spending enormous amounts of resources for preventing events whose occurrence is poorly credible is not what the planner ought to do, to the point that she discharges the onus of their consequences even in the case of their occurrence. Following this rationale, one could conclude that the level of individual responsibility relates to the level of (in)significance of risks.

Yet insignificant risks do not imply insignificant consequences. To the contrary, when it comes to site-specific hazardous technologies very low probabilities of occurrence of accidents are usually coupled with the most disastrous effects. In contrast with the probabilistic planner, the deterministic one would therefore act on the basis of a categorical imperative, that is, that individuals ought not to pose the risk of unacceptable consequences to others regardless of their probability. On the basis of this principle she would not embark on a risk/benefits calculation of given alternatives, but would only honor the principle of not allowing some to risk of causing unwanted consequences to others. To her the *possibility* of such consequences is what truly matters; their risk is not relevant to her decisions. Thus, the worst possible consequences would become her reference-scenario and she would establish the spatial measures preventing third parties from suffering from them. Restricting the land uses around the installation up to the distance which would prevent inhabitants from being involved in the consequences of the worst possible accidents would therefore be her most rational, and only morally justifiable action. The even smallest probability of dying due to a poorly credible accident would be eligible to become her reference-scenario. Any other decision which would contrast with the categorical imperative would lead to a contradiction that the deterministic planner would find irrational beside immoral: If she would accept that extremely low probabilities of occurrence of accidents may be considered as mitigating factors when dimensioning and establishing safety measures, she would have to accept that “individuals may pose risk to others.”

As the difference between the two described lines of reasoning is primarily due to a different attitude toward the relevance of probabilistic judgments to decision making and therefore, implicitly, toward the component of uncertainty in risk analysis, the probabilistic approach is defined as uncertainty acceptant whereas the deterministic one is defined as uncertainty avoidant. Both are grounded on rational assumptions and, similarly, lead to some rational distortions. The most evident distortions are that the probabilistic planner, in order to justify her action, needs to establish above which level risk becomes negligible and can hence be ignored. By her side, the deterministic planner will have to deal with the matter of infinitude of the conditions which may “worsen the worst.”

The former issue, that is the problem of setting a risk tolerability threshold under which decisions are “the right” decision, has been already debated in moral philosophy (see Peterson 2001, 2003 in particular). The de minimis risk, or “so low to be negligible” risk, is a controversial concept. The very attribute of “negligibility” obscures the component of

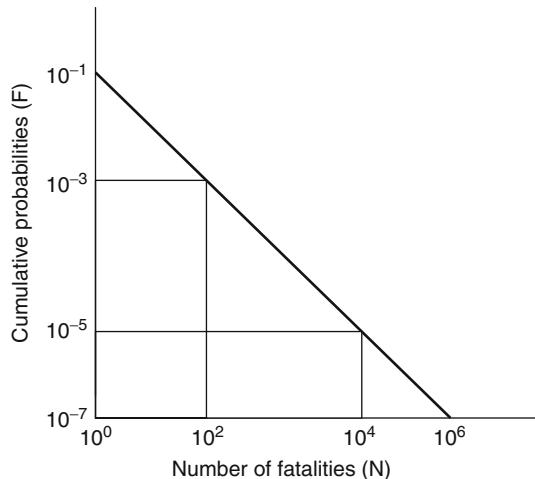

Fig. 11.1  
Fictitious FN criterion (Adapted from Jongejan 2008)

consequences that can be, by contrast, extremely disastrous. Furthermore, setting a quantitative limit under which establishing the de minimis risk is confronted with the problem of comparability: Mathematically speaking, two risks may be equivalent while having two different expected probabilities. This is illustrated in the following (fictitious) FN graph (Fig. 11.1).

The graph illustrates a fictitious FN criterion (i.e., the diagonal bold line), that is the acceptability threshold for a number of individuals  $N$  to die due to the involvement in a major accident with cumulative frequency  $F$  (for reasons of simplicity the difference between cumulative frequencies and cumulative probabilities is ignored here). As shown in the figure the rationale of the FN criterion is that the more probable the event, the lesser the number of acceptable fatalities. Any area below the FN criterion is equivalent, as the expected fatalities are the same for any product  $F * N$ .

Nevertheless, it is hard to defend that an extremely rare event causing the sudden death of 10,000 people is both politically and socially “as acceptable as” more probable events causing 100 deaths. Although statistically the cumulative consequences of the two events are the same, they cannot be considered equivalent in terms of gravity and postaccident response. The judgment that the sudden although rarer loss of thousands of lives is “worse” than the more frequent loss of tens of them is, in conclusion, a consideration that does not rest from mathematics. Rather, it follows a fundamental moral intuition, precisely the intuition that the capacity of society of functioning properly from the political, psychological, and economical points of view would be much more compromised in the former than in the latter case. The popular objection that individuals should be “rational” and thus touched by the occurrence of technological disasters as much as they are by the daily loss of lives in traffic misses a fundamental point. The “indicator” of the moral and emotional responses to the consequences of unwanted events cannot be reduced to the same indicators used by analysts to describe them. Paraphrasing, feelings and figures do not necessarily go together. The sense of devastation and distrust caused by major accidents in which individuals are involuntarily

involved, and that reveal the capacity of certain technologies to simultaneously kill thousands of people, cannot be reduced to the number of deaths. Relying on “risky numbers” for establishing what is negligible and what is not is limited by the fact that “negligibility,” when related to mono-criterion probabilistic calculations, is *per se* an attribute that cannot be captured solely through its mathematical representation.

Notwithstanding the clear limitations of the probabilistic reasoning also the deterministic one leads to several controversial implications. Brought to its extreme consequences the principle according to which referring to the worst-scenario is the only morally acceptable choice (and hence the proper rational guidance for decisions about risk) implies considering the simultaneous occurrence of all worst possible conditions. But designing technologies and organizing society in such a way to prevent the scenarios deriving from their simultaneous combination would orientate the allocation of resources toward the achievement of a virtually impossible “0 risk” status. The variables which may “worsen the worst” are innumerable: Technologies pose risks not only intrinsically, but also extrinsically. Technologies may not be hazardous *per se* and yet the human–technology interaction being so. A moral orientation bent toward the prevention of all possible unwanted consequences of (the interaction with) technologies would therefore end up with restricting not only hazardous technological developments, but all possible dangerous interactions with harmless ones.

It is beyond the scope and capacity of this chapter to provide a thorough account of how the reality created by a deterministic and a probabilistic planner would look like. However, it can be concluded that the former reality may be not less “risky” than the one resulting from a balanced consideration of the probabilities and consequences of the events humans want to prevent. This part of the chapter highlighted that opting for one of the two orientations moves from precise moral assumptions. This is of great relevance to spatial planning processes as it suggests that the underlying principles guiding land use planning evaluations in relation to technological risks are indeed of ethical and not solely of policy, technical, or economic nature. The suggestion of Boholm (2004) regarding the need of more participated spatial planning processes in relation to technological risks could be therefore extended to the involvement of stakeholders in the *choice of the approach to* spatial planning evaluations before in the *discussion about* their outcomes.

As shortly discussed in this section different ethical assumptions regarding the criteria to be used for planning purposes in the surrounding of Seveso facilities give form to different methodological approaches and, arguably, lead to different planning interventions. Such ethical assumptions are at the core of their moral justifiability and should therefore constitute the point of departure of any negotiated and informed decision on the “where” of hazardous technologies. These aspects of the problem will be further discussed in the conclusive section. In the following, this chapter discusses the equally crucial matter of framing siting controversies correctly, and does so by referring to the recent case of proposed siting of a CO<sub>2</sub> storage in the earth of Europe.

## Framing Siting Controversies: The Case of the CO<sub>2</sub> Storage in Barendrecht, The Netherlands

In the course of 2009, the municipality of Barendrecht (the Netherlands) engaged an open conflict with the Dutch government in relation to the proposed siting of a CO<sub>2</sub> underground

disposal. The pilot-project should lead to the installation of this recently designed technology within the next few years and was proposed by a known international oil corporation. The technology promises to contribute to abating carbon dioxide emissions as it consists of capturing the latter “at source” and storing them into exploited gas fields. The Dutch Applied Research Institute (in the following: TNO) assessed the most appropriate location for siting the storage within the national territory and considered 12 possible locations, precisely seven offshore and five inland locations (Breunese and Remmerts 2009). Among the 12 candidate sites, the one in the inland municipality of Barendrecht is also the more densely populated. Notwithstanding this the geological characteristics of the gas field underneath its surface and the technological requirements of the disposal (among which the limited possible length of the pipeline connecting refineries to the underground storage), according to the Dutch government made of the site in Barendrecht the most suitable candidate for proceeding with the pilot-project. The alleged general motivation is that “*capture and storage of CO<sub>2</sub> is a necessary transition technology to help cut carbon emissions*” (Reuters, November 18, 2009).

The story line of the Barendrecht case recalls a typical facility siting conflict. The opposition to the pilot-project saw local versus national actors and, implicitly, local versus national interests. The “owner” of the decision-making process is the central government. Consistently with a policy objective and in concert with a private actor the government delegated the feasibility study to a (supposedly) neutral technical advisory body. The latter assessed a number of candidate sites on the basis of several criteria, among which the geological characteristics of available gas fields, the costs of each alternative, and the technological requirements to be met. Among the candidate sites, the chosen area of Barendrecht was the most densely inhabited; nevertheless, the final assessment report hangs in favor of siting the disposal in that area. In response the local community manifested against the installation, and a lively debate started to occupy the media to the point of becoming of national resonance.

One of the predominant outlooks on these types of controversies favors their interpretation as a not-in-my-backyard (NIMBY) cases. In effect, the Barendrecht example could be simply understood as a NIMBY situation, consisting of the rejection of the controversial (although collectively beneficial) installation because of its negative impacts on the locality. Such impacts are not only future and potential, but considering the loss of property values and the stigmatization of the area also immediate and concrete. However not all siting conflicts relate to the rejection of a technology that is solely “locally” perceived as undesirable and unjustly imposed. Whereas “the problem is frequently constructed as meeting some national need whilst ensuring justice for local communities” (Owens 2004), siting conflicts are often to be understood as general oppositions to the promotion of given technological developments. Such oppositions are given voice locally but mirror a general societal rejection.

When approaching the matter of framing siting controversies correctly it is essential, for the planner, to identify the distinctive elements of NIMBY versus non-NIMBY situations. Spatial planning processes have a primary responsibility in preventing, and possibly solving, NIMBY situations, but become dangerously instrumental in all cases in which the object of controversy is not the “where” but the very “if” of the technology. As argued by Boholm (2004) risk proponents tend to simplify the debate by assuming that a dichotomy between a generalized greater good and a local self-interest exists. The further assumption is that locals have narrow-minded perceptions of the risk at issue. Phenomena of “risk panics” (Sustein 2005) would be therefore emphasized as irrational, selfish, and irrelevant to the “just” policy decision; notably, in the cases of site-specific risks, the latter is a precise *spatial* decision. Because of their public

nature by following this rationale, spatial planning processes become merely instrumental: By polarizing public and needed versus private and selfish interests, the public actor gains the unspoken right of forcing decisions through the mechanisms of spatial planning procedures. This, even when the opposition manifested at local level, mirrors a general lack of consensus regarding the proposed technology. How to overcome this dangerously instrumental model?

A possible reply to these questions is offered by going back to the controversy undergone between the Municipality of Barendrecht and the Dutch government. A recent study demonstrates that the quantity, quality, and possibility of accessing the information about the CO<sub>2</sub> disposal and the plans of its installation is perceived by the majority of the citizens of Barendrecht (precisely by the 66% of the interviewed) as informative and sufficient (see Daamen et al. 2010). This should cautiously lead to conclude that the information regarding the facility was provided timely and sufficiently and that Dutch citizens have had the possibility to develop informed opinions about it. Nevertheless it cannot be ignored that 44% of interviewed had a different opinion and that the debate around the Barendrecht case extended to the national arena, leading several political and social groups to take a firm position of rejection concerning the possibility of adopting the technology at national scale. Several Dutch municipalities anticipated that they would have refused to host a CO<sub>2</sub> disposal should a site within their territory having been chosen for it in the future.

What these facts suggest is that the conflict regarding the CO<sub>2</sub> disposal in Barendrecht extended from the actual facility to the overall technology: In other words, the conflict has lost its *spatial dimension*. The spatial dimension of hazardous facilities siting processes is therefore what may help in distinguishing NIMBY cases from a more general rejection of a given technology. In more simple words, it is the indicator of whether the public debate gravitates around the “where” or the “if” of the installation. Even more importantly, the spatial dimension of facility siting controversies is the only dimension that is fully relevant to spatial planning processes. This dimension will be called, in the following, the *hic* dimension.

A complementary dimension to be considered when identifying the nature of siting controversies is the temporal dimension. Risks are posed “here and now” and have, therefore, precise *hic et nunc* dimensions. However, their prevention implies a non-dynamic continuous process whose scope is guaranteeing a status of safety in time (Weick 1987). Risks, together with its counterpart safety, are “dynamic statuses” that evolve in time according to technological and social standards together with their contextual political conditions. The acceptable risks of today may become the unacceptable risks of tomorrow and vice versa. Nuclear technology offers a good example of the twofold temporal dimension of technological risks; whereas, controversies related to the siting of nuclear installations relate to the “nunc” dimension, that is the potential future “now” of accidents, the debate around nuclear waste disposal focuses on the potential intergenerational impacts of radioactive waste (see Taebi 2010 and Taebi and Kadak 2010 among others). Similarly, the debate around CO<sub>2</sub> disposals gravitates around their immediate impacts on localities but also around the intergenerational effects which may follow the release of CO<sub>2</sub> in the decades to come. More generally, it gravitates around the overall sustainability of a transition technology that rather than cutting emissions at source stores them underground in the equally “finite” resources of exploited gas fields.

To conclude, while the “here and now” of technological risks relate to given spatial and temporal dimensions and do therefore constitute the focus of siting controversies, the matters of their intergenerational impacts and (un)sustainability relate to indefinite spatial and temporal implications. These implications challenge the overall desirability of technologies

and their discussion is not a spatially relevant, but obviously a politically relevant discussion. These remarks suggest that local oppositions to the siting of controversial installations may lose identifiable spatial and temporal coordinates and, by so doing, voicing a general social opposition to their large-scale adoption. Identifying whether the siting conflict has precise *hic et nunc* dimensions is therefore essential for establishing the proper framework through which it can be solved.

It could be argued that the inherent weakness of this line of reasoning is that only the technologies that are not object of “indefinite” spatial and temporal rejection by the side of the public could be object of legitimate siting processes. This is not, however, what this chapter wishes to conclude. Having defined the *hic et nunc* dimensions of hazardous facility siting processes as possible indicators of NIMBY versus non-NIMBY cases is not the remedy against the inevitably controversial nature of these types of decisional processes. As a matter of fact technological developments worldwide do and will involve the installation of often necessary, although disproportionately impacting technologies (Owens 2004). Differences in purposes, values, and perceptions will continue to affect the process of their siting and lead to contentious situations.

However the arguments above invite to reflect on the fact that spatial planning processes, together with their regulatory and legal implications, are not necessarily the framework through which finding the right answer; they are rather the platform wherein actors can collaborate in formulating the right question. As a matter of fact society “meets” ultrahazardous technologies at the moment of their siting, and it is only then given the opportunity to acquire knowledge on and voicing its perceptions of it. Identifying whether the definite *hic et nunc* dimensions of the siting of the installation are the real object of discussion is therefore the precondition for formulating the right question, that is whether the situation is truly a “not-in-my-backyard” situation or not.

To conclude, approaching all siting controversies as NIMBY situations is analytically incorrect besides dangerously instrumental, as it leads decision makers to focus on sharpening the legal and procedural instruments which may force decisions through the mechanisms of spatial planning processes. The following section discusses how spatial planning frameworks can support those decisional processes whose object is the sustainable, morally justifiable, and hence acceptable siting of technological risks in their space and time.

## Safety as a Spatial Value: Siting Risks as a Matter of Distributive Justice

Living in, moving to, and experiencing different places contribute to shape individual identities. The living environment as experienced by individuals throughout their lives determines feelings of affection, discomfort, peacefulness, gratification, and frustration, leading to sentiments of belonging and attachment as well as extraneity. The relation between space (in its broad physical, social, and political connotation) and identity (both individual and collective) has therefore received great attention by the side of geographical, anthropological, sociological, policy, and spatial planning scholars (Keith and Pile 1993; Hague and Jenkins 2005; Taibakhsh 2001; Brown and Raymond 2007). Not surprisingly it received increasing attention also by the side of those scholars investigating the relation between space and technological risk (Boholm and Löfstedt 2004; Lesbirel and Shaw 2005) and by

philosophers investigating how spatial and architectural design determines individuals' experiences of reality (Vermaas et al. 2008).

Local identities and the values that are collectively attached to the living environment are crucial aspects of the experience of disruption brought by a new technological installation. Walker and Simmons (2004) made a step forward in describing the relevance of such aspects to spatial planning by demonstrating that the stigmatization of a place caused by a large industrial site may affect the own sense of identity also in relation to *others'* perceptions. The slow and inexorable expansion of the industrial site of their study affected the "space values" which were at the basis of the sense of comfort in and belonging to the area before the plant was installed. People felt stigmatized because of it and sometimes manifested embarrassment toward strangers in admitting they were living in the town. Aspects like the easy access to the countryside and the quietness of the streets were individually and collectively regarded as clear values by nearby residents; but when these values started to be threatened by the emission of fumes and the risk of accidents the very identity of the place and of the self-perception of individuals were affected accordingly.

The point of discussion of this section is whether *safety* may be also regarded as a *space value* and whether its relevance to the preservation of what individuals regard as nonnegotiable values of their living environment makes of it also a *right* to be guaranteed. How this twofold connotation of safety (i.e., the value and right connotation) would affect, and eventually benefit, hazardous facilities siting processes will be then explored.

To develop this discussion, I will briefly refer to the already mentioned work of Ulrich Beck on the *Risk Society* (1986:1992) and more extensively to the work of Moroni on the ethics of land use (Moroni 1994, 1997, 2004 and 2006). In the following, I will also refer to the work of Peterson and Hansson on the residual moral obligations to be observed for justifying the opposition between risk runners and risk posers during siting processes (Peterson and Hansson 2004) and finally to the known Theory of Justice of Rawls (1971).

Beck wrote his academic bestseller 25 years ago, hence at a time in which the debate around technological risks was ignited by the most disastrous accidents in history. The most broadcasted among them (like the already mentioned accidents of Chernobyl and Bhopal) occurred in the context of developing economies. The well-known Beckian theory that certain technological risks are as unequally distributed in society as wealth and that the contemporary risk distribution is therefore "unjust" hence found poor, if any, resistance (Beck 1986:1992). Site-specific risks are evidently among these unequally distributed threats.

The relevance of these arguments to the present discussion will become more evident after the introduction of the work of Moroni (1994, 1997, 2004, and 2006). In his work on the ethics of land use (1997), the author investigates how different ethical theories have historically influenced and keep being at the basis of spatial planning theories. For example, Moroni discusses how utilitarianism was evidently mirrored by the practice of "zoning" which dominated the land use planning approach of the second half of the past century at European level, or how libertarian theories would convert the predominantly detailed-oriented planning interventions to more open forms of structure-oriented interventions.

Among the ethical theories analyzed in this work, the most relevant to the present discussion is the Rawlsian theory of justice, whose alleged purpose is overcoming the distortions of utilitarianism in favor of a newly formulated deontological theory (Rawls 1971).

As mentioned in a previous section, the utilitarian paradigm rests on consequentialism and dictates to realize the maximization of the nonmoral value of utility. By contrast, deontology formulates categorical and universal imperatives whose neglect is not permissible in any circumstance. In a highly simplified way, it can be said that the unsolved distortion of utilitarianism is whether the sacrifice of some has to be justified when meant to preserve the lives of many; differently, the unsolved distortion of deontology is the matter of the justifiability of *not* acting in those circumstances in which the forced choice is between a greater or smaller sacrifice of human lives. Somehow utilitarianism leads to controversial dilemmas in the sphere of *acting* whereas deontology leads to similar moral dilemmas in the sphere of *not acting*.

The Rawlsian formulation of neo-contractualism tries to overcome the *impasse* of both theories by establishing, on the one hand, universal and inviolable principles which should provide the moral basis to a fair society and, on the other hand, by indicating the equal distribution of primary goods as the means to realize fairness. Justice, for Rawls, does indeed equal fairness. Central to the theory is therefore the identification of primary goods. This is achieved by means of a rational mechanism named *veil of ignorance* under which moral judges unaware of their racial, health, social, and religious statuses would identify the set of liberties and goods to be universally guaranteed. The rational assumption is that moral judges (whose characteristics are object of a thorough definition; see Rawls 1971) under the condition of not knowing the privileged or disadvantaged position they would have in a real societal setting would identify those liberties and goods that they would regard as essential to the realization of the own self.

When it comes to arguing on the fairness of their distribution, Rawls indicates the rule of “max-min,” following which the *maximum* amount of primary goods which can be *equally distributed* up to the *lowest societal level* acquires the status of the *minimum* amount to be guaranteed in society. It is in this sense that their distribution observes a principle of fairness and that primary goods acquire the status of *rights*. Freedom, for example, is a primary good whose most extensive form (speech, religious beliefs, etc.) should be equally guaranteed up to the most disadvantaged members of society.

The contribution of Moroni to the development of this theory consists of its application to spatial planning theory and, particularly, of the identification of additional primary *spatial* goods. The interesting exercise here is imagining what moral judges would deem as primary and non-violable spatial goods without knowing what their “spatial situation” would be in reality; for example, without knowing their income, their geographical location, and the relevant morphological, climate, and urban conditions. Housing, accessible green areas, access to transportation, and a *safe living environment* are the spatial primary goods that compare in the list compiled by Moroni. It follows that a just spatial planning practice should strive for their equal allocation in society.

Although not explicitly Moroni suggests that *safety* shall be regarded as a primary spatial good. It follows that a minimum level of *spatial safety* corresponds to a right all individuals shall have access to regardless of their spatial condition. This is an interesting conclusion as it provides a point of departure for a new interpretation of safety in the context of spatial planning evaluations. Following the rule of *max-min* the maximum level of spatial safety which can be equally distributed in society up to the lowest societal level acquires the status of the minimum level everybody has to be guaranteed access to. This level should not violate other fundamental rights, for example the right to life and to fundamental freedoms.

It is important to notice that having defined safety as a primary spatial good, and its fair distribution as the aim of the spatial planning practice, implies a “change of scale” in approaching the matter of siting hazardous technologies. The appropriate “where” of risks is no more a problem that regards a given locality, but the locality in relation to the future possible installation of hazardous facilities at regional and national scales. This takes us back to reflect on NIMBY from a totally different perspective. One of the most controversial aspects of the opposition between parties characterized as NIMBY situations is the clash of absolute principles between the right to life of individuals on the one hand and the pursuit of (collective) benefits on the other hand (Peterson and Hansson 2004). Considering that many hazardous establishments (like water treatment plants, energy facilities and energy-related infrastructures, chemical and pharmaceutical factories) produce vital goods to our society, their siting entails the opposition between two equally rightful “goods.” The authors suggest that in order to overcome the clash of absolute principles (and imposing versus opposing the installation of the facility in a legitimate way), so-called residual moral obligations should be observed. These obligations are the obligation to inform, improve, search for knowledge, and compensate, respectively.

It is indubitable that these residual moral obligations should guide morally acceptable siting processes. However when focusing on the single installation as done by Peterson and Hansson (2004) the mentioned unequal distribution of risks, which in the context of site-specific risks can be now rephrased as the matter of the *unequal distribution of spatial safety*, remains unsolved. The added value of a Rawlsian perspective on this matter consists precisely of the addition of the primary moral obligation, for the planning practice, of *distributing spatial safety fairly*. By taking this perspective risk runners acquire the right to oppose a proposed facility when its siting violates such equality, and would instead lose it in all circumstances in which the chosen location respects the principle of a fair spatial safety distribution.

Although debatable, from a spatial planning perspective this is an interesting indication. Coming back to the example of the underground CO<sub>2</sub> disposal in Barendrecht (The Netherlands) it is worth noticing that the research agency assigned to assess the appropriate site among 12 candidate sites focused on the characteristics of each of them according, principally, to their geological characteristics and the technological requirements of the underground disposal. The feasibility study focused on each candidate site as an isolated case, without considering the spatial safety (re)distribution which would have followed the installation of the disposal in each site when put into relation with the broader regional and national scales. More simply, the fact that Barendrecht was the most densely populated area and was already close to major industrial and infrastructural facilities has been overlooked. The fact that (the citizens of) Barendrecht would have been additionally disadvantaged in comparison to other sites has not been regarded as an important decisional element.

Considering the equal distribution of the spatial good of safety is the ideal aim of spatial planning would have instead allowed decision makers to anticipate the situation of (dis) advantage each case would have represented in relation to the wider regional and national context. This outlook does not put the relevance of the safety and technological requirements to be met when choosing the appropriate site for an hazardous installation under discussion; it only suggests to complement these criteria with the one of distributing spatial safety in society as fairly as possible.

Despite these indications are highly theoretical and at the early stage of investigation, they allow to strive for some important conclusions regarding the role of spatial planning processes in relation to technological risks.

## Concluding Remarks: Toward a Moral Understanding of the Relation Between Risks and Space

---

This chapter started with introducing some recent findings in the field of technological risk and spatial planning. The works of Boholm (2004); Boholm and Löfstedt (2004); Owens (2004); and Walker and Simmons (2004) in particular helped in identifying the main areas of investigations to be further explored in order to approach the matter of “siting risks” correctly. In the following, the most controversial aspects of the problem were discussed by referring to the work of other key-scholars in the field, ranging from sociology to ethics and land use scholars. This chapter proposed an ethical outlook on the matter of siting risks by taking together, in particular, ethical and planning theories. Perspectives of further integration will be discussed in the section dedicated to the further research. Hereafter a summary of preliminary conclusions is reported.

The probabilistic and deterministic approaches were identified as the two predominant “school of thoughts” guiding land use planning evaluations in relation to hazardous facilities. The divergences between the two approaches were explained as the result of a non-explicit application of different ethical theories, that are the utilitarian and the deontological theory respectively.

When discussing the matter of framing the “siting risks” issue correctly, that is by overcoming the tendency of interpreting all siting controversies as “not-in-my-backyard” situations, it was proposed that controversies which do evidently lose identifiable spatial and temporal dimensions (that are the *hic et nunc* dimensions) along their development are likely to reveal a more general social concern regarding the technology at issue. It is argued that neglecting the signal value that local oppositions may have in terms of societal rejection of given technological developments is, besides incorrect from an interpretational viewpoint, also highly questionable from a moral one. It is therefore proposed that capturing whether the *hic and nunc* dimensions of siting controversies are definite and identifiable may help in identifying NIMBY (and hence non-NIMBY) cases. Forcing siting processes through the mechanisms of spatial planning regulation and procedures regardless of this distinction does indeed consist of a form of “technological colonization” insensitive to individuals’ values and rights.

The third part of this chapter deepened the reflection on the moral acceptability of hazardous facilities siting by referring, in particular, to the theory of justice of the political philosopher Rawls (1971), the work of the spatial planning theorist Moroni (1997), and the philosophers of risk Peterson and Hansson (2004). This part proposed an interpretation of what was called “spatial safety” as a primary spatial good. By taking this perspective, the aim of the spatial planning practice becomes distributing the maximum possible amount of the primary good of spatial safety in society equally up to the lowest societal level.

This definition of spatial safety has a twofold implication. The first and perhaps most important is that by taking this perspective a morally justifiable imposition of the “here and now” of risks is based on an evaluative approach that puts these two dimensions in relation with the wider spatial and temporal horizons of the social group which has agreed upon the

principle of fairness. These horizons would concretely correspond to the regional or national scales. This means that the “where” of any technological risk should be thought in terms of the situation of spatial safety (re)distribution that the siting would create at regional or national levels. For example, according to the principle of fairness the planner may prevent situations of “risks encroachments” by opting for locating a given hazardous installation in a site wherein the risk profile is lower in comparison to other areas of the region.

The second implication of approaching spatial safety as a primary good regards the moral justifiability of the imposition versus opposition of hazardous facilities in NIMBY situations. The observance of the residual moral obligations of informing, compensating, and improving suggested by Peterson and Hansson (2004) is necessary for empowering actors to impose versus oppose the installation of an hazardous facility. However it is suggested that such observance does not suffice. The right of *opposing* the siting of hazardous installations should be granted to risk runners also in those situations in which they would put into a condition of evident and unnecessary disadvantage in comparison to other areas of their region or nation. In other words imposing “risks on risks” in certain areas due, for example, to the presence of existing infrastructures that facilitate the further installation of hazardous facilities should be regarded as unfair from a distributive justice perspective. Rather than being concentrated spatial *un-safety* should be distributed; hence, opposing the installation of hazardous facilities on the ground of unfairness should be regarded as legitimate.

These conclusions are highly general and still in their embryonic formulation. However they sign a promising research trajectory, whose outline concludes the present work.

## Further Research

---

Each part of this chapter presented the problem of “siting risk” under a policy, spatial and risk analysis light to end up with discussing its most problematic ethical implications. This is not casual. In front of technological risks, and more generally in front of the irreducible complexity of facing uncertainty, ultimately the discussion gravitates around precise, although often not explicit, ethical considerations.

This premise serves to point out that the further research needed to tackle the matter of siting hazardous technologies in a sustainable and technologically, socially, and morally acceptable way passes through the explicit adoption of precise ethical principles. As discussed along this chapter, different ethical theories may lead to substantially different approaches to the governance of risks in society and, in the specific case of site-specific technologies, to assessing their “where.” It is hence toward ethics that spatial planning should orient its vision when designing evaluative processes sensitive to the aim of achieving a morally acceptable relation between risks and space. This implies opening the spatial planning research to the inputs provided by the ethics of technological risks literature and striving for a solid synergy between the practice of spatial design and the application of (past and current) ethical theories.

This indication opens to two distinct research horizons. The one discussed in this work relates to the matter of siting risks by adopting a distributive justice approach. One issue that remains to be investigated in this regard is which is the level of the primary spatial good of safety that should be minimally guaranteed in society. As mentioned above this level should correspond to the one that does not violate the primary right to life. But this is evidently a deadlock, as there is no risk which per se does not threaten it.

Taking a neo-contractualist perspective could again help in solving the *impasse*. The challenge is imaging what moral judges would regard as the non-violable level of spatial safety (and hence as the acceptable level of risk) each member of society should be guaranteed regardless of her spatial condition. Intuitively in the era of technological dependency and constant exposure to involuntary (yet somehow necessary) risks this is not a straightforward answer. It is suggested that put in front of the dichotomy between determinism and probabilism moral judges would hang in favor of a cautious consideration of the latter. When their objects are hazardous technologies of proven necessity to sustain one's health and capabilities, rigorous deterministic considerations of the relevant risks are indeed poorly justifiable. It is suggested that it exists as a fundamental moral intuition that dictates to allocate societal resources toward the prevention of the risks associated to vitally beneficial technologies without cultivating the ambition of taking them to zero. The caution consists precisely in remembering that "quantity is the trap of all traps" when it comes to define an acceptable versus non-acceptable risk level. Paradoxically, without incorporating individuals' intangible values within the very characterization of risks the matter remains at the abstract level of calculating probabilities  $\times$  consequences. The question of what is the minimum level of spatial safety to be fairly distributed in society is legitimate only if safety is not regarded as the result of a mono-criterion assessment, but also as what individuals' regard as the nonnegotiable space values which are at the basis of their well-being.

The second research horizon indicated by this discussion developed along this chapter is of more general relevance and regards the need of making the ethical theories informing spatial planning theories explicit together with the moral implications of concrete spatial planning decisions. It is suggested that in a world of increasing complexity, but also of renewed attention for the most fundamental human values, there is no spatial planning decision that does not require precise ethical considerations. Planning the space equals designing our "present future" and determining our condition of liberty and equality into it; in this respect, design can be considered as the *longa manu* of ethics. This implies a fundamental responsibility for the spatial planning discipline at all levels; and that is a moral responsibility.

**Abstract:** Nuclear energy is one of the clearest examples of a technology that brings about risks beyond generational borders. These risks emanate particularly from nuclear waste that needs to be isolated from the biosphere for very long periods of time. Principles of intergenerational equity currently underlie waste management policies, arguing that we should not impose *undue burdens* on future generations. This chapter scrutinizes the way in which such intergenerational equity principles deal with the issue of long-term risks.

The present consensus within the nuclear community is that nuclear waste should be buried in geological repositories rather than kept in surface storage places. This is particularly based on the notion that repositories are believed to be safer in the long run. Such long-term safety seems to be disputable as it relies on great long-term uncertainties which, in turn, necessitate sanctioning a distinction between different future people. Putting distant future generations at a disadvantage does, however, lack solid moral justification, which should urge us to reconsider our temporal moral obligations in the light of recent technological developments. The technological possibility of substantially reducing the waste lifetime through Partitioning and Transmutation (P&T) is believed to challenge geological disposal, thus placing long-term surface storage in a new perspective. P&T is, however, a laboratory-scale technology which means that substantial investment will be required before industrial deployment can take place. Moreover, the deployment of this technology creates additional safety risks and economic burdens for the present generation. Nevertheless, the potential possibility to diminish “*undue burdens*” for future generations is too relevant to be neglected in discussions on nuclear waste management policies. The question that will furthermore be explored is to what extent should we rely on future technological possibilities in today’s policy-making?

## Introduction

---

The rapidly growing energy consumption level, future forecasts, and climate change have prompted a new debate on alternative energy resources. Alongside green energy such as wind and solar power, a new nuclear era seems to have dawned. According to the World Nuclear Association, there were 443 operational nuclear reactors in March 2011. In addition, a further 62 reactors are currently under construction, 158 have been ordered or planned, and 324 have been proposed ([WNA 2011](#)). Nuclear energy now accounts for almost 16% of all the electricity produced worldwide.

The main advantage of nuclear energy – when compared to fossil fuels – is that it can produce a large amount of energy from relatively small amounts of fuel while generating very low greenhouse gas levels. However, there are serious drawbacks attached to nuclear energy production such as those surrounding safety concerns in reactors; the recent series of accidents in the Fukushima Nuclear power plants in Japan serve to heighten such concerns. In addition, there are the proliferation threats if the technology is abused by being employed for destructive purposes and, as always, there is the issue of how to deal with nuclear waste. Nuclear waste remains radiotoxic for a long period of time before decaying to a nonhazardous level, a level defined by the radiotoxicity of the same amount of uranium ore. This period is known as the waste lifetime and for the remaining materials in a once-through fuel cycle that amounts to 200,000 years. Recycling technologies (reprocessing) are capable of reducing this waste lifetime to 10,000 years. Recent developments in nuclear waste management – Partitioning and

Transmutation (P&T) – demonstrate at laboratory level that it is possible to reduce the waste lifetime yet further, to a couple of hundred years (NRC 1996).

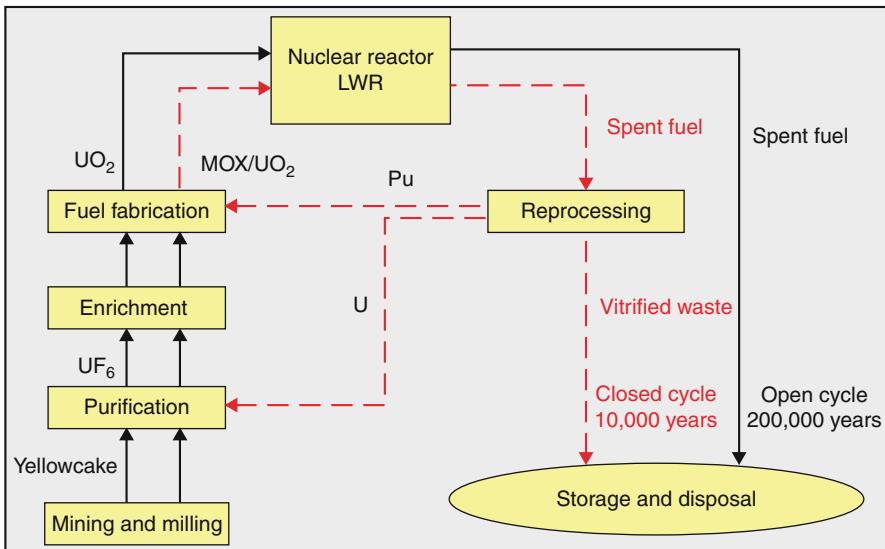

For the current and future protection of human health and the environment when it comes to dealing with radioactive waste, the International Atomic and Energy Agency (IAEA) has laid down certain principles for Radioactive Waste Management, one of which states that nuclear waste should be managed in such a way that it “will not impose undue burdens on future generations” (IAEA 1995, Pr. 5). This “undue burdens” clause could best be situated within the framework of intergenerational equity or equity across generations (NEA-OECD 1995). Current policy in nuclear energy-producing countries stems mainly from intergenerational equity considerations, and from the striving for an equitable distribution of risks and burdens inspired by the belief that the safety and security of future generations should not be jeopardized. Intergenerational equity also involves guaranteeing equal opportunities for future generations. In nuclear energy-related discussions, equal opportunity mainly pertains to the *retrievability* of waste and to its potential economic value.

The consensus within the nuclear community for the ultimate disposal of waste seems to be in favor of burying waste in geological repositories rather than storing it on the surface; this consensus is founded on the long-term safety (and security) assurances supposedly guaranteed by host geological formations (IAEA 2003). However, long-term safety depends on certain considerable uncertainties, which necessitate sanctioning a distinction between different future generations. I argue that this distinction lacks moral justification and that it would therefore be best for us to avoid these uncertainties. Implementing P&T allows for the latter, as the period of necessary care for P&T waste is substantially shorter.

This chapter is organized as follows. In the next section, I briefly discuss the production of nuclear energy and the different options for the final isolation of waste. In the section **● History of Intergenerational Equity in Nuclear Waste Management**, I elaborate on the way in which the notion of intergenerational equity has influenced nuclear waste management policies. The section **● Policy-making and the Principle of Diminishing Responsibility** scrutinizes the notion of “diminishing responsibility over the course of time” as a leading notion in nuclear waste policies. I then examine the moral legitimacy of distinguishing between future people, particularly when designing geological repositories. The state of the art in technology is discussed in the section **● State of the Art in Technology: Challenge to Geological Disposal**. The section **● Four Counterarguments to the Feasibility and Desirability of P&T** puts forward four possible counterarguments to the application of P&T. The concluding two sections present the findings in brief and highlight the further research possibilities.

## Nuclear Fuel Cycles and the Issue of Waste

Before moving on to the discussions on how policy-making has been affected by considerations of justice to future generations, let me first quickly present the methods for the production of nuclear power and elaborate on the question of how different waste types are dealt with. Nuclear energy is produced in a *nuclear fuel cycle* that starts with the mining of uranium (U), the fabrication of fuel and irradiation in a nuclear reactor (the front-end stage), and finishes with the possible treatment of irradiated fuel emanating from the reactor before ending with the final disposal of remaining waste (the back-end stage); see **● Fig. 12.1**.

**Fig. 12.1**

The open and closed nuclear fuel cycles, from uranium ore to final disposal

Irradiated fuel is referred to as *spent fuel* rather than waste because the way in which spent fuel is dealt with represents a crucial choice in terms of nuclear waste management. The first production method, or fuel cycle, is one in which irradiated fuel is viewed as waste and therefore has to be isolated from the biosphere for a long period of time, thus creating an *open fuel cycle*. The irradiating of uranium (U) produces other materials, including plutonium (Pu), which is a very long-lived radioactive isotope. Apart from plutonium, other residual radioactive materials, *minor actinides*, as well as *fission products* will be formed. Actinides are elements with similar chemical properties. Uranium and plutonium are the major constituents of spent fuel and so they are known as major actinides. Neptunium, americium, and curium are produced in much smaller quantities and are thus termed minor actinides. Fission products are a mixture of radionuclides that will decay to a nonhazardous level after approximately 250 years. The presence of major actinides in spent fuel defines the waste lifetime in an open fuel cycle; neither minor actinides nor fission products have a significant effect on long-term radiotoxicity. The waste lifetime of spent fuel in such a fuel cycle is 200,000 years and it is dominated by plutonium.

The second method is one in which we “destroy” or convert the very long-lived radionuclides to shorter-lived material in accordance with a *closed fuel cycle*. Removing plutonium from spent fuel can substantially diminish the waste lifetime. In a closed fuel cycle, plutonium and any remaining uranium are isolated and recovered during a chemical treatment phase which is referred to as *reprocessing*. Reprocessed uranium could be added to the beginning of the fuel cycle and both uranium and plutonium could be used to produce *mixed oxide fuel*, a combination of uranium oxide and plutonium oxide that can be used in nuclear reactors as a fuel (Wilson 1999). The closed fuel cycle waste stream is referred to as high-level waste (HLW) or *vitrified waste* and it has a waste lifetime of approximately 10,000 years.

Irrespective of the fuel cycle choice, the waste remaining after optional treatment needs to be disposed of. In waste management, a distinction is made between storage and disposal: storage entails keeping the waste in purpose-built facilities above ground or at a certain depth beneath the surface, while disposal entails isolating and depositing waste at significant depths (of several hundred meters) below the surface in engineered facilities. The latter are termed geological repositories or simply repositories.

Spent fuel is usually stored under water for a period of time – varying from a couple of years to several decades – after having been removed from the reactor core; this stage is called the *interim storage* stage. Water serves as a radiation shielding and cooling fluid; heat exchange facilities will remove heat from the circulating cooling water (IAEA 1998). The interim storage of waste is also a crucial factor in the safe management of radiotoxic waste, since it is designed to allow radioactive decay to reduce the level of radiation and heat generation before the final disposal stage. It is especially heat generation that very much influences the capacity of a repository (Bunn et al. 2001).

A commonly proposed alternative to geological disposal is long-term monitored surface storage. However, the technical community largely appears to disregard this option since it sees surface storage as merely an interim measure prior to disposing of waste in geological repositories (IAEA 2003; NEA-OECD 1999). Up until now, all the available facilities for spent fuel and high-level waste tend to have been located above ground or at very shallow depths, designed for interim storage. Some people are, however, concerned that this interim storage phase may well become, *de facto*, perpetual.

Depositing the waste in space or disposing of it in inaccessible deep-sea sediments – like for instance beneath the Antarctic ice – are the alternatives that have been proposed (KASAM 2005, Ch. 3). These options are not, however, being taken seriously, due to the unacceptable safety risks involved together with what would amount to the violation of international conventions.

## History of Intergenerational Equity in Nuclear Waste Management

Widespread concerns about depleting the Earth's resources and damaging the environment have recently triggered new debate on the equitable sharing of goods over the course of generations or, on *intergenerational justice*.<sup>1</sup> This concept of justice was first introduced by John Rawls (1971) who alluded to intergenerational distributive justice.

Intergenerational justice in connection with climate change has received increasing attention in the literature in recent years (Page 1999; Gardiner 2001; Athanasiou and Baer 2002; Shue 2003; Gardiner 2003, 2004; Meyer and Roser 2006; Page 2006; Gardiner 2006a; Caney 2006). In nuclear waste management this notion of justice or equity<sup>2</sup> across generations has been influential, particularly in promoting geological repositories as final disposal places for nuclear waste; later in this section I will elaborate on this issue. Before that I would like to pause for a moment to reflect on the claim that there is a problem of intergenerational justice that emanates from nuclear power production.

I shall adhere here to Stephen Gardiner's discussions about "The Pure Intergenerational Problem" (PIP), in which he imagines a world consisting of temporally distinct groups that can asymmetrically influence each other; "earlier groups have nothing to gain from the activities or attitudes of later groups." Each generation has access to a diversity of temporally diffuse commodities. Engaging in activity with such goods culminates in modest present benefits

and substantial future cost and that, in turn, poses the problem of fairness. Gardiner refers to the problem of energy consumption and anthropogenic carbon dioxide which causes climate change and has predominantly good immediate effects but deferred bad effects. Even if present benefits exceed future costs (assuming that we can compare these entities), this is a moral problem because just as with most theories of justice, distribution is independent of overall utility (Gardiner 2003, pp. 483–488).

There are two ways in which PIP relates to nuclear power production and to waste management. First of all, assuming that this generation and those that immediately follow will continue depleting uranium, a nonrenewable resource, there will be evident intergenerational equity considerations to bear in mind. Secondly, the production of nuclear waste, and its longevity in terms of radioactivity, signifies substantial present benefits with deferred costs, as stated in Gardiner's PIP.

Another cause for concern in nuclear energy-related discussions is our beneficial temporal position with regard to successive generations: “our temporal position allows us to visit costs on future people that they ought not to bear, and to deprive them of benefits they ought to have”; Gardiner refers to this as “The Problem of Intergenerational Buck Passing” (Gardiner 2006b, p. 1). As we can reasonably expect that the incentive structure remains the same for all generations, the Problem of Intergenerational Buck Passing will be exacerbated over the course of time, all of which gives rise to moral justification for limiting the impacts of our actions that have intergenerational consequences (Gardiner 2006b, pp. 2–3).

I argue that the intergenerational problem resulting from nuclear power production entails certain moral obligations and that contemporaries must not endanger the interests of future generations. These obligations can manifest themselves in two different ways. Firstly, there is the depletion of a resource, namely, uranium, that will not renew itself for future generations which justifies placing certain restrictions on depleting these resources.<sup>3</sup> Assuming that well-being significantly relies on the availability of energy resources – a claim that could be historically underpinned by considering developments from the time of the industrial revolution up until the present – we could be said to have an obligation to ensure well-being for the future. Another, perhaps more important obligation, relates to the longevity of nuclear waste and to the fact that its inappropriate burial can harm future generations. So the next moral obligation that the intergenerational problem creates is that of not harming future people.

There are, however, certain theoretical and practical objections to this reasoning. The theoretical problem is whether rights can be ascribed to future people to justify obligations and whether we can harm future people whose very existence depends on our actions and inaction. At the practical level of applying these ideas, we might consider the question of how far into the future these obligations extend and how we can deal with the uncertainties linked to such long-term predictions. In this chapter, I take the liberty of not extensively discussing such theoretical impediments. In the following paragraphs, I shall touch on the theoretical objections and briefly argue why I do not find them persuasive enough to free us from talking about the obligation not to harm future generations. In the next section, more attention will be given to the relevance and legitimacy of a distinction between different future generations in the light of long-term uncertainties.

Future people's identity and numbers are very much contingent on the actions and policy choices we make now. As it is the moment of conception that determines which individuals will come into existence and as different policy choices result in different individuals, we can never be accused of harming future individuals since, in line with Parfit's (1983) non-identity

problem, it is changing policy that will change the number and identity of all these still to be born individuals. The non-identity problem is a serious theoretical problem that theories of intergenerational justice, particularly the personal and harm-based theories, are facing. Certain solutions have been proposed, but they are either not definite or have a too small scope; the relevant philosophical inquiries should certainly continue to fix this theoretical ineptitude. The non-identity problem, however, does not reduce our moral obligations to posterity. This is a counterintuitive conclusion that is gladly supported by just a few people, Schwartz (1978) being one of them. It is also worth noting that Parfit (1984, p. 357) would disagree with such a conclusion as he states that the mere fact that we can influence the well-being of future generations creates a certain obligation toward posterity.

The next problem is whether we have any obligations toward these contingent people and whether these obligations are founded in rights. Some scholars argue that “the ascription of rights is properly to be made to actual persons – not possible persons” (Macklin 1981, p. 151); see also Beckerman and Pasek (2001). Here, I follow the interest theory of rights argumentation to the effect that if agent X has a right then that implies that “other things being equal, like aspects of X’s well-being (his interest) is sufficient reason for holding some other person(s) to be under a duty” (Raz 1986, p. 183). We can safely assume that there will be future generations and that these people will have interests which will depend on the actions of the current generation. “The identity of the owners of these interests is now necessarily obscure, but the fact of their interest-ownership is crystal clear” (Feinberg 1981, p. 148).

To conclude, the depletion of uranium and the longevity of nuclear waste cause the problem of intergenerational justice and that, in turn, creates moral obligations for present generations to ensure future people’s well-being – in terms of resource availability – and not to harm future people by inadequately burying nuclear waste. It should be clear that I am not intending to examine the extent of the stringency of these moral obligations nor to elaborate on any theoretical impediments that may arise (elsewhere I take up this challenge (Taebi 2011)). In this chapter, I am merely assuming that the production of nuclear power creates certain moral obligations, the extent of which remains a subject of ongoing discussion.

### Waste Management Policies: “a Desire for Equity”

Having discussed the moral obligations that ensue from the intergenerational problem that the production of nuclear energy creates, I shall now return to the nuclear waste management principles and to the overarching notion of intergenerational equity. The long-term concerns, as outlined above, have triggered a debate on how to deal with radiotoxic waste in an equitable way. The level of acceptance<sup>4</sup> of risks for present generations is proposed as a reasonable indication for the future. The International Atomic and Energy Agency (IAEA 1995) laid down several principles of radioactive waste management, in which concerns about the future were expressed in terms of the “achievement of intergenerational equity.” It was asserted that nuclear waste should be managed in such a way that it “will not impose undue burdens on future generations” (IAEA 1995, Pr. 5). The Nuclear Energy Agency (NEA) reiterated those principles in a Collective Opinion, which stated that geological disposal should be preferred to aboveground storage on the basis of considerations of intergenerational equity: “our responsibilities to future generations are better discharged by a strategy of final disposal [underground] than by reliance on [above ground] stores which require surveillance, bequeath

long-term responsibility of care, and may in due course be neglected by future societies whose structural stability should not be presumed” (NEA-OECD 1995, p. 5). All national programs have already subscribed to the concept of geological disposal as a “necessary and a feasible technology”; but some countries prefer to postpone implementation in order to first evaluate other options and alternatives (NEA-OECD 1999, p. 11).

In the following paragraphs, I will present current thinking on waste management policies in terms of the underlying philosophical and ethical considerations stemming from the principle of intergenerational equity. The basic notion is that the present generation is required to ensure that there is an equitable distribution of risks and burdens, which must ensure the safety and security of future people. In addition, equity across generations also involves the assurance of equal opportunities for future generations when dealing with nuclear waste. Three ethical values relevant to current nuclear waste policy – namely those of safety, security, and equal opportunity – will be reviewed below. I will furthermore focus on the issue of how these principles motivate geological disposal, as opposed to aboveground storage.

## Safety for People of the Future

From the early days of nuclear energy deployment, the safety of future generations has been a primary concern, as can be concluded from the guidelines laid down in 1955 by the US National Academy Committee on the Geological Aspects of Radioactive Waste Disposal (NRC 1966). In spite of this early recognition, it was a long time before the nuclear community explicitly mentioned the safety of future people as a concrete concern. In 1984, the Nuclear Energy Agency first pronounced “a desire for equity” and acknowledged a need for “the same degree of protection” for people living now and in the future (NEA-OECD 1984). The IAEA articulates these concerns in its Safety Principles where it states that nuclear waste should be managed in such a way that “predicted impacts on the health of future generations will not be greater than relevant levels of impact that are acceptable today” (NEA-OECD 1995, p. 6) and it refers to this as the neutrality criterion. Geological disposal is believed to ensure safety as it is seen as a resistance to containment of the waste over very long periods of time. The engineered facility, together with the natural safety barrier of the host geological formation must guarantee that “no significant radioactivity” will even return to the surface environment (NEA-OECD 1999, p. 11).

## Security for People of the Future

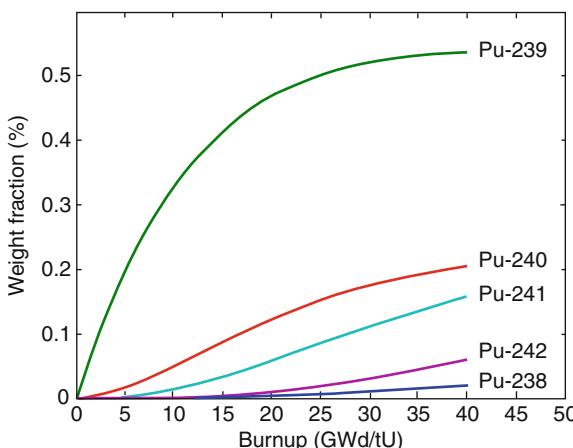

“[T]he same degree of protection” as that stated by the NEA (1984) not only refers to public health issues, but also to future security concerns. Security relates to the unauthorized possession or theft of radiotoxic waste in order to either sabotage or use these materials for the production of nuclear weapons (IAEA 2007, pp. 133–134). The main concerns relate to the threat of nuclear weapon proliferation which is extremely relevant given the current state of affairs in the world. Proliferation threats arise either from the using of highly enriched uranium (HEU) which has been enriched up to 70% (and higher) or from the production or separation of plutonium. Hundreds of tons of highly enriched uranium and weapon-grade plutonium derived from the dismantled nuclear weapons found in American and Russian stockpiles are

the “deadly legacy” of the Cold War that give rise to so much concern (Bunn 2000). Apart from deriving from disarmed nuclear warheads, both highly enriched uranium and plutonium can also be produced using the technology currently available in many nuclear energy-producing countries. As soon as uranium becomes more than 20% enriched, the intentions are evidently for destructive ends; such action in any declared facility is immediately detected by the IAEA. Enrichment facilities are not present in all nuclear energy-producing countries.

Plutonium, on the other hand, is produced during fuel irradiation and separated during reprocessing in countries favoring the closed fuel cycle approach. The extracted plutonium is destined for use as a fuel ingredient (as mixed oxide fuel), but it also carries proliferation threats. To illustrate the seriousness of these potential risks: 8 kg of *weapon-grade* plutonium ( $^{239}\text{Pu}$ ) is sufficient to produce a bomb with the devastation potential of the Nagasaki bomb. The kind of plutonium which, under normal circumstances emerges from a power reactor consists of different isotopes including  $^{238}\text{Pu}$ ,  $^{240}\text{Pu}$ , and  $^{239}\text{Pu}$ ;  $\circlearrowleft$  Figure 12.2 shows the buildup of different plutonium isotopes during energy production or fuel irradiation. When more than 93% of  $^{239}\text{Pu}$  is present, plutonium becomes a weapon-grade element and below 80% of this isotope it is referred to as *reactor-grade* or *civilian* plutonium. For destructive purposes, plutonium must contain as much as possible  $^{239}\text{Pu}$  in proportion to the relatively short burnup time, as can be seen in  $\circlearrowleft$  Fig. 12.2.

To conclude, “[d]eploying reactor-grade Pu is less effective and convenient than weapon-grade in nuclear weapons”, but still “[...] it would be quite possible for a potential proliferator to make a nuclear explosive from reactor-grade plutonium using a simple design that would be assured of having a yield in the range of one to a few kilotons and more, using an advanced design” (DOE 1997). Separated plutonium whether it is weapon-grade or reactor-grade carries serious security risks.

Let us now move on to the question of how these considerations relate to the choice of final disposal waste methods. Geological repositories are believed to ensure security which is perceived as “resistance to malicious or accidental disturbance [...] over very long times”

$\blacksquare$  Fig. 12.2  
Burnup of different plutonium isotopes in a Light-Water reactor<sup>5</sup>

better than easily accessible above ground storage facilities (NEA-OECD 1999, p. 11). “[W]aste stores [on the surface] are vulnerable to inadvertent or deliberate intrusion by humans if not kept under close surveillance. This places obligations on future generations” (IAEA 2003, p. 5). The IAEA (2003, p. 7) further asserts that “[p]utting hazardous materials underground increases the security of the materials.”

## **Equal Opportunity: Retrievable Disposal**

The third concern is how to act in accordance with our alleged obligations in order to minimize future burdens while at the same time not depriving people of the future of their freedom of action. NEA (1999, p. 22) states that the present generation “should not foreclose options to future generations.” This is termed the equal opportunity principle: “[i]t is of equal worth that we guarantee coming generations the same rights to integrity, ethical freedom and responsibility that we ourselves enjoy” (KASAM 1988). In other words, we should respect their freedom of action – conceived of by KASAM (1999, p. 14) as a moral value – by acknowledging that “future generations must be free to use the waste as a resource”, in view of the fact that spent fuel contains uranium and plutonium which have potential energy value. Two other factors in favor of creating the option to retrieve waste from disposal facilities are these: (1) to be able to take remedial action if the repository does not perform as expected and (2) to be able to render radiotoxic waste harmless with new technology.

Retrievability, as intended here, has to do with repositories that will be kept open for an extended period of time so that future societies have the option to retrieve the waste. One might thus argue that retrievable waste could compromise the long-term safety of any repository. However, retrievability as commonly understood in the literature implies having a temporary measure based on the assumption that at a certain point a decision will be taken to either retrieve the waste (for any purpose) or to close the repository (IAEA 2000, pp. 9–10). If one relates retrievability discussions to the question of final disposal, one can argue in favor of storage on the surface, as the “[r]etrieval of material is easier from surface facilities than from underground facilities, but geological disposal can be developed in stages so that the possibility of retrieval is retained for a long time” (IAEA 2003, p. 7).

The underlying intergenerational principles of nuclear waste management policies have been discussed in this section. We furthermore explored how a need for “the same degree of protection” for different generations has led to the conclusion that geological disposal is the most appropriate way to dispose of waste. In the following section, I shall challenge this view by reflecting on the assumptions that underlie the alleged long-term safety of geological disposal, arguing that the key weakness of this technological solution lies in the great accompanying uncertainty.

## **Policy-Making and the Principle of Diminishing Responsibility**

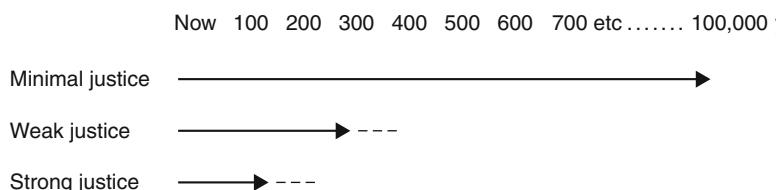

---

Elsewhere in this chapter I argued that the production of nuclear power creates certain moral obligations for the present generation to ensure future people’s well-being – in terms of resource availability – and not to harm people of the future. On the practical policy-making level, one could question to whom we owe these obligations and whether, when fulfilling these obligations, we should distinguish between people of the near and remote future

(Norton 1995). These questions date back to the early days of discussions on our obligations toward posterity. By introducing the notion of belonging to a “moral community” that shares our perception of what constitutes a good life, Martin Golding (1981, p. 62) argues that we have an obligation to produce “a desirable state of affairs for the community of the future [and] to promote conditions of good living for future generations.” However, “the more remote the members of this community are, the more problematic our obligations to them become,” Golding (1981, p. 69) states and he concludes that we should be more concerned about the more immediate generations. Daniel Callahan (1981), on the other hand, states that ignorance does not release us from our obligations when the issue at stake is whether we might harm future generations; Callahan’s notion of our negative obligations to posterity obviously extends much further than Golding’s stated positive obligations. In this section I will scrutinize the notion of reducing responsibility over the course of time, as a leading notion in policy-making, while arguing that such a distinction is inescapable when building geological repositories.

Two attempts to explore the legitimacy of a distinction between different future generations are worth mentioning, particularly as they have offered policy-making justification on nuclear waste management. The bodies to which I refer are the Swedish National Council for Nuclear Waste (KASAM) and the American National Academy of Public Administration (NAPA). The KASAM (1999, p. 27) argues along the same lines as Golding by stating that “our responsibility diminishes on a sliding scale over the course of time,” as “the uncertainties of our base of knowledge [...] of the system’s technical design, increase as a function of increasing time span perspectives.” KASAM (2005) contemplates a more extensive duty to the immediate future by introducing three principles of justice and distinguishing between the various periods of time in the future: (1) the next five generations (150 years) deserve our greatest attention; (2) the subsequent 150 years come in second place; and (3) the era beyond 300 years is considered last of all. These periods of time represent different concepts of justice in what is perceived as a “diminishing moral responsibility” perspective, as illustrated in **Fig. 12.3**.

The KASAM’s strong principle of justice states that we must ensure that our immediate descendants have “a quality of life equivalent to ours,” while the weak principle says that we need to respect and protect future people’s right to satisfy their basic needs. The minimal principle of justice, on the other hand, merely states that today’s people should not jeopardize future generations’ possibility for life. KASAM seeks justification for these proposed periods by asserting that if we define a generation as being 30 years then our imagination hardly extends beyond that of our grandchildren’s grandchildren; these five generations or 150 years are believed to represent the boundary of our “moral empathy.” Another justification that

**Fig. 12.3**

Three principles of justice with respect to the various time periods (Source: KASAM 2005, p. 440, with kind permission)

KASAM provides in connection with this principle of justice is that “our primary relationships” can barely have any influence beyond five generations. If one were to define local communities and nations in terms of “secondary relationships,” this timescale could possibly be extended to, as KASAM suggests, 300 years, beyond which predictability and positive influence “appears to be almost non-existent” (KASAM 2005).

The second initiative worth mentioning is that of the NAPA (1997, p. 7) which proposed establishing four principles of intergenerational decision-making. These principles state that we are trustees for future generations and that – according to the Brundtland’s sustainability principle – we should not deprive the future of a quality of life comparable to our own (WCED 1987). Since we know more precisely the needs and interests of our own generation and the immediately ensuing ones and since we are hardly in a position to predict the very distant future, a “rolling present” should “pass on to the next the resources and skills for a good quality of life”; NAPA (1997, p. 8) further states that “near-term concrete hazards have priority over long-term hazards that are less certain.” What remains questionable is whether the lower probability of long-term risks will make them morally less important; I will elaborate on this issue in the section [State of the Art in Technology: Challenge to Geological Disposal](#).

## Geological Disposal and Long-Term Uncertainties

---

One of the key arguments when opting for geological disposal rather than above ground storage is the alleged long-term safety issue. In safety studies it is assumed that canisters will inevitably breach and radioactive material will leak at some time in the future; canisters are therefore enclosed in engineered facilities to avoid unnecessary seepage into the environment. In addition, host earth formations are viewed as a natural barrier impeding further leakage into the biosphere, all of which should support arguments in favor of the long-term safety of repositories. This alleged safety seems, however, to be founded on a number of serious uncertainties and has therefore triggered a whole debate on whether geological disposal should not be reconsidered for the final isolation of radiological waste (this point has for instance been defended by Shrader-Frechette (1993, 1994)); more will be said about this issue in the following section.

It is curious to see how the problem of the technical unpredictability of the remote future and the associated uncertainties are addressed in long-term policy-making, particularly in relation to geological disposal. Let me illustrate this by pointing out how the radiation standards are set for the Yucca Mountains repositories in Nevada (US). According to the American Energy Policy Act of 1992, the Environmental Protection Agency (EPA)<sup>6</sup> is charged with the task of developing health and safety radiation standards for the designing of repositories.<sup>7</sup> EPA’s first proposed standards limit exposure to radiation to 15 per year, with a compliance time of 10,000 years millirem.<sup>8</sup> In objection to this it has been argued by the US National Academy of Science that “the peak risks might occur tens to thousands of years or even farther in the future” (NRC 1995); 10,000 years seemed both insufficient and arbitrary. In a successful lawsuit, the D.C. Court of Appeal subscribed to the latter conclusion ruling that the EPA had to revise these radiation standards (Vandenbosch and Vandenbosch 2007, Ch. 10). In 2005, the EPA proposed distinguishing between two future groups, i.e., the people of the next 10,000 years who could maximally be exposed to the already set 15 millirem per year standard and the period beyond 10,000 (up to one million years) for which a radiation limit of

350 millirem per year was proposed (EPA 2005). This two-tiered approach was necessary, EPA (2005, 49035) argued, in connection with long-term uncertainties which are “problematic not only because they are challenging to quantify, but also because their impact will differ depending on initial assumptions and the time at which peak dose is projected to occur.”

By applying KASAM’s Minimal Principle of Justice (of not jeopardizing the possible life of future generations) and NAPA’s preference for avoiding near-term concrete hazards in contrast to the long-term hypothetical hazards of spent fuel disposal, EPA (2005, p. 49036) concludes that “a repository must provide reasonable protection and security for the very distant future, but this may not necessarily be at levels deemed protective (and controllable) for the current or succeeding generations”. The proposed 350 millirem is the difference between the naturally occurring radiation in an average area in the USA (350 millirem per year) and that experienced in Colorado (700 millirem per year). EPA justifies this discrimination by stating that after one million years, people in Nevada will maximally experience the same level of radiation as people living in Colorado today.

On the one hand, this discrepancy in radiation standards seems understandable if one thinks that providing equal protection levels for such periods of time is virtually impossible in view of the fact that “the uncertainties for a thousand years [...] from now are large [and] they are almost incalculable when one goes to 10,000 or 100,000 years” (Kadak 1997, p. 49). On the other hand, we can question whether changing the standards for the latter reason is appropriate. As Vandenbosch and Vandenbosch (2007, p. 136) have correctly stated: “[i]f one were designing a bridge whose steel and concrete performance become more uncertain [over the course of] time, would one loosen or tighten the structural design standards if one realizes that the bridge was going to have to provide safe transport for a long period of time?” The justification provided by the EPA is furthermore believed to be flawed as these policies “threaten equal protection, ignore the needs of the most vulnerable, [and] allow many fatal exposures” of the people living in the distant future (Shrader-Frechette 2005, p. 518).

In its “final rule,” the EPA (2008) changed the radiation exposure limit for the period beyond 10,000 years to 100 millirem per year. It remains unclear what precisely motivated this change; a speculative conclusion is that that public opposition to the huge difference between the originally proposed 15 and 350 millirem for the stated periods might have triggered this adjustment in the final ruling. In June of 2008, the US Department of Energy submitted a license application to the Nuclear Regulatory Commission to build a long-term geological repository for the permanent disposal of spent fuel for a million years (DOE 2008).<sup>9</sup>

To conclude, in this section I have reviewed the underlying arguments for distinguishing between different future generations based on the low degree of predictability concerning the remote future and the fact that any positive influence on such societies is meaningless. Even though these arguments are sound, I argue that at most they provide explanations indicating why we cannot act otherwise, rather than solid moral justifications for discriminating future generations; ignorance does not release us from our temporal obligations when it comes to the question of harming future people, as correctly stated by Callahan (1981). If my arguments to the effect that the production of nuclear power creates a problem of intergenerational equity are sound, I consider the minimal principle of justice (of not jeopardizing the possibility for life) an undesirable one as it facilitates the serious discrimination of remote future generations; that is to say, we can dramatically reduce the well-being of future generations and jeopardize their health and safety without depriving them of “the possibility for life,” even though their quality of life might be much lower than ours. Whether the present level of well-being has

sufficient moral relevance to serve as a point of reference is a claim that I leave unanalyzed; I simply assume that it does; see for more information on this dispute the he debate between Wilfred Beckerman (1999) and Brian Barry (1999).

The distinction that is made in policy-making, for instance with the setting of radiation standards for Yucca Mountain repositories, seems to be rather a pragmatic solution making it possible for such repositories to remain within the margins of technical predictability for the remote future. This should urge us to reconsider our temporal moral obligations and what, in the light of recent technological developments, we ought to do with regard to future generations, assuming that “ought to” implies “can.” The following section contemplates the technological possibility of substantially reducing the waste lifetime and challenging the need for geological disposal.

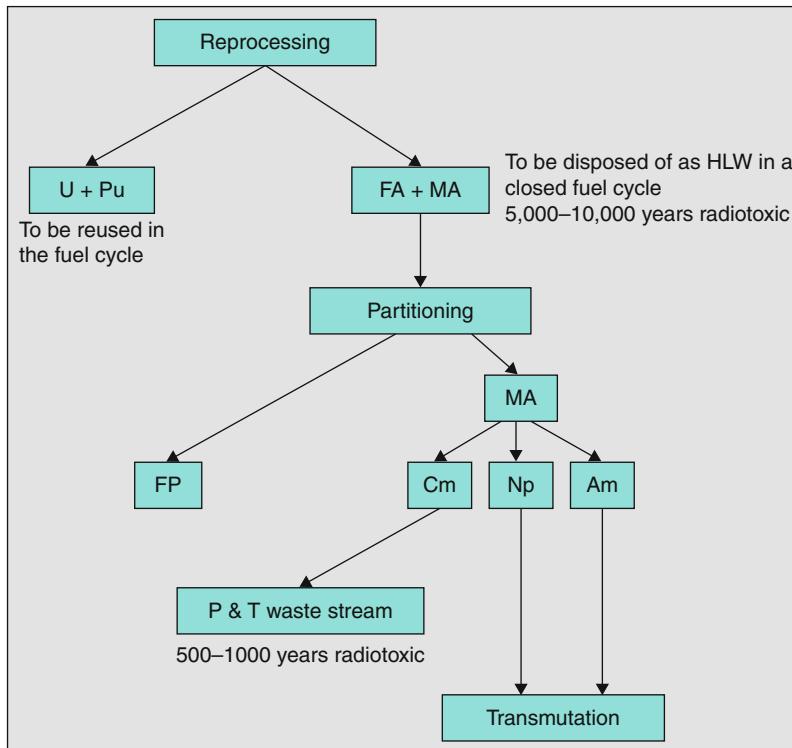

## **State of the Art in Technology: Challenge to Geological Disposal**

---

As nuclear waste is perceived to be the Achilles’ heel of nuclear energy production, serious attempts have been made to further reduce its lifetime and volume. A new technology for the latter purpose is that of Partitioning and Transmutation (P&T). Remember that spent fuel in an open fuel cycle contains uranium and plutonium, minor actinides, and fission products. Uranium and plutonium are separated during reprocessing in order to be reused; that is what amounts to a closed fuel cycle. P&T focuses on “eliminating” minor actinides, as illustrated in  Fig. 12.4. P&T complements reprocessing but does not provide an alternative solution; P&T is also referred to as an extended closed fuel cycle.

If completely successful, P&T will, it is expected, make the waste lifetime five to ten times shorter when compared to closed fuel cycle waste. After P&T, waste radiotoxicity can decay to a nonhazardous level within the space of hundreds of years (i.e., 500–1000 years). This estimated reduction in the waste lifetime is based on the assumption that all minor actinides are transmuted except for curium; the waste stream would therefore only consist of relatively short-lived fission products and curium isotopes. The latter is considered to be too hazardous to be recycled at reasonable expense and without excessive risk; curium would dominate the waste lifetime. There is a dispute about what exactly the waste lifetime will be after successful P&T. It goes beyond the scope of this work to enter into such discussions. However, for the sake of argument I adhere to the mentioned period, arguing that the scientific possibility to reduce the waste lifetime to a couple of hundred years urges us to revisit some intergenerational arguments relating to waste management. For the sake of clarity, the three different types of waste, their constituents, and the relevant waste lifetimes are all illustrated in  Table 12.1.

Some experts in the nuclear community hailed P&T in nuclear waste management but then went on to reject it for two reasons: (1) because it necessitates the building of new facilities and (2) because even after successful application some materials still remain radiotoxic (IAEA 2000; NEA-OECD 1999). Even though both arguments are sound, they do not provide sufficient grounds for rejecting P&T. In this kind of reasoning P&T is wrongly presented as an alternative to geological disposal. If my arguments in this chapter are correct, it must be asserted that P&T challenges the need for final disposal underground and places the serious alternative of repositories – for long-term storage on the surface – in a new perspective. Let me start supporting this claim by reevaluating the three main intergenerational arguments that underlie nuclear waste management policy.

**Fig. 12.4**

A schematic representation of Partitioning and Transmutation. FP stands for fission products, MA stands for minor actinides that contain curium (Cm) neptunium (Np) and americium (Am). Uranium (U) and Plutonium (Pu) are the major actinides

**Table 12.1**

Three different states of waste, the constituents, and the waste lifetimes

	Contains	Waste lifetime	Dominated by
Spent fuel	U, Pu, MA (Np, Am, Cm) + FP	$\pm 200,000$ years	Pu
HLW or vitrified waste	MA (Np, Am, Cm) + FP	$\pm 10,000$ years	Np + Am
P&T waste	MA (Cm) + FP	$\pm 500\text{--}1,000$ years	Cm

FP stands for fission products, MA stands for minor actinides that contain curium (Cm) neptunium (Np) and americium (Am). Uranium (U) and Plutonium (Pu) are the major actinides.

In objecting to above ground storage places, the IAEA (2003) draws attention to “some structural degradation of the packages and their contents [...] over time”, which makes further transfer of the waste to other storage facilities or geological repositories inevitable. The argument is that long-term safety is therefore not well served by very long periods of time in above ground storage facilities. In its recommendations in favor of geological disposal, IAEA

takes long-term safety for granted. However, the long-term safety of geological disposal depends on certain considerable uncertainties, which necessitate the sanctioning of a distinction between different future generations. If we now accept the conclusion drawn in the last section to the effect that this distinction lacks moral justification, we can argue that it would be best to avoid such uncertainties. Implementing P&T allows for the latter, as the period of necessary care for P&T waste amounts to a couple of hundred years, a period in which it is presumed that more reliable predictions can be made about a canister's status and possible seepage into the environment and whether that can reach the biosphere.

Likewise, security concerns will change. Security has to do with the unauthorized possession or theft of radiotoxic waste for the purposes of sabotage (e.g., dispersal) or proliferation. As far as sabotage is concerned, geological disposal has obvious advantages for all three above-mentioned types of radiotoxic waste as listed in ➤ *Table 12.1*: i.e., potential hazards will literally and figuratively be buried at very difficult to access depths under the ground. Hence, any sabotage concerns associated with radiotoxic waste remain evidently less in the case of geological disposal. In the case of the proliferation of nuclear weapons, however, we must distinguish between the three types of waste. Spent fuel has potential proliferation hazards, as there is still plutonium that could be separated; spent fuel might therefore best be disposed of underground (Stoll and McCombie 2001). High-level waste, however, has no potential proliferation threats, as the fissionable materials (uranium and plutonium) have already been largely extracted<sup>10</sup> and the remaining waste (minor actinides and fission products) does not lend itself to proliferation purposes. Similar reasoning is applicable to P&T waste; in other words P&T waste does not necessitate geological disposal from the avoidance of proliferation point of view.

Equal opportunity is the third intergenerational equity consideration that underlies policy-making in nuclear waste management. Nuclear waste should always be disposed of in a retrievable manner for (1) the possible future resource value of spent fuel, (2) remedial action if the repository does not operate as expected, and (3) rendering radiotoxic waste harmless with the help of new technology. By including P&T in these discussions as a technological option, one can conclude that considerations about future resource value cease to be relevant, since P&T waste comprises no potential source value in view of the fact that plutonium and the remaining uranium are separated during the earlier stage of reprocessing prior to P&T. However, retrievable disposal remains desirable in conjunction with the second and the third reasons above; i.e., even with P&T waste streams it might be necessity to adjust repositories or to render the waste harmless. This retrievability argument does not, however, support geological disposal, since retrievability is, in principle, more feasible in aboveground storage places.

P&T thus enables us to avoid the long-term uncertainties that accompany the geological disposal of long-lived spent fuel. In other words, it helps us to avoid ending up in situation in which – from a pragmatic point of view – we need to discriminate remote future generations through the way that we design and build repositories. P&T therefore puts contemporaries in a better position to fulfill the obligations emanating from the intergenerational equity problem caused by uranium depletion and, just as importantly, the longevity of nuclear waste.

Before going on to review the possible counterarguments to P&T, let us just focus on another issue, namely that of whether more predictable risk is necessarily more justifiable. As stated above, P&T helps us to avoid putting distant future generations at a disadvantage as it increases the degree of predictability. Does such increased predictability imply that the risks in the coming 500–1,000 years are justifiable? Making the relevant timescales more predictable

makes appropriate risk assessment possible. However, the questions about the acceptability of these risks for future generations and, more importantly, the additional risks posed to the present generation remain unanswered. This brings us back to the issue at the heart of this matter, namely that of intergenerational equity. Together with Kloosterman I have compared open and closed fuel cycles in terms of their conflicting moral values and have argued that the fuel cycle choice should be presented within the framework of intergenerational equity (Taebi and Kloosterman 2008). The closed fuel cycle improves uranium supply certainty and brings fewer long-term radiological risks and proliferation concerns. On the other hand, it compromises short-term public health and safety, and also security. The trade-offs inherent in opting for the fuel cycle are, as we have argued, reducible to a primary trade-off between the present and the future. If we view P&T as an extension of the closed fuel cycle – since without reprocessing the deployment of P&T is useless – and if we assume that P&T requires extra nuclear activities for the further irradiating of HLW so as to eliminate minor actinides, then more or less the same time-related conflicts will arise. There are conflicts of interest between the present generation and future generations; advocates of P&T need to justify why they are willing to accept additional risks as a result of P&T in order to reduce risks to people living in the distant future.

Let me clarify these intergenerational conflicts by focusing on one of the issues involved, namely, the economic considerations. NEA has evaluated the viability of P&T through Fast Reactors and Accelerator-Driven Systems and has concluded that a considerable amount of R&D will be required in the coming decades before utilization at industrial level can be considered (NEA-OECD 2002). In addition, more nuclear facilities will be needed for the further elimination of minor actinides. Why are these additional economic burdens upon the present generation permissible or even desirable? Precisely specifying the time-related dilemmas and trade-offs that need to be considered before P&T can be deployed should be a subject of future study; see for a preliminary discussion of this issue (Taebi and Kadak 2010).

## Four Counterarguments to the Feasibility and Desirability of P&T

So far I have argued that there are good reasons to believe that P&T is a potential future possibility and that if P&T is industrially feasible we might want to reconsider geological disposal for the final isolation of nuclear waste. There are, however, unanswered questions (or even objections) when it comes to applying this technology. The four main ones are (1) the reliance on industrially not yet proven technology for changing policy, (2) the continued need for final isolation and building repositories, (3) public resistance to additional nuclear facilities, and (4) the inappropriateness of relying on future societies to deal with our waste. These four counterarguments will be reviewed below.

At present P&T is only available in the laboratory; a considerable amount of R&D effort will be required before P&T can be industrialized (NEA-OECD 2002; IAEA 2004). The first question is whether the prospect of future technology should change current policy. Some people argue that envisaged technological progress justifies the current postponing of action as far as the building of repositories goes. KASAM (2005, Ch. 8) has evaluated the validity of postponing actions based on potential P&T possibilities as follows. On the one hand, it could be asserted from a utilitarian point of view that technologically better final disposal technology increases safety and reduces the risks for future generations. On the other hand, it is doubtful

whether that provides sufficient reason to shift the burden of finding a solution for final disposal to future generations. In addition, we need to make very explicit assumptions about the progress of technology in order to justify postponing action; this is referred to as the *technological fix* position as, for instance, defended by Beckerman and Pasek (2001). Although there has been evident technological progress during the last few centuries and although inductive reasoning forecasts its continuation, we cannot be sure that such progress is sufficient to deal with the risks we have created (Skagen Ekeli 2004) and we do not know whether future societies will be able to dispose of radiotoxic waste more appropriately than we are able to at present. More importantly, there is no guarantee of whether and, if so, when and to what extent P&T, at industrial level, will live up to the expectations it has created.

In Sweden, on the basis of P&T technology as it was in 2004, KASAM recommended that the nuclear waste program should be neither interrupted nor postponed and that the building of repositories should be continued as P&T cannot be cited as an alternative to final disposal (KASAM 2005). Nevertheless, it is believed that P&T development and future possibilities seriously call for the retrievability of waste so that future people's freedom of action to deal with such waste in a more appropriate way can be respected. The Canadian Nuclear Waste Management Organization (NWMO 2005) also finds P&T an interesting option as it reduces waste radiotoxicity and volume, but the organization has serious reservations about the economic and practical aspects of this technology and therefore maintains that it is not a desirable option for Canada.

The second problem is that P&T fails to make ultimate isolation redundant which means that some materials will remain hazardous and must therefore eventually be isolated from the environment. P&T cannot therefore entirely replace repositories that are, for instance, needed to dispose of tons of highly enriched uranium and weapon-grade plutonium emanating from dismantled nuclear warheads dating from the Cold War period. The American National Academy of Sciences acknowledged these concerns and called for the urgent implementation of a program (1) to burn this plutonium in reactors of existing types as mixed oxide fuel and (2) to mix this weapon-grade plutonium with highly enriched uranium and vitrify it for final geological disposal (NAS 1994). Likewise, the highly enriched uranium extracted from the dismantled nuclear warheads could, to some extent, be blended down to reactor-grade uranium suitable for use in a reactor. However, for the time being, there is no realistic way to fission all these materials in reactors, in spite of all the technical possibilities we have at our disposal. If we bear in mind that uranium and plutonium are the long-lived isotopes that necessitate geological disposal and if we take for granted the fact that the nuclear community is right about the appropriateness of geological repositories for the long-term disposal of long-lived isotopes, the need for geological disposal for military waste containing these materials will subsequently remain unchanged. Nonetheless, one can argue that we should consider the need for repositories that are directly related to nuclear energy production and realize that P&T will challenge this need, as fewer long-term concerns will be involved. Even though some repositories will still be needed (particularly for dismantled military material), successful P&T deployment would substantially reduce this need.

The third issue that the application of P&T might raise is that of the lack of public acceptance of more nuclear facilities. As was noted in the section [State of the Art in Technology: Challenge to Geological Disposal](#), P&T should be preceded by reprocessing (See [Fig. 12.4](#)), which is a chemical process that has, in the past, been met with considerable public opposition, for instance in Germany. It is conceivable that P&T might elicit similar objections.

In addition, the implementation of P&T necessitates the building of more fast reactors so that the troublesome actinides can be eliminated, all of which will culminate in a shorter lifetime for the remaining waste. In light of recent accidents in the Fukushima reactors in Japan, it is to be expected that the building of new nuclear facilities might meet with public outcry. However, these kinds of objections should be viewed in the light of the central issue at the heart of this chapter, namely, the matter of intergenerational equity. On the one hand, it is true that engaging in more nuclear activities will increase the risks and potential burdens for present generations, all of which might not be easily accepted by the public. On the other hand, we should realize that the already generated waste needs to be dealt with anyway. If my arguments are sound and if the current solution involving geological disposal necessitates a distinction between different future generations that is morally indefensible, then it is worth discussing different possibilities to reduce future burdens, one of which is the P&T solution. Nevertheless, the issue of public acceptance is highly relevant and will probably remain problematic.

The fourth objection to surface storage (irrespective of the waste lifetime) is that it forces us to rely on future societies for the possible further treatment and final disposal of waste (NEA-OECD 1995). It has been argued that near future geological disposal complies better with intergenerational equity, as it does not involve passing on our responsibilities to our descendants and it imposes fewer safety and security burdens on the present generation. Axel Gosseries (2008), for instance, argues that from the viewpoint of intergenerational equity, the “seriousness risk of malevolent use” calls for the early disposal of spent fuel rather than for storage.

The latter objection reveals an intergenerational conflict, not one between the interests of present and future generations (as has been outlined in this chapter), but rather one between the interests of different future generations. One can indeed defend the argument that disposing of waste now complies better with equity toward generations of the near future since, instead of passing on the responsibility of dealing with this problem, we will have taken care of it ourselves. On the other hand, assuming that geological disposal will put distant future generation at a disadvantage, it would be a good intergenerational equity argument to avoid such discrimination. The key question here is how can we rank the interests of people living during different eras in the future. If my arguments in the section [Policymaking and the Principle of Diminishing Responsibility](#) are sound and if it is the case that we ought not to treat distant future generation differently just because they happen to live in the more distant future, then it becomes less defensible for intergenerational equity to require us to dispose of the waste in geological repositories.

## Conclusions

---

Nuclear energy is one of the clearest examples of a technology that creates risks beyond the generational borders and which therefore brings about issues of intergenerational equity; because with nuclear energy production and consumption we are depleting a nonrenewable resource (uranium) that will not then be available to future generations and because, more importantly, the remaining waste needs to be isolated from the biosphere for a very long time. Principles of intergenerational equity have already been influential in nuclear waste management policies, the argument being that we should not impose *undue burdens* on future generations. In concrete terms, we have been urged to ensure future people’s safety and security whilst giving them equal opportunities. In this chapter, I have explored how these

intergenerational equity principles have been included in policy-making and especially, how they deal with the issue of long-term risks and the associated uncertainties.

The consensus within the nuclear community seems to be that burying spent fuel in geological repositories rather than keeping it in surface storage places is the best solution as repositories are believed to be safer and more secure in the long run. This long-term safety seems to be disputable, though, as it relies on great long-term uncertainties which, in turn, necessitate making a distinction between different future people. The latter distinction does, however, lack solid moral justification, which should urge us to reconsider our temporal moral obligation and what we ought to do with regard to future generations, in the light of recent technological developments. The technological possibility of substantially reducing the waste lifetime through Partitioning and Transmutation (P&T) is believed to challenge geological disposal, placing long-term surface storage in a new perspective. Deploying P&T sheds new light on the social and technical predictability capacity for the future and enables contemporaries to discharge their temporal obligations better, particularly, the obligation not to harm those living in the distant future.

In the nuclear community, P&T was wrongly presented as an alternative to geological disposal and so it was subsequently rejected as a possibility. The related misunderstanding hinged on the fact that new facilities do have to be built and the need for final isolation does remain. Even though both arguments are sound, P&T challenges the need for final disposal underground, thus placing long-term surface storage in a new perspective. Before P&T can be phased in on an industrial scale in the next few decades substantial investments will first have to be made and there is no guarantee of success, as the future development depends on very many technical, social, political, and economic factors. More importantly, the introduction of P&T creates additional risks and burdens for the present generation and serious trade-offs need to be made before acceptance and deployment can be achieved. There are also other objections to the application of P&T, such as the reliance placed on near future societies to deal with the waste and the not to be overlooked fact that it is an industrially not yet proven technology. Nonetheless, P&T helps us to avoid ending up in situation in which we – from a pragmatic point of view – need to place remote future generations at a disadvantage because of the way in which we design and build our present-day repositories. Even the potential possibility to diminish “undue burden” with respect to the future is too relevant to be neglected in discussions relating to nuclear waste management and how we perceive our moral obligations toward posterity.

---

## Further Research

Before P&T can be introduced it is, above all else, further research that is needed so that the required technology can be further developed. It is both the reprocessing technologies (multiple recycling) and the development of fast reactors that needs to be further refined. In terms of philosophy further research is required in at least the following three subject areas. Firstly, there is the issue of how to defend obligations to future generations. The matter of how to deal with the non-identity problem remains a philosophically moot point. Secondly, we need to spell out the extent of our obligations to posterity, particularly when they conflict with obligations to present generations; some thoughts on this issue could be read in the present discourse (Taebi 2011). Thirdly, further research should be conducted into the matter of how to balance intergenerational equity with intragenerational equity. In other words, what should we do

when complying with intergenerational equity creates a situation of injustice within the present generation? This problem manifests itself in the case of multinational waste repositories. In other words, from the perspective of intergenerational equity, multinational repositories are beneficial since the total number of facilities that carry a potential burden for future generations will inevitably be reduced. On the other hand, multinational repositories create the problem of intragenerational *injustice* between the participating countries, since host nations must accept the waste of other nations.

## Notes

---

1. For detailed discussions on intergenerational justice readers are referred to these articles: Gosseries (2002), Meyer (2008), and the following two collections Gosseries and Meyer (2009) and Tremmel (2006).
2. Justice, fairness, and equity are used interchangeably in the relevant literature sources. In this chapter I do not intend to go into great depth on these philosophical discussions. *Intergenerational equity or justice* are referred to here as the equitable distributions of risks and burdens across generations.
3. If the same rate of uranium consumption as that of 2008 were continued there would be enough *reasonably priced uranium* available for approximately 100 years. However, it has been forecast that many countries will join the nuclear club in the next couple of decades, all of which will substantially affect the demand for uranium; in the high-growth scenario approximately half of these resources will be depleted by 2035. It is important to note that this uranium availability constitutes a reference to its geological certainty and production costs. If we include estimations of all the available resources, this will rise substantially to thousands of years; (see IAEA-NEA 2010). Furthermore, there is another fission material available that could be used for the production of nuclear power, namely, Thorium (Th). Thorium is naturally more abundant than uranium, but it brings with it different issues such as substantial security burdens (IAEA 2005); None of the above points do, however, undermine the basic rationale that the present generation is depleting a nonrenewable resource, particularly, the currently reasonably priced supplies.
4. The term “acceptance” might be misleading here, as we are not referring to what is actually *accepted* by the public, but rather to what is taken to be the greatest allowable risk in policy-making, e.g., as in maximum exposure when setting current radiation standards.
5. I received this Figure following personal contact with Jan Leen Kloosterman from the Department of Radiation, Radionuclides and Reactors at Delft University of Technology.
6. The Environmental Protection Agency is the United States’ federal agency in charge of protecting human health by protecting the natural environment. Projects that involve affecting the natural environment – such as the disposal of nuclear waste – need to be first approved by EPA.
7. These standards must further be incorporated into licensing by the Nuclear Regulatory Commission (NRC) regulations. Compliance with these standards must then be demonstrated by the US Department of Energy (DOE). For an overview of how these organizations are connected to each other, see Vandebosch and Vandebosch (2007, Ch. 8).
8. Rem and Sievert (Sv) indicate radiation exposure in order to determine radiation protection. 1 sievert (Sv) = 100 rem.

9. The first draft of this chapter was written in 2008 when the Yucca Mountains repository was still considered to be the most feasible option for the geological disposal of American waste. However, following the most recent presidential elections in the USA, the Obama administration has excluded the Yucca Mountains site as an option; (see Josef Hebert 2009). Precisely how the American waste (that is currently stored at nuclear reactor sites) should be dealt with remains a subject of discussion. In 2010 a Blue Ribbon Commission on America's Nuclear Future started exploring the possibilities; see <http://brc.gov>.
10. It is important to notice that during reprocessing some trace amounts of plutonium will remain in the waste stream. This amount is, however, insignificant for proliferation or energy production purposes.

## Acknowledgments

---

An earlier draft of this chapter was presented at the Energy and Responsibility conference which was held in May 2008 in Knoxville, Tennessee. I wish to thank the audience of that conference and in particular Dennis Arnold. I further wish to thank Ibo van de Poel, Stephen Gardiner, Jan Leen Kloosterman, Dominic Roser, and Lara Pierpoint for their useful comments and corrections. The usual disclaimer with regard to authorial responsibility applies.

**Abstract:** This chapter analyzes the types of uncertainties involved in climate modeling. It is shown that as regards climate change, unquantified uncertainties can neither be ignored in decision making nor be reduced to quantified ones by assigning subjective probabilities. This poses central problems as therefore the well-known elementary as well as probabilistic decision approaches are not applicable. While a maximized-utility approach has to presuppose probability estimates that are not at hand for climate predictions, the precautionary principle is not capable of adequately implementing questions of fairness between different nations or generations. Thus an adequate response to global warming must deal with an intricate interplay between epistemic and ethical considerations. The contribution argues that the epistemic problems involved in modeling the climate system are generic for modeling complex systems. Possible paths for future research to circumvene these problems are adumbrated.

## Introduction

---

Human beings are part of the biosphere and as such always have and always will impact the Earth's ecosystem. Due to the large number of humans living presently and due to technological changes, this impact is greater than ever. But, for the purpose of this handbook more important, unlike past generations we are well aware of our impact on the ecosystem Earth. And even more so: Science provides us with sophisticated tools that estimate this impact and tells us, for example, that the climate system is particularly vulnerable to present anthropogenic impact.

Though it is moral considerations that make us reason about global warming, determining the adequate response to this threat relies on findings from the empirical sciences. Assessing, for example, the adequate greenhouse gas reduction scheme, the pros and cons of cap and trade or carbon tax, or even the very question as to how much we have to cut down the emissions hinges on empirical prognoses. Decisions are to be based on the best knowledge available. Most scientists agree that, at least for the time being, unquantified uncertainties are inevitably connected to predictions of climate models. This, however, does not imply that these predictions are unscientific. Nor do uncertainties justify political inaction. For climate change, just like for many environmental problems, the best knowledge available today is provided by science (e.g., Oreskes 2004). This knowledge comprises not only the prognoses themselves – prognoses on, say, the increase of global mean temperature, sea level rise, or the effects all these changes have on the fishing industry. Our best scientific knowledge available today is the prognoses *plus* information on their reliability (Hillerbrand 2010). Increasing the reliability commonly coincides with reducing the uncertainties of the predictions – an enterprise of major significance within climatology. However, uncertainties remain and will remain. When practical reasoning is based on scientific facts, these uncertainties have to be considered, one way or the other.

Though uncertainty is nothing peculiar to climate modeling or even scientific forecasts, uncertainties arising here seem to differ from uncertainties associated with everyday prognoses. We expect science to provide us with quantitative information – even on the uncertainty of its predictions. And indeed, this is particularly what climatology provides us with. The Intergovernmental Panel on Climate Change (IPCC), for example, predicts that a doubling in carbon dioxide concentration “is likely to be in the range 2°C to 4.5°C with a best estimate of

about  $3^{\circ}\text{C}$ , and is very unlikely to be less than  $1.5^{\circ}\text{C}$ . Values substantially higher than  $4.5^{\circ}\text{C}$  cannot be excluded, [...]” (IPCC 2007, p. 12). Expressions like *likely* or *very unlikely* are thereby interpreted as probability statements: *Likely* corresponds to probabilities higher than 66%, while *very unlikely* denotes probabilities smaller than 10%.

In the first part of this chapter, the climate and impact models and, if applicable, the probabilistic statements they provide are analyzed. It is argued that, despite to all appearances, uncertainties arising in quantitative scientific predication cannot be fully quantified. Section [● Climate Science or Climate Fiction?](#) addresses the question as to what is the very thing that is uncertain about present climate predictions. Not aiming at an exhaustive overview, this section highlights difficulties in modeling the climate system and climatic impacts on humans. On epistemic grounds, two types of uncertainty are distinguished, namely, *parameter* and *conceptualization uncertainty*. In section [● Predicting Complex Systems](#), problems in predicting the impact of anthropogenic greenhouse gas emissions are related to more general problems concerned with complex systems. There exists a widespread and appropriate scientific specification of the demotic notion of a complex system. It defines a complex system as one with more than three degrees of freedom which are coupled to each other via feedbacks. Mathematically, this is expressed by nonlinear evolution equations. This notion must presuppose a model of the target system, that is already on such a high level of abstraction that the notion of a *degree of freedom* makes sense. As this is a chapter mainly on epistemic aspects, it does refrain from this technical notion and adopts Shackel’s definition of a complex system throughout the paper. Shackel’s notion is completely in epistemic terms and allows to picture the climate system as complex with respect to some features, while simple with respect to others. Section [● Knowing-How in Scientific Modeling](#) contends that in modeling complex systems, non-propositional knowledge, that is, competencies or abilities, as opposed to propositional knowledge become of great importance. Unlike the latter, these competencies may only be learned by practice – by working within a certain scientific field. What is good practice cannot be captured in explicit definitions or in numerical figures assessing the reliability of the practice. Assigning numerical figures, for example, in the form of probabilities, to the reliability of models and the conceptualization uncertainty associated to their predictions thus is (at least in parts) misleading. It is shown that as regards climate change, unquantified uncertainties can neither be ignored in decision making nor be reduced to quantified ones by assigning subjective probabilities. As argued in section [● Limits of Common Decision Approaches When Applied to Climate Change](#), this epistemic feature of the climate system is of central relevance for practical reasoning as unquantified uncertainties render the applicability of standard decision approaches impossible. Particularly, the uncertainties with which decision making based on these prognoses has to deal with comprise but go well beyond what scientists commonly refer to as uncertainty (i.e., the variance or width of some probability distribution). On the basis of the distinction between risk, uncertainty and ignorance as known in technology assessment, the impact of greenhouse gas emissions are identified as a genuine situation under uncertainty because the reliability of the models involved cannot be fully quantified. It is asked as to how classical decision approaches like expected utility maximization as well as a precautionary approach may deal with the uncertainties specific for climate modeling. Section [● Summary and Further Research](#) provides a summary resulting in an outlook on future research that may provide a way of how to adequately incorporate unquantified uncertainties into practical decision making.

## Climate Science or Climate Fiction?

---

Prognoses on the future are always uncertain, and so are prognoses on the future climate. So what exactly does uncertainty mean as regards global warming? Before sketching some features of models relevant for the discussion of uncertainties in this chapter, a word of caution. This contribution does not aim at an exhaustive overview on virtues and vices of present climate modeling, hence the analysis is, willy-nilly, biased. This shall, however, not distract from the fact that, despite all the shortcomings, these are scientific models and the best ones available. Present climate models are readily able to well reproduce the natural climate variability (e.g., Houghton 1995). Predictions obtained from various models widely agree with one another, the connection between carbon dioxide concentration and global average temperature seems to be well supported not only by numerical simulations, but also by measurements in ice cores (e.g., Wilson et al. 2000).

## Human Influence on the Climate

---

Not only the emission of greenhouse gases like carbon dioxide, emitted when burning fossils fuels, but various human activities impact and have always impacted on the climate: Building development, slash and burn, farming, the regulation of inland waters, etc., change the earth's surface and thus the amount of radiation backscattered from the earth into the universe as well as ground-level atmospheric currents (e.g., Mackenzie et al. 2001, pp. 51–82; Wilson et al. 2000, 240ff.). This in turn impinges on the atmospheric mean temperature on local and, in parts, on a global scale. The settling of man some thousand years ago, for example, and the corresponding crossover from nomadism to farming was accompanied by vast forest clearing and thus had significant and sustainable impact on the climate.

Already in as early as 1896, S.A. Arrhenius predicted a climatic change due to anthropogenic emissions of carbon dioxide in the wake of the industrial revolution. Today, we know not only that carbon dioxide is a greenhouse gas (i.e., it absorbs and emits radiation within the thermal range), but also that its atmospheric concentration increased from 280 ppm (parts per million) before the industrial revolution to 379 ppm in 2005. What we do not fully understand, however, is as to how the increase in atmospheric greenhouse gas alters the global mean temperature. Due to feedbacks between various components of the climate system, which comprises not only the atmosphere, but also bio-, hydro-, litho-, and cryosphere, it is not isolated cause-and-effect chains that determine the state of the climate system. An initial warming of the atmosphere caused by an increase in greenhouse gas concentration may be significantly enhanced or reduced. Higher mean temperature enhances, for example, the growth of oceanic phytoplankton (cp. Mackenzie et al. 2001, pp. 51–82; Wilson et al. 2000, 240ff.). On dying, this phytoplankton produces cloud condensation nuclei. More phytoplankton thus may increase the backscattering ratio of the sky cover and hence counteract the initial temperature rise (e.g., Idso 2001, p. 325). At the same time, increasing the atmospheric temperature reduces the level of the permafrost soils in the tundras of Siberia and Canada; huge amounts of the greenhouse gases carbon dioxide and methane that are stored in these permafrost soils are released and thus reinforce the warming of the atmosphere.

The state of the climate system results from a complex interplay between various factors. Due to feedbacks, the future course of the climate system cannot simply be determined from an extrapolation of its past or present state. Climate models, aiming to represent the major causal mechanisms in the climate system and investigated numerically, are the only way today to gain insight into the future climate. Not all feedbacks are known or understood in every detail; the resolution of some feedbacks requires too high spatial and temporal resolution to be achieved with today's computational power. Climate predictions, like those reported in the IPCC reports are commonly based on so-called general circulation models (GCM). Here, only atmosphere and hydrosphere are dynamically simulated, coupled via material and energy exchange; all other spheres of the climate system – bio-, litho-, and cryosphere – are only incorporated as static boundary conditions (cp. Betz 2009a, b). Hence major feedbacks in the climate system are not fully resolved in the models, for example, the interchange of carbon dioxide between plants and atmosphere. But also purely atmospheric processes may not be adequately represented: Following the IPCC reports, uncertainty in present climate predictions is mainly due to a lack of understanding of the radiative properties of clouds.

The sketched complexity of the climate system with its numerous components that are linked to each other via feedbacks and the intricate nature of the processes induce that not all causal mechanisms are captured by climate models. This renders their predictions uncertain. This type of uncertainty is referred to as *model conceptualization uncertainty* (Hillerbrand 2010). Note that this terminology does not distinguish between sources of uncertainty and the uncertainty itself; however, this equivocation does not seem troubling. Next to the model conceptualization uncertainty, there is yet another source of uncertainty, referred to as *parameter uncertainty* here. Climate models require input concerning, for example, the future level of greenhouse gas or aerosol concentrations; the numerical value of these quantities hinges on factors like the growth of world population, economic growth, and the course of future energy or social policy. The term "parameter uncertainty" is broadly understood here, encompassing what, for example, Refsgaard et al. (2006) refer to as uncertainty due to model input and model parameters (more narrowly understood). Apart from the twofold distinction and the threefold distinction by Refsgaard et al. (2006), various authors distinguish also uncertainties arising due to model context, model assumptions, expert judgment, or indicator choice (cp. van der Sluijs 1997; van der Sluijs et al. 2003; Walker et al. 2003). These and other more detailed distinctions prove very useful for practice; however, from the epistemic point of view pursued in this chapter, there is no need to distinguish model parameters and model input.

So-called energy scenarios assess, amongst others, rates of future anthropogenic release of greenhouse gases and aerosols and thus provide the input for climate models. The relation between the release of gases and political and economic developments is rather intricate. The second largest anthropogenic source of atmospheric carbon dioxide, for example, is land use – an area very sensitive to political and economic decisions (e.g., Houghton 1995). Also of great importance is the efficiency of future energy conversion systems or the energy intensity of industries – factors determined by future technological developments which are hard to predict. The input parameters provided by the energy scenarios are, and remain, highly uncertain. This uncertainty translates to the uncertainty of the climate models that take these parameters as input. The IPCC (and others) reacts to this uncertainty and invokes the term *climate projections*, instead of *predictions* in order to highlight the dependency of the output on the considered energy scenario.

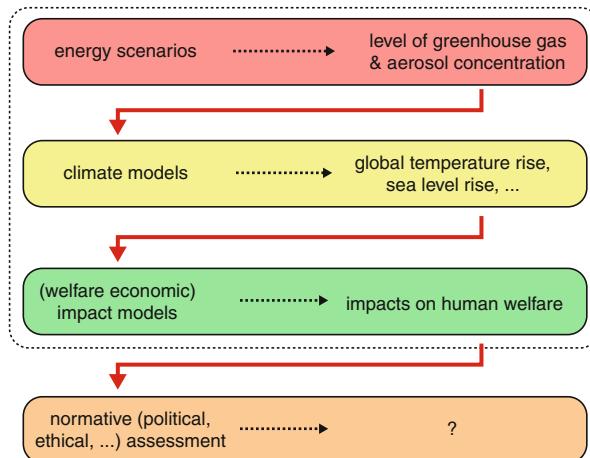

## Impacts of Climate Conditions on Humans

---

Model conceptualization and parameter uncertainty render it impossible to predict with certainty the exact impact anthropogenic actions have on the future climate. Likewise, the precise effect climatic changes exert on humans can never be predicted with certainty. That these influences may be very severe, however, does not stand to reason. For example, the European revolutions of 1789 and 1848 – though a result of the longstanding social, political, and economic disparities – were initiated after years of bad weather, bad crops, and high corn prices. Not only local, but also global weather phenomena had known impact on societies. In the tenth century, for example, worldwide drought may have wiped out the Tang Dynasty in China and that of the Mayan civilization in Mexico (Yancheva et al. 2007). Only minute changes in average climate conditions may significantly impact human well-being. A drop of average annual global temperature by, say, only 1°C may shorten the vegetation period near the polar circle, that is, in Canada, Finland and Iceland, by 3–4 weeks. Note in particular that, despite the large variations in the atmospheric temperature throughout Earth's history, the prognosticated temperature rise is much faster than all changes currently known within the last 10,000 years. The presently predicted change in global mean temperature leads in most assessments to overall negative consequences, which are most severe in those countries that are already the worst off today.

The impact, which changes in mean temperature have on humans, hinges on many factors, ranging from the way of farming to the height of landmass above sea level and people's capability to adapt. Major global warming impacts are expected via rising sea level, or increased frequency and intensity of extreme weather events such as floods, extreme droughts, heavy storms, or rainfalls. The expected changes in these factors are commonly provided by climate models. This information then serves as input to so-called impact models that estimate the influence of global warming and its geological consequences on human well-being. Hereby, well-being is understood very broadly, synonymous with welfare or a good life; a more detailed understanding is not required for the purpose of this chapter. Most often, impact models are welfare economic models estimating the impact of global warming, related changes in weather, etc., on a wide range of market and nonmarket sectors (e.g., Tol 2002; Nordhaus and Boyer 2000; Solomon et al. 2007; Stern 2007; Nordhaus 2008). Note that, unless one assigns an intrinsic value to the climate system (or some of its components), the practical debate on how to react to the threats of global warming must be based on the predictions of these impacts models: Within an anthropo- or pathocentric approach, a mere rise in the global atmospheric mean temperature is not per se morally wrong or even morally relevant; climate change only becomes a moral problem because of its impact on the well-being of human (or other sentient) beings (cp. Hillerbrand 2009, 2010; Hillerbrand and Ghil 2008). It is important to note that also non-consequentialists may agree with this claim. The linkage of climate and impact models yields an uncertainty cascade as depicted in  Fig. 13.1.

The information provided by the energy scenarios supplies the input for the climate models which in turn serves as input for the impact models. Here the uncertainties associated with the modeling on all three levels add up. It is the output of this impact assessment level that provides the input for the practical evaluation of how to react to climate change. Hence even if we had perfect understanding of the climate system, we may not know the effects this change of mean

**Fig. 13.1**

**Estimating the impacts of anthropogenic emissions of greenhouse gases on the living conditions of future generations.** The *straight arrows* (broken arrow, black) correspond to “yields the output,” while *long oblique (heavy arrow, red)* arrows correspond to “is input for”. The *dashed rectangle* indicates the combination of scientific prognoses that, as a whole, serve as an input for a normative (political or moral) evaluation (c.p. Hillerbrand and Ghil 2008)

temperature, say, has on the well-being of future generations which we need to know for a moral or political assessment based on an anthropocentric approach.

Model conceptualization uncertainty is unavoidable high for impact models as they model socioeconomic processes on large temporal and spacial scales (cp. Stern 2007). This welfare-economic modeling is exacerbated as major global warming damage is expected in nonmarket sectors; the models, however, commonly monetarize all losses. For a notable exception, see Lumer (2002). This leaves many losses unconsidered or only partly considered as money has properties that nonmonetary losses do not have or have only very rudimentarily: Money may be lent and exchanged, bear interest, etc., monetary losses may be (partially) compensated by investments, . . . (Lumer 2002). Not so the loss of habitat, friends, or relatives in, for example, extreme weather events. Note that the classification depicted in Fig. 13.1 is ideal typical nature. Often impact and climate models mix (e.g., Nordhaus 2008). Moreover, in impact models, epistemic and moral values mix which further adds to the model conceptualization uncertainty. Such a (partial) mixing of impact modeling and normative assessment cannot be avoided completely: Normative assessment is needed for determining which aspects of human life are worth or necessary to consider. More problematic is the fact that modeling assumptions like the discounting rate for nonmonetary losses have to be discussed (also) on moral grounds (cp. Stern 2007). Merging of a normative and a descriptive assessment, though impossible to fully avoid, however blurs many (normative) assumptions and may render the evaluation rather opaque.

## A Short Plea for an Anthropocentric Approach

---

Though this contribution focuses on epistemic aspects, I want to dwell a little more on the presupposition of an anthropocentric ethical framework that values nature or its parts only as far as they provide some value for human (present or future) well-being. This is in sharp contrast with many popular scientific publications that seem to presuppose a clear moral obligation to preserve the climate system or (nonhuman) parts of it as such. If there is a moral obligation to preserve the climate in its present state, where does it stem from? In approaching climate-change issues from an anthropocentric moral point of view, it is only the output on the level of impact modeling and the associated uncertainties that are of relevance: There are no *a priori* obligations toward nature or its parts, and any action has to be evaluated as to how it promotes overall human welfare. Various environmentalists have criticized valuing the environment solely as a basic resource for humanity, as discussed in the present paper. Movements like “deep ecology” (Devall and Sessions 1985) or “land ethics” (Thoreau 2004) recently attracted considerable attention in environmental discussions. Their positions are genuinely non-anthropocentric: either nature as a whole or parts of (nonhuman) nature are assigned some moral value. Hence the whole ecosystems or even the climate system have to be valued for their own sake, that is, not merely due to their value for a sentient being. Note that though this avenue is not pursued in this contribution, the welfare-based approach can be generalized to other sentient beings in a straightforward manner.

Most of the proposed non-anthropocentric approaches in the literature have difficulties in dealing with moral dilemma (Krebs 1999). This is not a crucial shortcoming of such approaches, though, as a hierarchical value structure could solve this problem. A key shortcoming of non-anthropocentric approaches, however, is that they contradict Occam’s razor: a larger number of premises are needed in arguing for physiocentrism or holism, and these added premises cannot be justified any further (cp. UNFCCC 1992). Keeping the number of such metaphysical assumptions as low as possible is, however, particularly important within environmental ethics. In order to become effective, norms that, for example, rule the emissions of greenhouse gases have to be implemented on a global scale and by future generations as well. The metaphysical background shared by different cultures – or, within one culture, over several generations – seems rather limited. The assumptions of a welfare-based approach are the most likely to be shared by people from different cultural backgrounds. As impact models consider other sentient beings, if at all, only as of instrumental value, in the following, well-being refers to human well-being only.

## Predicting Complex Systems

---

Feedbacks between various subcomponents, which manifest in nonlinear evolution equations of the modeled quantities, are characteristic for the climate and socioeconomic systems. In the language of the mathematical sciences, such systems are referred to as *complex systems*. To be more precise, a complex system is one with more than three interacting degrees of freedom. Systems that are complex in this way may exhibit chaotic behavior and thus, though deterministic in principle, cannot be predicted in every detail: Very similar causes may not lead to similar effects.

Though both the climate system and socioeconomic systems are complex in the mathematical sense, this notion is not adopted here. This chapter is on epistemic issues, therefore Shackel's epistemic definition of a complex system is deployed – a nontechnical definition given purely in epistemic terms (June 2008, private communication). Here, a complex system is defined as a non-simple one. For simple systems, knowing one or reasonably many features gives reliable information of another feature (or some other features), such as the one in which you are interested. For complex systems, this relation does not hold. A system therefore may be complex either because (1) only knowing many features gives reliable knowledge about the feature of interest or (2) the relation between the feature of interest and others is unclear. Note that the two ways in which systems are complex distinguished above comprise Kuhlmann's (2010) distinction between compositionally and dynamically complex systems, respectively. However, the terminology above is broader than Kuhlmann's as he follows the mathematical modeling.

As regards information about future global warming and its impacts, the climate and socioeconomic systems are complex in the epistemic sense: Only knowledge of many features gives insight into the features of interest, and the interdependence of various features is unclear. Note that only one reason for this is that the system is complex in the mathematical sense. The two ways in which a system may be complex directly link to the (sources of) uncertainties that were introduced in section [Climate Science or Climate Fiction?](#), parameter and conceptualization uncertainty. First, not all of the numerous parameters in the models may be known with the required precision. Second, as only a complicated interplay between its numerous features determines the state of the climate system of interest here, not all relevant causal mechanisms may be adequately incorporated into the model. This may be due to a lack of knowledge or due to contingent limitations like finite computational power.

Complexity and simplicity are, in the definition adopted here, purely epistemic features. They not only depend on the modeled system, but also on which feature of the system one is actually interested in, the desired accuracy of the feature of interest, the available background knowledge, etc. Unlike the mathematical one, the epistemic notion of a complex system is neutral with respect to whether a mathematical or less rigorous description of the system is pursued. It also encompasses a less strict usage of the term that follows its demotic meaning (e.g., Parker 2006). The adopted definition of a complex system is vague, both as regards to what counts as *reasonably many* and *reliable*; there are borderline cases. It is an epistemic notion and systems which are complex as regards one feature, may be simple as regards another. Hence the very same (ontological) system may be (epistemically) complex or simple depending on the feature of interest or the required reliability. Strictly speaking, the model may represent some (real) target system as complex or simple; however, like for the mathematical use of the term, complexity is applied to systems, keeping in mind the problems associated with models and representation (e.g., Giere 2004). Note that likewise, the classification of parameter and conceptualization uncertainty is always relative to some model focusing on certain features of interest.

Consider the example of the orbital motion of the earth around the sun. This is a simple system as regards its approximate period; it is complex when one is interested in more precise information, the deviation from the ellipsoidal motion, etc. Likewise, the climate system is simple with respect to some features, and complex with respect to others. It is simple as regards the question as to whether human activity impacts the climate, but also simple with respect to the question which countries will be most harmed by climate change. Determining that it

is the less and the least developed countries that, on average, will suffer most from climate change does not invoke running nonlinear models; a close inspection of, for example, the sensitive behavior of crop yield on aridity and the limited means of adapting to such changes suffices. Following the epistemic notion of complex systems introduced above, answering the very question as to why climate change is of moral significance thus does not invoke predicting complex systems. The question, however, as to how exactly we have to react (if at all) to the global warming threat, is a question that relies heavily on more detailed information of atmospheric temperature, say, and thus on information obtained from the analysis of a complex system.

## Knowing-How in Scientific Modeling

---

### Epistemic Uncertainties

---

By specifying a range for the uncertain parameters and assigning corresponding likelihoods, the uncertainty in the modeled quantity may be expressed by the width of the corresponding probability distribution and thus by a numerical figure. This procedure is known within nonlinear science as sensitivity analysis. If the range of the height of future emissions, say, is varied within a certain interval, one may specify a parameter range for the mean atmospheric temperature. When climatologists refer to “reducing uncertainties,” they aim at curtailing the width of the probability distribution. Model conceptualization uncertainty is often treated in a similar fashion to parameter uncertainty: By varying not only the input parameters, but at the same time also varying the underlying model, the IPCC, for example, is able to specify an interval for, say, the expected range of temperature increase (e.g., IPCC 2007, p. 12). However, as shown in the following, model conceptualization uncertainty may not satisfactorily be treated in the same way as parameter uncertainty is and thus uncertainties cannot be fully quantified. There have been several attempts recently to quantify conceptualization uncertainties (e.g., Moss and Schneider 2000), but these all remain rather fragmentary.

Scientific predictions are derived from some model representing the target system of interest. Particularly in climatology, these models are implemented numerically which may cause additional complications which are, however, not considered in this chapter. Uncertainties capture the reliability of model predictions and are thus related to the reliability of the models, that is, their structure and the numerical values of their parameters. In the following, it will be shown that as regards complex systems, the reliability scientists may assign to their models is only apprehended within the community of scientists working in the field under consideration. When communicating to outsiders, essential information gets lost; hence capturing the reliability in quantitative figures is highly misleading.

The argument builds on two premises that are argued in more detail below: (1) Just like any model, climate or impact models cannot be derived from theories in a straightforward way. (2) There is no exhaustive propositional account of this derivation. For complex systems, deriving a model involves centrally what Ryle referred to as *knowing-how*, an ability or disposition, and not merely *knowledge that*, a relation between some thinker and a (true) proposition. Before defending the two premises, let me briefly dilate on the usage of the term model and theory in this contribution. Theories here are not only understood as well-developed theoretical bodies like Newtonian mechanics, but also as theoretical background

assumptions that form common beliefs within a field, for example, the efficient market hypotheses. In the semantic interpretation of theories, the relation between model and theory is well defined; its notion of model, however, is a great distance away from the usage of the term *model* within climatology or economy. Deriving a model from a theory invokes more than merely setting numerical values for some free parameters. This chapter thus follows the more recent accounts of models used by Cartwright, Giere, Morrison, and others. One unifying theme in the different terminology of these authors is that while theories are related with general propositions (often in the form of laws of nature), models are less general, but closer to the phenomena (or data). For the purpose of this paper, this vague intuitive understanding of models and theories suffices.

Let us first consider again our simple model of the earth's orbital motion around the sun. This model is derived from Newton's theory of gravitation and Newton's second law. Deriving the model invokes neglecting the internal structure of the two bodies, neglecting other planets or comets, and approximating the motion as a two-body problem with only point masses. As argued by Bailer-Jones (2003), the adequacy of the assumptions made in deriving the model of the earth's motion around the sun is not captured in their propositional content alone. The assumptions are simply wrong; transcribing the "message" of the model solely into propositions would yield to a false model. This, however, does not do justice to scientific practice. Nonetheless, the statement made above reaches further than the observation that the content of a model cannot be equated with its propositions; rather it was claimed that in deriving models it is less knowledge, but abilities that are involved. As stated in section [● Predicting Complex Systems](#) the system of the earth's movement around the sun as considered here is not complex. The message of the model may not be translatable into propositions, but the derivation seems not to involve much skill either. This is different for complex systems.

Note that in the past it may not have been the case that the earth–sun motion is a simple system in the epistemic sense adopted here. The perturbation theory showing the adequacy of the assumptions made, that is, showing that the two-body problem gives a first approximation to the real motion of earth and sun and all other factors may be treated in a perturbation expansion, was only shown more recently. The classification of a system as complex or simple therefore depends crucially on our background knowledge and thus, as indicated in section [● Climate Science or Climate Fiction?](#), may change over time.

As outlined in section [● Climate Science or Climate Fiction?](#), important feedbacks are neglected between various components of the climate system when deriving climate models from more fundamental theories like atmospheric chemistry or hydrodynamics. Our present understanding of the climate system does not allow us to "prove" the correctness or adequacy of all assumptions. Making the right assumptions is, in parts, an ability, a skill that has to be trained rather than a knowledge of facts (broadly understood) that can be learned from text books. Note that this feature of climate modeling is associated with the complexity (in Shackel's sense) of the modeled system and thus holds also for models of other complex systems.

The argument that not only knowledge, but also skill is involved in deriving models representing complex target systems seems easy to buy; however, it has wide-ranging consequences. The assumptions involved in deriving a model may not be correct, but as they are propositions, one may assess the deviations of what is currently perceived as true. For example, one may assess the wrongness of the assumption that both Earth and Sun are point masses

considering the distance between the two bodies. When abilities are centrally involved in deriving a model and these abilities cannot be reduced to propositions, this seems out of reach. Not only can the abilities be interpreted as part of an intricate web of background knowledge; rather they involve knowledge as to how to pursue the specific experimental paradigm, the accepted practice, and the general research experience within the field. These factors cannot be defined explicitly, but must be learned by working in the field. In this respect, a scientific community can be seen as an instance of a Wittgensteinian language community (Wittgenstein 2001, p. 10):

- ▶ [T]he term “language game” is meant to bring into prominence the fact that the speaking of a language is part of an activity [...].

As an example of a language game, Wittgenstein himself refers to “presenting the results of an experiment in tables and diagrams” (Wittgenstein 2001, p. 10). Likewise, assessing the reliability of climate models is, at least to some extent, something that is learnt by the practice of carrying out and verifying such predictions.

As there are borderline cases which are neither clearly complex nor simple, it may remain unclear whether the reliability of some models may be quantified. Nonetheless, there are clear cases for which they can or cannot be quantified; regarding the impacts of the greenhouse effect on humans, the climate system is an example of a complex system and thus the reliability of the models cannot in full be communicated outside the scientific community.

## Reducing Uncertainty

---

As argued above, due to model conceptualization uncertainty, the reliability of complex models cannot entirely be communicated to outside the scientific community. Estimating as to how well a model represents the relevant causal mechanisms if these are still unknown has not much prospect of success. Quantitative figures aiming to capture this reliability are misleading and miss central points. Hence a model pluralistic approach as pursued by the IPCC is also unable to capture all uncertainties because it cannot reflect different reliability of different models.

However, there are other ways of assessing the reliability and thus the uncertainty of forecasts that do not take the circuit via the model's reliability. One may, for example, fall back on a Bayesian account: Via subjective probabilities, the reliability of scientific outcomes may be quantified directly. But it is first impossible to choose a meaningful prior probability due to the large timescales on which the climate system reacts to changes. Second, there is insufficient data for updating these probabilities. The Bayesian method thus fails for climate change. Note that when scientists refer to Bayesian approaches, they quite often estimate a priori probabilities via frequencies and thus by conditional probabilities (conditioned on the models used to determine the respective frequency). These types of Bayesian approaches are, however, model dependent. For further criticisms of the Bayesian approaches, see, for example, Sober (2005).

Another way as to how to assign subjective probabilities may follow Laplace's principle of insufficient reason: All possible effects are taken as equally probable. This approach was put forward, for example, by Harsanyi (1975, 1982). But there is no logical superiority of Harsanyi's assumption of equiprobability over Rawls' focus on the worst outcome as per se there is no logical need to assign subjective probabilities to uncertain decision outcomes based on

Harsanyi's equiprobability assumption or other. We do have information on the likelihood of certain effects of climate change – albeit these are hard to communicate outside one's own narrow scientific community.

Though this chapter is on epistemic issues and thus I do not want to dwell on the interpretation of probabilities in detail here, note that a weak objective interpretation of probability is adopted here: Our most successful method for tackling uncertainty has been to regiment situations of uncertainty by the use of probabilistic propositions. But unless one is a certain kind of subjectivist about probability, one wishes that one's probabilistic beliefs be constrained by objective facts so that they approximate objective variables. The term probability in its everyday use captures something real in the sense that the probability that it rains tomorrow is somehow linked to the real world, in this case the likelihood that it will rain tomorrow. Note that even a modest subjective interpretation of probabilities, which takes probabilities to be belief functions that obey certain restraints, may be consistent with this weak objective interpretation.

As argued above and elsewhere (cp. Frame et al. 2007), there is no reliable basis for assigning probabilities in the above sense to the empirical input needed for a practical assessment. However, there is good practice of how to deal with uncertainties. When the conditions of Bayesianism are not met as in the case of climate change, dealing with uncertainties always invokes the reliability of the model's representation of the considered target system. There is no distinct science as to how to deal with uncertainty; good practice of dealing with uncertainty is always sensitive to the context. It must be learnt by doing and unlike propositional knowledge, it cannot be simply acquired, but the competence must be trained to reach a higher grade. It is beyond the scope of this chapter to address these rather technical issues; the reader is referred to Moss and Schneider (2000), van der Sluijs et al. (2005), and references therein.

## Limits of Common Decision Approaches When Applied to Climate Change

### Interdependencies Between Moral and Epistemic Issues

Summarizing the epistemic part of this chapter a terminology of technology assessment, how to react to global warming is a genuine decision under uncertainty as we lack probability estimates on (at least some of) the possible outcomes. This is distinguished from both decisions under risk in which we do have some reliable probability estimates and from decisions under ignorance where we lack even information on the nature of the possible outcomes. It was argued that presupposing a weak realistic understanding of probability, it is not possible to reduce the global warming issue to a risk problem. This was linked to the fact that predicting the exact impacts of greenhouse gas emissions involves modeling of complex systems. In deriving such models, next to propositional knowledge, certain abilities are of importance. The latter can only be learned by doing, by working in the field. Assessing the “reliability” of certain steps in deriving complex models cannot entirely be communicated to outside the scientific community. A distinction between conceptualization and parameter uncertainty was introduced that may provide the ground for practical decision making to incorporate the uncertainties: While the former is related to the non-propositional content of

a model and thus may not be satisfactorily reflected in a quantitative figure, for the latter quantitative estimates may be given.

All these uncertainties of climate predictions are discussed intensively within the scientific community – not only among climate skeptics. However, uncertainties are often kept under wrap when scientific findings are communicated to the public. Just compare, for example, the full IPCC report and its summary for policy makers (Solomon et al. 2007). It is not the scientists who are to blame here. Rather the practical debate seems incapable of adequately reflecting uncertainties in modeling predictions. If these uncertainties were communicated, sound scientific research runs the risk of being discredited as unscientific; the public seems to prefer black and white instead of the scientists' shades of grey: Often predictions are taken either as correct and unquestionably reliable or simply as wrong. However, most scientific models are neither true, in the sense that they exactly predict future events, nor simply wrong and useless (cp. Giere 2004). The preceding sections aimed to show that uncertainties that cannot be reduced to quantitative figures are necessarily involved in climate modeling. It is argued in this section that in order to incorporate aspects of inter- and intragenerational justice, practical decision making has to carefully consider the shades of grey that affect the reliability of climate models in practical decision making. Thereby, the focus of this section is not, like in Gardiner (2006a), Hanson and Johannesson (1997), Lumer (2002), and others, on the question of how much, if any, reduction of greenhouse gases is ethically legitimate, but rather on what kind of decision-making criteria should guide our reasoning about this very question. Thereby, a very simplified and rather unrealistic setting is considered, namely, that a well-defined decision maker (or a group of well-defined decision makers) dealing with climate change issues exists.

Why, after all, do we have to worry about epistemic problems when reasoning about issues of inter- and intragenerational justice? You may wonder why we cannot – even if unquantified uncertainties are a problem in principle and cannot be evaded even with future research – just simply wait until climate models and global and long-term economic predictions have overcome their teething troubles. For sure, climatology as well as impact modeling are huge scientific research fields that have advanced a great deal over the last years – and most likely will do so in the near future. However, practical decision making facing the threats of climate change cannot wait for better prognoses. The climate system only reacts very slowly to changes in its parameters, such as changes in carbon dioxide contraction. Hence the atmospheric concentration of persistent greenhouse gases like carbon dioxide can only be stabilized by reducing emissions (Solomon et al. 2007). The large inertia of the climate system necessitates timely countermeasures. Once particular effects occur, it may well be too late for a systematic response. Note again that this chapter deals with a sound discourse about how to react to climate change, not with the issue of correct reduction, mitigation or adaption strategies. The practical discourse may or may not come to the conclusion that instead of mitigating now, we should wait and adapt later. However, this decision cannot wait for better and less uncertain predictions: it has to be taken now.

A need to address epistemic uncertainties in practical debates can be deduced from three (fairly weak) assumptions: First, practical decision making has to be based on the best (empirical) knowledge available. Second, practical problems related to environmental issues can be formulated as scientific problems. Third, science gives us the most reliable understanding of the natural world. There seems to be no need to justify these suppositions, as all three

seem to be both weak and rather intuitive. From these epistemic and practical assumptions, it follows that we have to consider epistemic uncertainties in practical decision making: The best available information that we have today is our scientific forecasts *plus* information on their reliability. Though the latter may not be expressed or even be able to be expressed in numeric terms, information on the quality of various climate predictions is available. If, for example, quantified uncertainties that arise from insufficient knowledge on the input parameters were the only uncertainties we had to deal with, common probabilistic decision criteria like utility maximization could be applied in a straightforward way. As argued above, unquantified uncertainties, however, that arise from insufficient understanding of the model conceptualization pose a severe problem. Quantitative figures may be misleading, but they can be communicated easily to people outside one's own discipline. Even if scientists in a given field tend to assign "higher-order beliefs" that express their confidence in an underlying theory, the methodology used, the researcher or the group who carried out the work, etc., these higher-order beliefs are only very rarely quantifiable themselves in terms of, say, subjective probabilities.

## Expected Utility Maximization and the Precautionary Principle

---

The lack of probability estimates on the level of impact models renders a maximized utility approach impossible. Maximizing the expected utility is an adaption of the utilitarian maxim of the *greatest good for the greatest number* to decisions under uncertainty: It is not the overall utility (or "good") that is to be maximized, but the expected utility, that is, the sum of different utilities weighted by their probability of occurrence. The assignment of utilities to possible climate-change effects raises many difficult problems, but I do not want to dwell on them here. These problems are not specific to decision making under uncertainty or even related to problems of welfare-based ethics. In particular, the problems about determining the utility of an event, or deciding what utility actually amounts to, parallel to some extent problems of the precautionary approach discussed below when deciding as to how to actually determine the worst-case scenario. Note that nonetheless the problem of the precautionary approach is somehow easier, as it needs only an ordinal concept of well-being, while an expected utility approach presupposes a cardinal welfare measure. Only when the welfare function fulfills certain restraints, ordinal measures may be mapped onto cardinal ones (von Neumann and Morgenstern 1947).

As this paper's focus is on uncertainties (of expected utility and of the worst-case scenario), the problems associated with measuring human welfare and how to equate it with utilities are not discussed here. For the purposes of this paper, it suffices to assume that the impact on human welfare estimated in economic models on level 3 in  Fig. 13.1 can be associated with (intersubjective) utilities in a meaningful way. How to actually assign meaningful utilities has been discussed extensively in the literature. It raises rampant problems particularly for intergenerational ethics; see, for example, Lumer (2002) for a discussion as to how assign utilities in the context of climate change.

When outcomes are highly uncertain, it is often suggested that we fall back on the precautionary principle. This principle was first made popular within environmental ethics by H. Jonas in his *imperative of responsibility* in the late 1970s. As the phrase *precautionary*

*principle* is fraught with ambiguity, let us briefly explicate the term and its use within ethical, juridical, and political contexts. The Rio Declaration on Environment and Development, for example, formulates the precautionary principle (rather vaguely) as follows (cp. UNFCCC 1992):

- ▶ Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.

In this weak formulation, the precautionary principle provides no distinct directive for practical decision making. Instead it constitutes a meta-criterion stating that uncertainties in scientific forecasts have to be taken seriously. Strong formulations of the precautionary principle constitute a genuine decision criterion. The following is an example of the *precautionary principle* in a strong formulation (The Wingspread Statement 1998):

- ▶ Where an activity raises threats of harm to the environment or human health, precautionary measures *should be taken* if some cause and effect relationships are not fully established scientifically [my italics].

Note that apart from the two versions discussed in this paper, various other formulations of the precautionary principle exist (cp. Sandin et al. 2002). Proponents of the precautionary principle like C. Raffensberger and J. Tickner suggest the following core idea behind all formulations of the *precautionary principle* (Raffensberger and Tickner 1999, p. 1):

- ▶ In its simplest formulation, the precautionary principle has a dual trigger: If there is a potential for harm from an activity and if there is uncertainty about the magnitude of impacts or causality, then anticipatory action should be taken to avoid harm.

In this chapter, the precautionary principle is understood as a genuine decision-making criterion that, loosely following Gardiner (2006b), interprets the strong formulation as a variant of the minimax rule in decision theory: Minimize the maximally bad outcome. Given certain assumptions about how to quantify harm and well-being, this may be reformulated as a maximin rule and reads (for climate change): Maximize well-being in those scenarios in which the involved humans are worst off (minimally benefited), regardless of how uncertain these scenarios are.

At first glance, a precautionary approach seems well suited to avoiding an ethically unjustifiable discounting of future damage caused by our present greenhouse gas emissions: We cannot exclude with certainty the possibility that the release of greenhouse gases has the potential to cause severe harm to future generations; hence emissions of greenhouse gases ought to be abandoned. A precautionary approach seems adequate when the stakes are high – the living conditions of all future humans may be endangered by severe climatic changes. Though there is considerable disagreement within the economic community on the costs of reducing greenhouse gases (cp. the response of Weitzman (2009) and Nordhaus (2008) to Stern (2007)) there are some economic assessments suggesting that reducing anthropogenic greenhouse gas emissions is not very costly. Following Stern (2007), a commitment of only 1% of global gross domestic product (GDP) is needed to avoid the major hazards that may arise from climate change. At first blush, this appears very affordable; but if we base our calculation on current GDP value, it amounts to an investment of US\$450 billion per year. For comparison:

the current estimates of the money needed to provide 80% of rural populations in Africa with access to water and sanitation by 2015 amounts to US\$1.3 billion per annum (cp. Martinez Austria and van Hofwegen 2006). Clearly, societies (or other organizations) are able to part with only a certain amount of money or other resources for altruistic endeavors, and the mitigation of major changes in future climate is only one such endeavor. Investing in the mitigation of climate-change effects means forgoing other investments which we have a moral obligation to make. One central requirement of the practical debate is a decision about which investment has priority over others. Presupposing an answer to this question from the very beginning of the debate – for example, by assuming that climate change is currently humanity's most pressing problem – preempts the moral debate, cp. [Fig. 13.1](#). Applying the precautionary principle to global warming as a singular problem thus does not allow us to adequately deal with the valid claims of groups that are adversely affected by natural or societal “disasters” other than climate change. This approach is clearly incapable of adequately incorporating considerations of inter- or intragenerational justice as it does not address the question as to why suffering arising from climate change has priority over suffering caused by other sources.

The critique raised here, however, is not a charge against the precautionary principle itself; it only disqualifies common applications of the precautionary principle. Suppose that one can show that – given certain ethical standards, which are not under debate here – the worst-case scenario regarding the effects of climate change is that these effects are worse than any other type of human suffering, present and future. This means that if our (possibly very unrealistic) assumptions are indeed correct, then following the precautionary principle, we have to mitigate climate change at any cost. We are trading the certain suffering of people living presently against a possibly more severe, but yet uncertain suffering of people living in the future. If the worst-case scenario is as uncertain as currently estimated for global warming, and is balanced against certain other scenarios whose bad effects are certain (like the actual suffering of many people in third world countries, for example), it is unreasonable to completely mask all other scenarios and focus on mitigation of the uncertain, but worst outcome. Note that this argumentation needs refinement when the worst-case outcome is a singular event like the end of human life on Earth (cp. Ord et al. 2009). Current empirical evidence seems to exclude the possibility that climate change is of this severity.

As noted above, the available information on the effects of anthropogenic global warming includes information about the “likelihood” of the worst-case and other scenarios. This information is not quantified and may not be fully quantifiable at all. However, we do have information that suggests that, while present suffering is certain, future suffering caused by global warming is uncertain. Good arguments for neglecting this information should be given. But to the best of the author's knowledge, no such arguments have been presented in the literature. Problems with a precautionary approach as an action-guiding principle have been discussed extensively in the literature (cp. Peterson 2006; Clarke 2005, and references therein). This paper only addresses one central issue of importance in any intergenerational ethics, namely, how to balance obligations toward future generation against obligations toward people living presently. Even if one argues for the ethical legitimacy of trade-offs between losses and gains experienced by different people, one cannot deny that presently living people have a right to safe water and sufficient nutrition. One needs to argue at least that uncertain future losses are worse than the current suffering. But a mere precautionary

approach to global warming is incapable of simultaneously incorporating considerations of inter- and intragenerational justice.

## Summary and Further Research

---

Sections [Climate Science or Climate Fiction?](#), [Predicting Complex Systems](#), [Knowing-How in Scientific Modeling](#) focused on epistemic aspects of climate and impact models and brought forward the argument that not all uncertainties involved in modeling complex systems may be adequately captured by probabilities. Arguing that not all aspects of scientific uncertainties may be captured in numerical figures and that they may be misunderstood outside the scientific community is not to be mistaken as putting the case for a dictatorship of experts. Rather it puts pressure on the scientists to provide standards of good practice. If anything, this chapter aims to invoke not to trust any numerical figure only because its predictions and uncertainties are captured in quantitative terms – its prognoses may not be better or more scientific than qualitative ones. In addressing the uncertainty of climate predictions from an epistemic view, this paper wishes to provide a basis for incorporating all the scientific findings into the practical debate, that is, climate or impact model predictions plus the associated uncertainty including those that may not be quantified.

As argued in section [Limits of Common Decision Approaches When Applied to Climate Change](#), the precautionary principle, due to its sole focus on the worst-case scenario, is incapable of dealing with issues of inter- and intragenerational issues as they are relevant in the climate debate in an adequate way. Instead of focusing on the worst-case scenario, an expected utility approach considers all possible outcomes and the associated utilities, weighted by their occurrence probability, or, to put it in more technical terms, we are to maximize and take into account all possible scenarios. The extreme scenarios of runaway climate change or very little temperature change, for example, are thus taken into account, as is the scenario in which the temperature change exactly equals the estimated mean value. The latter scenario being the most probable is given the greatest weight. However, an expected utility approach is not applicable for climate change in a straightforward way as there are no reliable probability estimates at hand on the level of impact modeling. This is unfortunate as maximizing expected utility has one clear advantage over a precautionary approach: By incorporating an inter-temporal as well as an international perspective, maximizing expected utility is, by its very nature, able to trade-off the costs and benefits of different people living at different places and times.

The lack of (subjective) probabilities in the objective sense defined above does not imply, however, that one has to fall back on non-probabilistic decision criteria such as the precautionary approach. This chapter's proposition should not be misunderstood as a kind of reformulation of the precautionary principle in its weak form, that is, "Take uncertainties seriously and therefore address also the uncertain outcomes." Rather this contribution aims to argue that uncertain effects are not to be (mis)taken as certain ones, which seriously undermines the use of the precautionary principle.

In the literature, decision methods are suggested, which parallel expected utility maximization, to cope with the lack of reliable prior probabilities and information about how to update these priors on the basis of the conditional probability calculus (e.g., Shafer 1990).

An adequate decision procedure for global warming would assign meaningful utilities to various outcomes in a first step by political decision makers, moral philosophers, and others. As to the occurrence of unquantified uncertainties, however, the second step, the actual cost-benefit analysis (understood in a broad sense), should be conducted by experts on the empirical forecasts. Without expecting a detailed casuistic from the philosophical analysis, such a blueprint can only work when philosophical ethics does not shy away from context-variant information on the very decision. The 1970s debate on the “rationality” of expected utility maximization or maximin, whose main protagonists were Harsanyi and Rawls, shows that answering the question of whether the precautionary principle or expected utility maximization is adequate has to, willy-nilly, implement context-variant features of the decision situation. Note that this paper argues against the precautionary principle only when applied to global warming. The given arguments do not discredit this principle as a decision-making criterion in itself. Concerning an adequate decision-making approach to global warming, this chapter has, so far, turned a blind eye to factors that actually precede the debate on whether the precautionary approach or expected utility measures seem most adequate. So, concluding this paper, let me briefly touch on this problem: Before being able to actually talk about uncertain outcomes of the decision to reduce (or not reduce) greenhouse gases, we have to decide what this decision is actually all about – is it about the welfare of future humans?, do we need to discuss the pros and cons of alternative energy supplies that do not emit greenhouse gases as well?, etc. Any analysis of a specific decision must start with some delimitation of the decision itself. It is not always well established how to determine the “decision horizon” (Hansson 1996, p. 371): The scope of the decision, or even which problem the decision is supposed to solve might be unclear. The further in time the consequences of our decisions lie, the more difficult it is to determine the decision horizon.

Currently, the decision horizon is most often set by pragmatic considerations only, however there is more systematic work for philosophers to be done here. It seems that here – just like for the question as to what decision criteria can adequately deal with uncertainties – rule-based approaches are at their limits, both at the ethical as well the epistemic level. Investigating of how virtue ethics (cp. Luntley 2003) or virtue epistemology, particularly virtue responsibilism, may help to solve these problems seems thus a worthwhile endeavour. Virtue approaches by their very nature are capable of incorporating the vagueness and uncertainties of decision situations by fostering certain dianoetic, that is, epistemic virtues. An example is given by the Aristotelian phronesis that provides the moral agent with the mental capacity to adequately judge the unquantified uncertainties connected to the scientific predictions. Virtue epistemology may provide new insights into the field of risk research that supplement the debate on how moral virtues and moral emotions can help in an adequate response to risks and uncertainties such as those posed by global warming.

## Acknowledgments

---

I am particularly grateful to my colleagues Steve Clarke, Peter Taylor, Nick Shackel, and Martin Peterson for constructive input on the issues discussed in this chapter and comments on (earlier versions of) this manuscript. I thank Kai Hennes for help in finalizing the manuscript. Parts of this chapter were published in Hillerbrand (2010, 2009).

**Abstract:** The aims of this chapter are to present a brief history of ideas in the interdisciplinary study of volcanic and seismic risk, to discuss the current state of the subject, and to suggest pathways for further research. This is a very extensive topic – while much of the scientific literature tends to focus on hazard assessment (and, increasingly, risk assessment), the social sciences have tended to focus on vulnerability reduction and risk communication. There have been very few holistic epistemological studies of the broader context of risk. Yet the philosophical aspects of uncertainty are increasingly important for scientists in particular as they seek to assess and understand these risks, not least because of heated debates within both fields concerning the relative values of deterministic and probabilistic methods and the ways in which they deal with uncertainty. Social scientific and philosophical methods therefore have significant potential to inform this discussion, and are also increasingly important in assessing vulnerability and popular understanding of risks in hazardous areas. There has been a large volume of work done in recent years to examine seismic and volcanic risk perception and communication, much of which suggests that these risks are not high on the social agenda until an event happens. This calls for new approaches to population management, preparedness, and proactive roles for scientists and social scientists.

## Introduction: Lithospheric Risk

---

In recent years, population growth around the world has led to huge increases in the number of people at risk from geophysical hazards (taken in this chapter to refer to those associated with earthquakes and volcanoes – perhaps more accurately risks from within the lithosphere). It is estimated that over half a million people have died as a result of earthquakes in the last 10 years (Spence 2009), and that almost a billion are at risk from volcanic activity (Ewert and Newhall 2004). Globalization, raised life expectancy, and indeed technological development have all contributed to the increased risk: While the “risk society” (Beck 1992, 1999, 2009) has largely been associated with technological risk, the amplification of natural risks is an unfortunate side effect – and one that is often overlooked in the risk theory literature. Yet natural risks have been increased as a result of population growth – which can be linked to medical advancements and technological enhancements to the quality of life. There are also complications arising from technologies like aviation, demonstrated dramatically by the 2010 “ash crisis”: The eruption in Iceland was relatively small, but the vulnerability of aircraft significantly increased its impact (Donovan and Oppenheimer 2010).

Beck himself, in *World at Risk*, wrote that “even though human interventions may not be able to prevent earthquakes or volcanic eruptions, these can be predicted with reasonable accuracy” (p. 50): a widespread opinion among the general population in the West, but one that is not backed up by the state of the science. Indeed, some seismologists do not believe that it is possible to predict earthquakes (e.g., Geller 1997; Matthews 1997), and volcanologists cannot predict eruptions (Sparks 2003). Scientific understanding of volcanic and seismic processes is advancing rapidly, but the nature of the events is such that even with greater knowledge, the uncertainty about the natural system is very high. Monitoring events deep in the earth is extremely challenging and often logically impossible – scientific methods are largely, at present, dependent on measurements made in the upper crust.

The volcanic island of Montserrat in the West Indies awoke on July 18, 1995, to explosive activity from its long-silent volcano (Druitt and Kokelaar 2002). Over the following few

months and then years, Montserratians learned that science could not give them the answers that they needed – their capital city was evacuated for the third and final time in 1996, and now sits under several meters of pyroclastic debris. A key breakthrough in the communication of risk on Montserrat was simply that the science was very uncertain: Relationships between scientists, between scientists and the public, and between scientists and policymakers were particularly tense in the early years of the eruption in part as a result of high expectations of science (Pattullo 2000; Donovan 2010). The scientific community responded by developing new methods for risk assessment. The Montserratian community responded either by learning to live with the volcano, or by relocating. Both communities (and the many subgroups within them) have been changed by the events.

## Defining Hazard, Risk, and Uncertainty in Disaster Response

In natural hazards research, variations of the conceptual formula,  $\text{risk} = \text{hazard} \times \text{vulnerability}$  are frequently used to distinguish between the natural event and its impact on populations (e.g., Wisner et al. 2004; Wang 2009). This has frequently led to a decoupling of research cultures, with physical scientists working on hazard assessment and modeling, and social scientists working on vulnerability mapping, risk perception and communication studies, and resilience-building. Engineering studies in seismic hazard management have bridged this gap to some extent, seeking to develop mitigation measures of various kinds, such as earthquake-resistant housing. There is then a further division, between those who do the research and those to whom it might be of use – and this division may be characterized by widely differing perceptions of the importance of the topic, since low-probability, high-impact hazards rarely impact daily life unless the event occurs (Gaillard 2008). This is particularly true in developing countries, where the need to survive on a daily basis precludes longer-term planning. In this case, there is a very important role for NGOs and international organizations such as the UN, which specialize in disaster management. However, communication between these institutions and academic researchers is often poor.

Given the lack of predictive skill in geophysical hazard assessment, much work is focused on responses to events – reducing vulnerability and increasing resilience preemptively can prepare communities to maximize their capacity to survive geophysical hazards. The Hyogo Framework for Action (HFA), adopted in 2005, identified the following areas for concentration (shown graphically in Fig. 14.1):

Fig. 14.1  
Disaster response chain

- Ensure that disaster risk reduction is a national and a local priority with a strong institutional basis for implementation.
- Identify, assess, and monitor disaster risks and enhance early warning.
- Use knowledge, innovation, and education to build a culture of safety and resilience at all levels.
- Reduce the underlying risk factors.
- Strengthen disaster preparedness for effective response at all levels.

Relatively little of this relates to the purely scientific realm of understanding the physics and chemistry of active volcanoes and faultlines. It has rather to do with the ways in which different stakeholders respond to the risks posed by natural phenomena. Governments, scientific assessment, social scientists, NGOs, and local communities are all involved in reducing the risk from natural disasters. This raises social, cultural, philosophical, economic, and epistemological issues that require a transdisciplinary approach that is context-sensitive. Nevertheless, the importance of scientific research into the physical processes involved in generating geophysical hazards, and into modeling them, should not be underemphasized: researchers are still mapping faults and volcanic systems, and uncovering new risks. A further challenge for these researchers is to ensure that their research is appropriately translated for stakeholders in relevant areas: there is a very real danger that research will enter the published literature of the academic community without impacting at local and national levels in government. This was demonstrated on Montserrat: an academic risk assessment of the volcano was carried out in the mid-1980s, but failed to penetrate government agencies, in large part because of its format as a scientific document (Wadge and Isaacs 1988).

Where warning is given of a likely large earthquake, there are several mitigation measures that can be put in place. The most widely recognized is the application of building codes, which typically outline the minimum acceptable precautions that have to be taken in the construction of particular buildings. For example, a hospital might have to be built with steel-reinforced walls, while residential accommodation might be exempt from such costly considerations. Building codes are compulsory in some areas of the world, such as California, where earthquake risk is high. However, there are complexities involved in their enforcement in areas where building techniques are still highly culturally controlled, as in rural Iran, for example. Building codes force contractors to design buildings that are able to absorb some of the shaking from the earthquake, thus making them less likely to collapse.

In volcanic eruptions, engineering solutions are less well developed, partly because there are multiple hazards involved. There have been attempts to redirect lava flows, for example, but these have been erratic in their success. One area that has been relatively productive is the building of channels for mudflow (lahar) redirection: Volcanic mudflows may occur for years after the end of an eruption, when heavy rain remobilizes volcanic ash and debris around the volcano. They tend to be very powerful and very destructive, but may follow predictable paths, allowing for some mitigation measures to be put in place (e.g., Tayag and Punongbayan 1994). Another volcanic hazard where encouraging developments are being made is that of ash and tephra fall. Structural reinforcement of roofs in areas of volcanic risk can lower the risk of roof collapse during ashfall (e.g., Spence et al. 2005). However, this has been done in relatively few locations as yet, and is limited to moderate-sized eruptions. Other volcanic hazards are more problematic, most notably perhaps pyroclastic flows, which are very mobile, fast, and hot, destroying everything in their paths. While some attempts to construct flow-proof buildings

**Table 14.1****Hazards from earthquakes and volcanoes**

Hazards from volcanoes	Hazards from earthquakes
Lava flows	Ground shaking
Pyroclastic flows	Liquefaction
Ash clouds	Building destruction
Ballistics (lava bombs)	Fires
Tsunami	Ground rupture
Earthquakes	Tsunami
Jokulhlaups (flooding due to glacial meltwater)	Floods
Gas and aerosols (e.g., can cause climate forcing)	
Lahars (volcanic mudflows)	
Lightning	
Blasts (e.g., at Mount St Helens in 1980)	

have been made, they have not as yet been adequately tested (e.g., Spence et al. 2008). In summary, **Table 14.1** shows a taxonomy of seismic and volcanic hazards.

## Geography of Risks and the Problem of Induction

Risk from geophysical hazards is strongly geographically constructed, both humanly and physically (e.g., Jackson 2006). Clearly, the risk from volcanoes is amplified in areas where there are volcanoes – although as the 2010 eruption of Eyjafjallajökull demonstrated, volcanic eruptions can affect much larger areas. For very large eruptions, this can extend to global climactic impacts, as noted above. Volcanism and seismicity tend to occur at plate boundaries, where the relative motion of plates causes melting and faulting (**Fig. 14.2**). However, there are important exceptions to this. Intraplate volcanism can occur either at hot spots (mantle plumes) like Hawaii, the Galapagos Islands, and the Azores or at rift zones like the East African Rift. Earthquakes may also occur in these locations, and at other areas like the New Madrid region in the central USA, which is thought to be a failed rift system (e.g., Johnston and Nava 1985; Cox et al. 2001). Additionally, small earthquakes may occur throughout tectonic plates due to stress changes in the crust, and isostatic rebound. Since earthquakes occur around the world very frequently, global seismic hazard based on the distribution of large earthquakes through time can be estimated and mapped (**Fig. 14.3**). However, in seismology there is considerable debate about the relationship between the temporal and spatial distribution of earthquakes, their magnitude, and the physical properties of a particular fault. This discussion will be detailed below.

In volcanology, the problem of forecasting the next eruption is compounded by several complexities, not least the wide variety of types of volcano: Some volcanoes tend to produce evolved, viscous lavas, which often erupt explosively as gas is trapped and becomes pressurized, while others produce relatively benign lava flows. In addition, volcanic activity is the result of

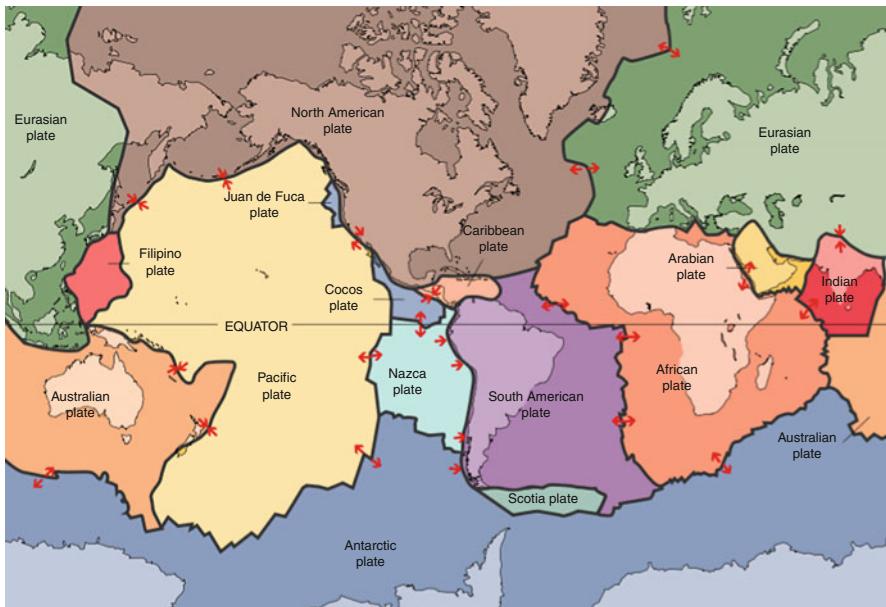

Fig. 14.2

#### GLOBAL SEISMIC HAZARD MAP

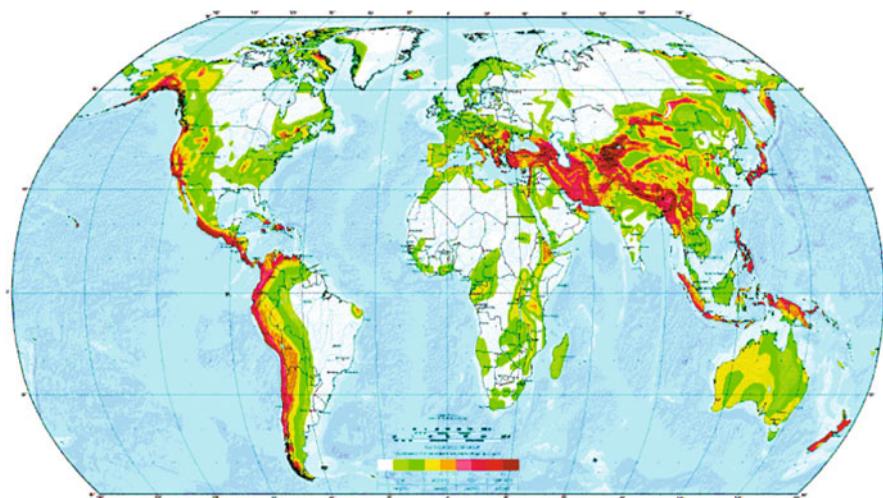

Fig. 14.3

Global seismic hazard map, courtesy of the Global Seismic Hazard Assessment Program. The Global Seismic Hazard Assessment Program (GSHAP) was launched in 1992 by the International Lithosphere Program (ILP) with the support of the International Council of Scientific Unions (ICSU), and endorsed as a demonstration program in the framework of the United Nations International Decade for Natural Disaster Reduction (UN/IDNDR)

a combination of highly nonlinear geophysical and geochemical processes, which may have localized geological controls. At a single volcano, an eruption may alternate between explosive and effusive phases, for example. The fact that relatively few eruptions have been observed with modern technologies renders prediction and forecasting very challenging, particularly given the long periods of repose between eruptions at potentially dangerous volcanoes. Volcanologists are very reluctant to compare volcanoes, at least quantitatively: There is a geographical problem of induction. Extrapolating the behavior of one volcano because of the way a similar volcano has behaved in the past has been shown repeatedly to involve dangerous assumptions – although it is often necessary.

• *Table 14.2* shows some of the key parameters in defining and handling earthquakes and eruptions, and gives some examples of the complexities involved. These can have scientific, social, economic, and cultural implications, and are often highly geographically and indeed historically specific. At the same time, the global nature of societal interactions in the “risk society,” and the structure and resourcing of academic research, means that many of those involved in managing a crisis will be from overseas: on Montserrat, for example, many scientists came from the UK and the USA. In volcanic crises in particular, many volcanologists may wish to be involved, not least because eruptions are relatively rare, spectacular, and present data-gathering opportunities, and the chance to apply one’s expertise for social benefit. Local scientists in developing countries may be dependent upon collaborations with outside scientists for state-of-the-art equipment and labor time (though this can also create some tensions where conflicting agendas are being pursued). This is particularly true on volcanoes, where expensive monitoring networks are simply not available to poorer countries (Donovan 2010).

The impact of global social inequalities on disaster risk has already been touched upon. Developing countries are very vulnerable to natural disasters, especially where populations are expanding rapidly. In Caracas, Venezuela, for example, there is a very high seismic risk because the city is built in an alluvial basin, and this amplifies the shaking from earthquakes. Housing

■ **Table 14.2**

**Key parameters in calculating and managing geophysical hazards and examples**

Problem	Volcanoes	Earthquakes
Duration	Chronic crisis mentality	Aftershock risk
		Duration of shaking
Frequency	Is it constant through time?	Is it constant through time? Stress-dependent?
Magnitude	Volcanic Explosivity Index	Moment Magnitude Scale
	Fluctuation with time	
Location	Lack of surface evidence? Multiple vents?	Faults not mapped?
	Areas at highest risk?	Relationship between adjacent faults?
		History of regional movement?
Area affected	e.g., Topographic controls	e.g., Geological site effects

in Caracas is very dense indeed, with poorly constructed houses almost on top of each other. Poverty, population growth, and lack of awareness have led to massively increased risk. This is a problem around the world, and one that is growing. It also occurs on multiple scales, from local to international. Tragedies such as the 2004 tsunami affect the global community, not only because citizens from around the world were impacted (for example, on the beaches in Thailand), but also because of the networks of trade agreements, NGOs, and the moral responsibility of wealthier nations to provide aid. The human geography of natural disasters is thus extremely complex. While working at the local level is of prime importance in providing resilience and education, national and international plans are required so that the broader economic and societal impacts are mitigated.

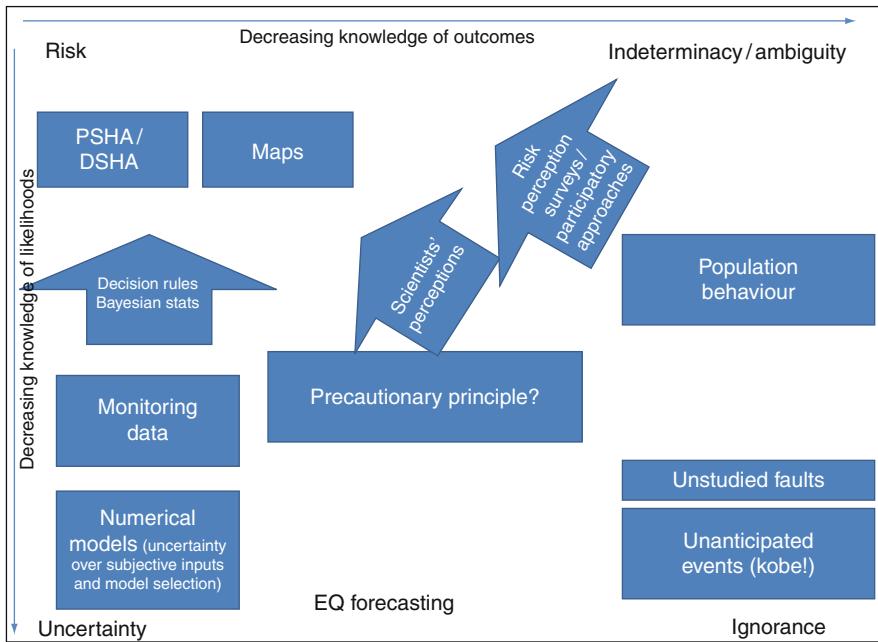

## Summary: Categorizing Uncertainty

---

This chapter deals with two rather different risk discourses: earthquakes and volcanoes. However, there are some key similarities: both suffer from the lithospheric problem (they originate in the deep earth and so are difficult to analyze from the surface); both are very difficult to predict; scientific knowledge about each is growing but relatively youthful; and both are generally high impact but low probability, particularly at higher magnitudes. These are fundamentally issues that are embedded within epistemology, philosophy, and sociology, but seldom discussed in this context. The chapter will therefore begin by discussing the history of each of these risks, how they have been dealt with by the scientific community and how publics and governments have responded to the risk. It will then discuss current themes in risk assessment and management research for each risk, and finally suggest some future directions.

Much of the information available about geophysical risks comes from the scientific community. This means that the role of scientists in crisis management can be very important, and therefore that there is a lot of pressure on people who are not trained as policy advisors. The social context of scientific data gathering, modeling and use is therefore fundamental in understanding the social role that scientists have, and the extent of their accountability – which has been questioned in recent years. This chapter will therefore seek to provide a highly interdisciplinary discussion of some of the key issues in the management of risks from geophysical hazards. It is not intended to focus on scientific methods and models: there is a huge literature on this subject. Rather, it examines the social context both of science, and of the hazards themselves, proposing a holistic and context-based approach to understanding risk and uncertainty.

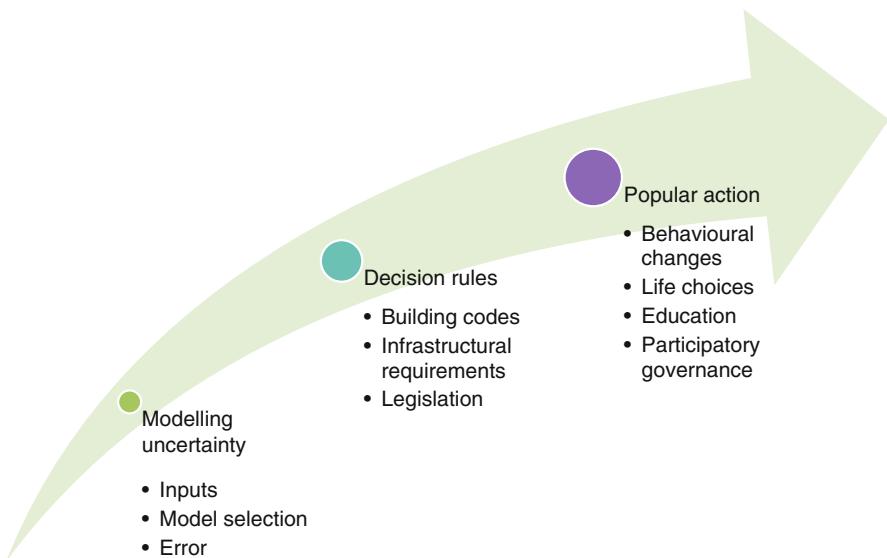

In order to provide further structure to this vast topic, Fig. 14.4 shows a potential framework for use in thinking through the transdisciplinary context of the geophysical hazards. It is tailored to earthquakes; a volcanic version is given in Donovan (2010), and the framework is based on Stirling (2007) and Wynne (1992), with some alterations for the specific case of geophysical hazards. It is a useful framework because it distinguishes between different types of uncertainty. Risk refers to uncertainty that is quantifiable and identifiable: a specific threat for which a probability can be calculated – and this definition is more focused than the traditional hazard times vulnerability formulation, though that remains conceptually helpful. It is in this part of the diagram that most risk assessments take place. However, Stirling (2008) argues that many attempts to manage uncertainty “close down” to risk, ignoring the other three aspects of

**Fig. 14.4**  
Contextualizing the issues in seismic risk research

the uncertainty, or smoothing them over. In this framework, “uncertainty” applies to situations where the outcome is known, but a probability cannot be put on it. This might be true, for example, for nonlinear numerical models, where there is uncertainty about input parameters and model selection, and about how the results of the modeling can be translated to risk assessment. “Indeterminacy” (or, for Stirling (2007), “ambiguity”) refers to situations that can be dealt with quantitatively in theory, but the outcome is unknown. This most often refers to social behaviors in the present context – understanding how populations and policymakers, and indeed scientists, will respond to events and information. Finally, “ignorance” is a very important aspect of geophysical risk assessment. It refers to the “unknown unknowns,” those things that are not anticipated. There are multiple examples of these in the recent history of the geophysical hazards, such as new phenomena observed on Montserrat, or the failure to anticipate seismic risk in particular areas.

The high level of uncertainty inherent in predicting the geophysical hazards has produced several major challenges for those seeking to manage and mitigate them. The uncertainty of the scientific methods coupled with the procedures involved in mitigating these risks and the need to involve populations in the preparation leads to a snowballing of uncertainty and indeterminacy from the scientific domain through the policy domain and into the wider public. This is illustrated in [Fig. 14.5](#). One response to this from the academic community has been to carry out risk perception and communication surveys. However, this is one area where qualitative methods are very important, and where philosophy and sociology have a useful role to play.

**Fig. 14.5**  
The snowballing-uncertainty effect

## History

The history of “geophysical risk” as a concept is relatively recent: the understanding of geological hazards and their sources has developed exponentially in the last 200 years, as their causes have been analyzed with increasingly accurate and reliable instruments. In part, this relates to technological and scientific development in other areas – the prediction and awareness of geophysical hazards is in some respects a luxury of the modern world, and is very dependent on plate tectonic theory, which was introduced by Alfred Wegener in 1912, but did not become widely accepted until the 1950s and 1960s. The definition of the theory is generally attributed to McKenzie and Parker’s 1967 *Nature* paper and Morgan’s 1968 essay. Thus, the cornerstone of modern geophysical theory is very young (Oreskes and Le Grand 2003), and scientific methods for earthquake and eruption prediction are correspondingly youthful. There are therefore several challenges in documenting the historical context of volcanic and seismic risk – volcanology and seismology as scientific disciplines have discrete histories, and it is not entirely clear at what point the idea of risk in relation to these endeavors really took hold. In general, it was reactive, and this chapter suggests that current research in both of these disciplines has been dominated in many ways by past earthquakes and eruptions, rather than pure “blue skies” research: Individual events have played key roles in the progression of understanding – both of the physical processes and of the nature and concept of geophysical risk.

Earthquakes and eruptions themselves have of course occurred throughout the earth’s history, and have been associated with mass extinctions and the collapse of civilizations (Francis and Oppenheimer 2004). The broader recognition of these possibilities is however relatively modern – those affected by the AD 79 eruption of Vesuvio, for example, were unaware of the risk prior to the eruption. Indeed, social acceptance of volcanic and seismic risk is

currently a major project in many parts of the world – one that has unfortunately postdated much infrastructural development. Both volcanic and seismic risks have been relatively slow to penetrate the social consciousness, in spite of their long histories. This is partly a function of their geographical distribution and of the long return periods of events in a specific area.

This section will outline the recent history of geophysical risk awareness, using examples to highlight some of the major issues in risk assessment and management. It is important to note at the outset, however, that risk assessment in seismology and volcanology is extremely unusual, though increasing. Much of the focus to date has been on hazard assessment, in recognition that risk assessment requires further (uncertain) input about populations, infrastructure, and mitigation measures (e.g., Wang 2009). However, risk assessments are increasingly being demanded by governments, and the scientific community is attempting to bridge the gap between what science is capable of doing, and the results that are required for policy making. Some examples of this will be given under “Current research,” below. First, however, the recent history of seismic and volcanic risk will be discussed.

## Earthquake Risk

---

It could be argued that the first “modern” earthquake in the West was the 1755 Lisbon earthquake, which was the largest documented event to affect Western Europe (Chester 2001), and which generated a tsunami in the Atlantic. This event generated a renewal of interest in seismology in the eighteenth century, and also precipitated the development and use of earthquake-resistant building techniques. Further devastating earthquakes occurred in Calabria in 1783, and then in Chile in 1835 (for a full list of large earthquakes, see [Table 14.3](#) and <http://earthquake.usgs.gov/earthquakes/world/historical.php>). Following the famous 1906 San Francisco earthquake, Henry Reid observed that earthquakes are the response of the crust to the buildup of stress on fault-lines (“elastic rebound theory”). Faults fracture as a result of stress buildup, and the fracture may propagate long distances along the fault depending on the energy of the earthquake. The 1906 earthquake has become notorious for its societal impact, too: fires burned in the city for 3 days, 3,000 people were killed and 225,000 left homeless. As a result of this event, scientific knowledge about earthquakes increased dramatically – and the San Andreas fault became one of the most feared in the world.

In 1960, a magnitude 9.5 earthquake – the largest ever recorded – occurred in Chile, sparking a Pacific-wide tsunami that killed people as far away as Hawaii, Japan and the Philippines. Four years later, in 1964, a magnitude 9.2 earthquake occurred in Alaska, again causing a tsunami that killed over a hundred people on the US West Coast. These events marked a renewed interest in the prediction of earthquakes and the assessment of seismic hazard. In the late 1960s, the Probabilistic Seismic Hazard Assessment procedure was devised in Mexico and the USA, based on modeling earthquakes as Poisson processes (McGuire 2008). It also has a strong history of Bayesian methods – used by Esteva (1969) to facilitate decision-making – thus combining frequentist and subjective probabilistic methods. The emphasis, however, is on the magnitude and frequency distributions of the earthquakes on a particular fault – a fact that assumes that this in some way represents the physical parameters of the system. Complexities may arise as a result, for example, of multiple, interlocking fault systems whose stress distribution affects one another: as knowledge about the system increases, epistemic uncertainty can also increase because scientists become aware of more unknowns in the natural system.

**Table 14.3**  
**Significant earthquakes in the historical record**

Date	Location	Magnitude	Deaths
856 AD	Damghan, Iran	Unknown	200,000
1138	Aleppo, Syria	Unknown	230,000
1556	Shensi, China	8.0	830,000
1693	Sicily, Italy	7.5	60,000
1700	Cascadia	9.0	N/A
1755	Lisbon, Portugal	8.7	70,000
1783	Calabria, Italy	Unknown	50,000
1811	New Madrid, USA	7.7	Several
1819	Gujarat, India	Unknown	2,000
1838	San Francisco	6.8	
1843	Leeward Islands	8.3	5,000
1857	Naples, Italy	6.9	11,000
1868	Big Island, Hawaii	7.9	77
1868	Arica, Peru (now Chile)	9.0	25,000
1875	Northern Colombia	7.3	16,000
1877	Offshore Tarapaca, Chile	8.3	34
1892	Imperial Valley, California	7.8	
1899	Cape Yakataga, Alaska	8.0	
1899	Menderes Valley, Turkey	6.9	1,100
1902	Guatemala	7.5	2,000
1903	Turkey	7.0	3,500
1905	Kangra, India	7.5	19,000
1906	Offshore Esmeraldas, Ecuador	8.8	1,000
1906	San Francisco, California	7.8	3,000
1907	Qaratog, Tajikistan	8.0	12,000
1908	Messina, Italy	7.2	70,000
1915	Avezzano, Italy	7.0	32,610
1920	Ningxia, China	7.8	200,000
1923	Kamchatka	8.5	
1923	Kanto, Japan	7.9	143,000
1927	Tsinghai, China	7.6	40,900
1931	Xinjiang, China	8.0	10,000
1933	Sanriku, Japan	8.4	2,990
1934	India–Nepal	8.1	10,700
1935	Quetta, Pakistan	7.5	30,000
1939	Chillan, Chile	7.8	28,000

**Table 14.3 (Continued)**

Date	Location	Magnitude	Deaths
1939	Erzincan, Turkey	7.8	32,700
1948	Ashgabat, Turkmenistan	7.3	110,000
1949	Khait, Tajikistan	7.5	12,000
1952	Kamchatka	9.0	
1957	Andreanof Islands, Alaska	8.6	
1960	Agadir, Morocco	5.7	10,000
1960	Chile	9.5	1,655
1962	Qazvin, Iran	7.1	12,225
1964	Prince William Sound, Alaska	9.2	128
1968	Dasht-e Bayaz, Iran	7.3	12,000
1970	Yunnan Province, China	7.5	10,000
1970	Chimbote, Peru	7.9	66,000
1974	China	6.8	20,000
1976	Guatemala	7.5	23,000
1976	Tangshan, China	7.5	255,000
1978	Iran	7.8	15,000
1985	Michoacan, Mexico	8.0	9,500
1988	Spitak, Armenia	6.8	25,000
1989	Loma Prieta, California	6.9	63
1990	Western Iran	7.4	50,000
1994	Northridge, California	6.7	60
1995	Kobe, Japan	6.9	5,502
1999	Izmit, Turkey	7.6	17,118
2001	Gujarat, India	7.6	20,023
2003	Bam, Iran	6.6	31,000
2004	Sumatra-Andaman, Indian Ocean	9.1	227,898
2005	Northern Sumatra, Indonesia	8.6	1,313
2005	Pakistan	7.6	86,000
2007	Southern Sumatra, Indonesia	8.5	25
2008	Eastern Sichuan, China	7.9	87,587
2009	L'Aquila, Central Italy	6.3	295
2010	Haiti	7.0	222,570
2010	Offshore Bio-Bio, Chile	8.8	577
2011	Near east coast of Honshu, Japan	9.0	13,538+ (14,000 missing)

The selection here is based on magnitude, fatalities, and significance in the scientific debates. This list is only a small fraction of the available data. As the historical record improves exponentially in the last few decades, the distribution here cannot be taken as representative. Data is taken from the USGS. Figures for the Japan 2011 earthquake are correct at time of writing (April 2011)

The recent history of earthquake activity demonstrates the challenges of deciding whether or not to attempt to predict events. In 1983, the USGS predicted that there would be an earthquake in the Parkfield area within 5 years of 1988. It actually occurred in 2004 – after the window had expired. In 1989, the Loma Prieta earthquake occurred (e.g., Reasenberg and Simpson 1992). Loma Prieta had been associated with a seismic gap (an area of fault that had not moved for some time), but a prediction was not made. Both of these events led to public questions about the scientists' credibility and responsibility. Then, in 1995, the Kobe earthquake occurred in Japan. Kobe had not been recognized as an area of high seismic risk, and there was a level of complacency in Japan about its ability to cope with earthquakes – perhaps because there had not been a major earthquake for many years (Wisner et al. 2004). The devastating impact of the Kobe earthquake, killing over 5,000 people and destroying 136,000 buildings, came as a huge shock to Japanese infrastructure. It resulted in the shutdown and replacement of Japan's "earthquake prediction program," and an extensive national disaster preparedness campaign. In recent years, disaster managers from Kobe have been involved in assisting other countries as they recover from earthquakes, such as the Iranian response to the 2003 Bam earthquake, demonstrating the usefulness of global knowledge economies in managing geophysical hazards.

The last decade (2000–2010) has witnessed several major earthquakes. Two of these were particularly devastating in terms of casualties: the Sumatra-Andaman earthquake in 2004, and the Haiti earthquake in 2010 (► *Table 14.3*). The 2004 earthquake was very large – 9.2 on the moment magnitude scale – and caused considerable seafloor deformation, which generated a tsunami. This was responsible for most of the casualties, and the death toll could have been significantly reduced by provision of early warning (Sieh 2006; Kanamori 2006). The absence of a tsunami warning system in the Indian Ocean – in spite of there being one in the Pacific – was partly the result of social and economic inequalities, and partly a lack of recent memory of tsunami in this region (though in 1883 the eruption of Krakatau caused a tsunami; see below). The global distribution of wealth can have a very large impact on the ability to respond to geophysical risk – and many of the risks are higher in the developing world (Wisner 2004).

The 2010 Haiti earthquake, by contrast, was a moderate-sized event – 7.0 on the moment magnitude scale. Its destructive power was related to its location close to Port au Prince, its relatively shallow depth (8.1 km), and the inadequacy of local infrastructure to withstand the shaking. Buildings in Haiti had not been built in accordance with earthquake building codes, and thus collapsed due to the effects of ground shaking. This was exacerbated by several strong aftershocks, and the soft geology of the region (which amplified the shaking). Thus, a lack of preparedness and awareness of the risk were major factors in the high death toll (222,570). This demonstrates the importance of an integrated approach to disaster risk reduction and management.

On March 11, 2011, a magnitude-9 earthquake struck Honshu, Japan, and caused a Pacific-wide tsunami, killing people around the Pacific Rim, and devastating large areas of the Japanese coast. Disruption to the power supply of a nuclear plant in Fukushima caused a Level-7 nuclear crisis – the highest level on the international scale. In part, this was due to the age of the plant and the underestimation of likely tsunami height when defenses were constructed. This incident demonstrated the vulnerability of the most developed nations to natural disasters: In terms of earthquake-preparedness and engineering, Japan is arguably the most advanced nation in the world. In this case, technological advancement both decreased vulnerability and

increased it – while buildings in Tokyo were able to withstand substantial shaking, the presence of nuclear facilities and a heavy dependence on power supplies significantly increased the risk. Additionally, the hazard itself was of a higher magnitude than defenses on the coast had been designed to withstand. The combination of earthquake and tsunami in Japan did not cause the same loss of life as the similar event in Indonesia in 2004, perhaps because of engineering solutions, but it showed that there is some way to go in multihazard designs for key facilities, particularly in a technologically advanced society.

## Volcanic Risk

---

Recent archaeology has revealed the dramatic impact of volcanic eruptions on civilizations throughout history – most notably perhaps in the destruction caused by the eruption of Thera on Santorini around 1650 BC, associated with the destruction and burial of Akrotiri (Francis and Oppenheimer 2004), and also with several Mediterranean legends. The notorious eruption of Vesuvius in AD79 could be taken as the first documented volcanic eruption, described by Pliny the Younger in some detail. The extensive looting of Pompeii and Ercolano in the seventeenth and eighteenth centuries demonstrates the interest that was accorded to them, and the travels of early scientists such as William Hamilton are indicative of the growth of curiosity about the workings of the Italian volcanoes in particular. Hamilton documented the lava flows on Vesuvius, and identified the older Mount Somma as the source of the AD 79 eruption (Hamilton 1772). The Enlightenment period was crucial in the development of the geological sciences in general, and of interest in volcanology in particular – and this continued throughout the nineteenth century (for excellent accounts of the history of ideas in volcanology, see Sigurdsson 1999 and Young 2003). This is reflected too in artistic endeavors, such as the Romantic movement, which were inspired by the “sublime and terrible wonders of nature”.

The eighteenth and nineteenth centuries also have a rich history of volcanic eruptions, particularly in terms of climactic impacts – the injection of sulfate aerosols into the stratosphere can cause climate forcing, resulting in cooling and heating in different areas depending on the location of the plume. In 1783, the Lakagigar eruption in Iceland caused failed harvests across northern Europe (Witham and Oppenheimer 2004). Then, in 1815, Tambora volcano in Indonesia erupted. This was the largest eruption in historical time, and caused spectacular sunsets around the world, as well as altering the climate (Zerefos et al. 2007). The early nineteenth-century eruptions of Vesuvius prompted the founding of the Osservatorio Vesuviano in 1841 to monitor the volcano, as growing numbers of tourists were visiting it.

Several major eruptions have had significant impacts on social and scientific awareness of volcanic risk. An important example was the 1883 eruption of Krakatau in Indonesia, which caused a tsunami in the Indian Ocean that killed 36,000 people. It has been argued that this was the first natural disaster to be communicated globally at speed (Winchester 2003): It appeared in the London newspapers shortly after it occurred. Nineteen years later, Mount Pelée on Martinique in the French West Indies erupted, killing all but two of the population of St Pierre. This event is often taken as the origin of modern volcanology. It was described by Alfred Lacroix in 1904 (Lacroix 1904). In 1924, the Bulletin of Volcanology was founded, to promote academic research in the subject. Researchers observed and began to analyze precursory signs, such as earthquakes prior to eruptions (e.g., Finch 1943; MacGregor 1949) and changes in ground tilt (e.g., Waesche 1942). As far back as 1937, R.L. Ives noted that “our modern civilisation is more easily damaged

than ever before in history” – documenting an awareness of growing societal vulnerability to both earthquakes and volcanoes (Ives 1937). Again, persistently active volcanoes were the source of a great deal of data – most notably the Italian and Hawaiian volcanoes.

A major turning point in societal awareness and scientific understanding of volcanic risk was the 1980 eruption of Mount St Helens in Washington, USA, which killed 57 people and produced a huge ash cloud that dispersed over large parts of the USA (e.g., Moore and Rice 1984). It was caught on film, and the pictures have become classics in the volcanological literature. While the eruption was in a relatively remote place, 57 deaths occurred as a result of it. Those who died had either refused to move, or had been working for the timber industry, which had put pressure on the Governor of Washington to keep access open to its workers. Prior to the eruption, there had been long-term warnings that an event was likely given the history of the volcano, and some hazard perception studies had been carried out. During the eruption, further studies of hazard perception were carried out among local residents (Perry and Greene 1983; Lindell and Perry 1993). These studies suggested that, unsurprisingly, popular perception of the risk from the volcano increased dramatically during the first few months of the eruption, and followed patterns described in other disciplines – with people being more open to information from trusted sources, for example. Lindell and Perry (1993) also discuss the transition in risk perception from the acute threat to a chronic threat (Mount St Helens continued erupting throughout the early 1980s): This is an important aspect of risk perception during eruptions, and has also been witnessed on Montserrat, where the eruption has been ongoing, episodically, for 15 years. The potential for “chronic crisis mentality” in the governance of long volcanic eruptions has been recognized by scientists working on Montserrat, and increasingly by local officials. There is thus a long-term mental shift that has to take place as procedures for risk assessment and management are established and refined. Examples of this include the management of long-term eruptions on Etna and Hawaii. Adjustments have to be made on an individual level, and on a societal level. Ongoing volcanic eruptions can have significant impacts on national identity and human geography.

The largest eruption of the twentieth century occurred in 1991 at Mount Pinatubo in the Philippines (Newhall and Punongbayan 1996). This eruption was regarded in many ways as a successful management of volcanic risk, because thousands of people were evacuated and many lives were saved. Scientists in this case were able to gather sufficient data to be convinced that an eruption was very likely, and eventually managed to convince local officials – and, via lobbying the Pentagon, the nearby US air base – that an evacuation was necessary. However, volcanic mudflows continue to affect the area many years later, even after the end of the eruption.

Other important events in the recent history of volcanology include the 1993 eruption of Galeras volcano in Colombia and the eruption of Mount Unzen in Japan – both of these involved the deaths of volcanologists, demonstrating the uncertainties not only about eruption prediction, but also about the extent and capabilities of volcanic hazards such as pyroclastic flows. This was highlighted on Montserrat in 1997, when 19 people were killed (in the exclusion zone) by highly mobile pyroclastic flows. In this case, scientists were almost killed, and the microzonation of the island was regarded with hindsight as extremely dangerous (Aspinall et al. 2002): geographical definition of the hazardous areas was subject to high errors, partly because the mobility of pyroclastic flows was poorly understood. The eruption allowed pyroclastic flows to be studied and modeled in detail.

It would be remiss to conclude this section without a brief discussion of the 2010 eruption of Eyjafjallajökull in South Iceland – a small eruption that brought aviation in Northern

Europe to a standstill because of the risk to aircraft from the volcanic plume. It is a fascinating example of the problems of geophysical governance. As was reported ad nauseam during the “ash crisis,” the threat to aircraft from volcanic eruptions has been known for decades. In February 2010, for example, an explosion at the Soufriere Hills Volcano on Montserrat suspended air traffic in the Eastern Caribbean and closed the international airport in Antigua. The lack of preparedness in Northern Europe was largely the result of industrial and political apathy: The event was not a surprise to the scientific community. This emphasizes a further point about the nature of geophysical risks: The scientific community and the lay community may differ greatly in their view about the importance of a particular threat, and this renders any definition of risk thresholds problematic.

Thus, in spite of the long history of volcanic crises, in 2009 Louisiana Governor Bobby Jindal criticized Obama’s government for funding “something called volcano monitoring”: The recognition that volcanoes pose a serious threat to human welfare is still not widely accepted even in the most developed parts of the world. When the volcano on Montserrat began erupting in 1995, for example, very few of the islanders even knew that it was a volcano. New volcanic phenomena are still being observed and documented, and there are types of volcanic eruption that have not been observed in recorded history – such as so-called supervolcanic eruptions. There is a frequency–magnitude relationship in the geological record: Larger eruptions occur more rarely than smaller ones (Mason et al. 2004). However, the nature of that relationship, its relationship to physical processes, and thus its reliability for predictive purposes is contested. For example, Katla volcano in South Iceland erupted 20 times in a 1,000-year period. It therefore erupts every 50 years. However, the last eruption was in 1918; is it therefore meaningful for scientists to argue that it is “overdue”? Or has the magmatic system shifted in some way? This tension between statistical and physical models will be discussed below.

## Summary

---

This section has discussed some of the defining moments in the history of volcanic and seismic risk. It has shown some of the key ideas that have emerged in the last century, as well as the challenges. In particular, the importance of specific events has been emphasized, both for producing data and scientific advancement, and for raising social awareness of risk. In earthquake hazard, the scientific challenges that have arisen from recent events concern the nature and appropriateness of earthquake prediction, which are debatable. The Kobe earthquake and the Bam earthquake both demonstrated unpreparedness in the absence of physical evidence, as well as faulty assumptions in earthquake prediction methods, for example. Societal challenges related to this include the need for public education, enforcement of building codes, and a precautionary approach. In volcanology, scientific challenges relate to multidisciplinary consensus-building, managing uncertainty in models, and preventing overconfidence in the face of the “unknown unknowns”. Socially, education remains very important, as do emergency planning and infrastructural preservation.

## Current Research

---

This section is structured around two aspects of risk research in the geophysical hazards – the technical, scientific management of uncertainty, and the social aspects of risk. This is not

intended to be dichotomous, but to provide a framework for examining the different discourses involved. While scientific research in volcanic and seismic risk does tend to “close down” toward risk (Stirling 2008) – quantification of probabilities being the goal – combination of social scientific and scientific methods via reflexive awareness and narrative management may be a powerful way forward for the physical and social sciences to work together. This will be the argument of the final section of the chapter.

## Scientific Uncertainty

---

The challenge of handling uncertainty in science has been increasingly recognized (e.g., Taleb 2007) – not least through the climate change discourse and the controversy surrounding the limitations of scientific knowledge and practices. In seismology and volcanology, very high levels of uncertainty may be associated with predictions. This uncertainty comes from a number of sources – such as model selection and inputs (e.g., Oreskes et al. 1994), historical/geological data and its gaps, expert judgment and interpretation, observational error, computational error, and instrumental error (see also Shackley and Wynne 1996; Shackley et al. 1998). A distinction that is commonly in use separates epistemic uncertainty (lack of knowledge) and aleatory uncertainty (randomness of nature; e.g., Woo 1999). The problem with this distinction is that it oversimplifies the problem somewhat – both are generally combined in the occurrence of particular events, and the distinction between them is not always clear. In addition, even models that attempt to calculate both uncertainties are not foolproof – the “unknown unknown” element is increasingly recognized (Spiegelhalter and Riesch, *in review*) as problematic, and this has been demonstrated in the recent history of volcanic and seismic crises, where previously unobserved phenomena have been documented. The development of scientific models for these phenomena is encouraging, but models are limited by their simplification of natural processes – and may be misinterpreted by the public, particularly where they look impressive (Hulme and Mahony 2010). The authority of scientific knowledge is contingent on a variety of scientific and social considerations (Fischer 2004; Hulme 2009). This section will discuss the current state of research in seismic and volcanic risk and uncertainty in turn.

## Earthquakes

Seismologists have been carrying out probabilistic seismic hazard assessment (PSHA) for over 40 years. It is based on historical seismicity in particular areas, and has been for some time the dominant method for calculating seismic hazard (e.g., by the US Senior Seismic Hazard Analysis Committee). Bayesian inference has also been applied (e.g., Faenza et al. 2010). However, in recent years, there has been a growing dissatisfaction with probabilistic methods, and new techniques – “deterministic seismic hazard assessment” (DSHA) or “neo-DSHA” – have been developed. This has led to a heated debate about the nature of earthquake prediction (e.g., Krinitzsky 1995; Bommer and Abrahamson 2006) and the most appropriate methods for representing earthquake hazard for policymakers. In part the problem is one of managing aleatory uncertainty – not included in the original formulations of PSHA in the 1960s (McGuire 2008; Bommer and Abrahamson 2006), but later added to the procedures.

However, as McGuire (2001) argues, probabilistic and deterministic approaches can be complementary and for decision-making purposes, probabilistic assessments are necessary, even though they can include deterministic methods (Bommer and Abrahamson 2006).

The nature of uncertainty in seismic hazard assessment is particularly disputed, with some authors claiming that DSHA does not take all the uncertainty into account, and others that it does (Wang 2010). A problem that is well recognized in DSHA is that it does not take return period into account – a problem that is significantly complicated by evidence that, for example, earthquakes may occur in clusters, and the measurement of return period in PSHA (usually by representing it as a Poisson process) may thus not be adequate. It is clear from this brief review that seismic hazard assessment remains a highly contested area of research. Terminology is a big problem: “Deterministic” is not always used in the sense of classical determinism, and “probabilistic” assessments may be frequentist or subjectivist. This can cause significant confusion. However, there are also authors who argue against the use of probabilities in general (e.g., Castanos and Lomnitz 2002), on the ground that they cannot be reproduced by experiment. This is a particularly interesting aspect of scientific understandings of uncertainty: the emphasis for some scientists has to be on what is verifiable and physically observable. In DSHA, this refers to all the information that it is possible to obtain for a particular faultline – “hard facts” rather than statistics (Castanos and Lomnitz 2002). These authors would dispute the use of statistical methods at all as a means of quantifying uncertainty, arguing that statistics “works best with plenty of data”.

The selection of probability distributions to represent the process of earthquake recurrence (particularly Poisson distributions) in PSHA is inevitably subjective itself: All model selection is subjective, as is the selection of data and inputs used in the assessment. There is no way of knowing whether or not all the information has been taken into account – as the cluster problem shows. Even in deterministic methods, there are possibilities that geological information has been misinterpreted, that instruments have been inaccurate, and so on. It is therefore difficult to argue that any earthquake hazard assessment can be truly objective – as pointed out by several authors. However, those that make extensive use of expert judgment have been particularly vulnerable to attack. Expert elicitation, for example, involves quantification of data using experts as processors, and is therefore highly subjective, rendering it open to accusations of being unscientific and inappropriate. At the same time, it allows the translation of scientific data into risk assessments, bridging the gap between science and the need to advise policymakers.

Different theories about the recurrence rates of earthquakes have been put forward, and some faults appear to corroborate particular models. However, there is no foolproof explanation for the behavior of faults in general. Thus, some faults seem to have “characteristic earthquakes” of a particular magnitude that recur at relatively predictable intervals, but others do not. Other faults exhibit clustering of earthquakes in time. The nonlinear behavior of faults requires detailed mapping studies to be carried out. However, geological mapping can be a matter of interpretation, and this requires particular care in managing uncertainty: For example, distinguishing a large earthquake from a series of small earthquakes that occurred in close temporal proximity can be challenging in the field. Thus, there are a variety of conceptual and quantitative challenges in understanding the physics of earthquakes. Nevertheless, the existence of relatively robust probabilistic maps is a necessity for planning, and has been applied in many key areas (e.g., Stein et al. 2006).

Uncertainties also arise in the expression of the outcomes from seismic hazard assessment: There are several possible variables that can be estimated and different ways of expressing the same variable (Wang 2010). Thus, for example, the magnitude of a particular earthquake could be stated in terms of its moment magnitude, or its likely peak ground acceleration. Similarly, the temporal spread of earthquakes may be expressed in terms of return period (how often, on average, an earthquake of that magnitude occurs in a particular place), or as the “probability of exceedance” for particular degrees of ground shaking in a particular time period. As well as expressing magnitude and frequency, the likely spatial distribution of shaking has to be expressed, and this is commonly done using maps. Unfortunately, the ability of members of the public – and policymakers – to understand hazard and risk maps is not clear (Newhall et al. 1999; Haynes et al. 2007). This is a further area for social and physical scientists to work on together.

Seismic risk, to take the argument a step further, involves a much greater range of variables, including potential economic losses and fatalities. This is complicated by the involvement of multiple parties in assessing and mitigating risk, not least because the language used by earthquake engineers often differs from that used by seismologists – and that used by disaster managers may well be different again! Spence (2009) details some of the challenges currently facing the seismological and earthquake engineering communities, particularly with respect to building code implementation around the world. He notes the importance of international collaborative ventures in meeting some of these challenges. In particular, the need to estimate losses can be problematic because obtaining data about buildings and infrastructure is not straightforward and may be politically sensitive. Efforts are underway, however, to facilitate loss modeling on a global scale (Spence 2009).

## Volcanoes

Volcanology is a smaller discipline than seismology, and while tremendous advances are now being made, they have perhaps been slower to occur – perhaps because of the relative paucity of volcanic eruptions and hence observational data. In addition, there are complexities induced by the nature of volcanism – the need to understand seismicity, ground deformation, gas emissions, gravitational variation, electromagnetic signals, hydrochemistry, and other types of signals, for example, some of which might appear to give contradictory indications of whether or not a particular volcano will erupt. Most volcanoes, however, are not adequately monitored (Ewert and Newhall 2004), or not monitored at all: This may render any kind of prediction for a particular location very challenging because there is no baseline data and the first discernable activity may be explosions from the crater (Tilling 2008; Lowenstern et al. 2006). Monitoring networks allow the detection of migrating magma in the volcanic system; this data has to be interpreted in order to ascertain how likely it is that the magma will reach the surface. This has been increasingly attempted using subjective probabilistic methods, particularly as the presence of aleatory uncertainty in the natural system is recognized by scientists. The main methods currently in use are Bayesian Event Trees (e.g., Newhall and Hoblitt 2002; Marzocchi et al. 2006, 2007) and Belief Networks (Aspinall et al. 2003; Hincks 2005), and structured expert elicitation (Cooke 1991; Aspinall 2006, 2010; see also O’Hagan et al. 2006). However, these methods are by no means universally accepted in the

scientific community (Donovan 2010). Many other methods for loss modeling, for example, can be controversial because of the need to value human lives (e.g., Marzocchi and Woo 2009).

Bayesian methods are a challenge to determinists because of the selection of the prior, which is subjective (Gelman et al. 2004; Gelman 2008) and a matter of interpretation. However, many scientists support the use of these methods in recognition of the need to display the available information logically, and to produce probabilistic risk assessments. Probabilities to populate event trees may be calculated using frequentist priors – based on the historical record of volcanism in a particular place – or using subjective methods such as expert elicitation. Elicitation is gaining popularity as an effective way to quantify risk assessments using all the available data, but again faces criticism from scientists who are concerned about subjective methods: “Evidence-based volcanology” (Aspinall et al. 2003) faces many of the criticisms faced by its predecessor, “Evidence-based medicine” (e.g., Sackett and Rosenberg 1995; Sackett et al. 1996). Deterministic models have also been produced to forecast volcanic eruptions (e.g., Voight 1988; Kilburn 2003; Kilburn and Sammonds 2005; Melnik and Sparks 1999). As scientific knowledge about volcanoes increases, and further data is gathered from volcanic systems around the world, possibilities arise for more sophisticated modeling of global volcanism – perhaps using ensemble models. This is the aim of several large projects that are currently gathering data of different kinds and developing cybertools for its analysis. Some multidisciplinary projects in recent years have generated some very practical and important resources for emergency planning. One example was the Exploris project (Baxter et al. 2008), which examined four European volcanoes and generated probabilistic models for eruption scenarios (e.g., at Vesuvius; Neri et al. 2008; Spence et al. 2008; Zuccaro et al. 2008).

The importance of the social context of scientific activities in volcanology has been commented upon in the literature since the failed eruption of La Soufrière de Guadeloupe in 1976, where a dispute between leading volcanologists became public and undermined the scientific effort to monitor the eruption (Tazieff 1977; Fiske 1984). It was partially in response to the problem of achieving consensus that the expert elicitation procedure now used regularly onMontserrat was introduced in 1995, and these issues also led to the production in 1999 of a set of guidelines for the conduct of scientists during volcanic crises (Newhall 1999). This was a significant development because the guidelines highlighted the impact of the social context of science on scientists’ ability to provide advice. They also emphasized the potential for tension between those with social responsibilities for monitoring volcanoes and those who wish to carry out research (Donovan 2010).

## Social Aspects of Risk and Uncertainty

### Risk Perception and Communication

As discussed in the previous section, social uncertainty may be a major factor in scientific uncertainty, in that different scientists have different ideas about what uncertainty itself is, what the role of models is, and how the natural world works. However, the management of uncertainty in the broader population – and indeed the communication of risk to the public and policymakers (e.g., Solana et al. 2008; Barclay et al. 2008) – provides a wealth of further challenges. In the geophysical hazards, this may be compounded by a lack of interest in the

events because of the challenges of daily living (Gaillard 2008). It is also complicated significantly by cultural variation in the perception of risk, which can be very strongly influenced by worldview and cognition. The psychology of risk perception has discussed a variety of heuristics that are applied by people in the presence of uncertainty (e.g., Slovic 2000; Slovic et al. 2004; Sjoberg 2000, 2008; Pidgeon et al. 2003).

On many volcanoes – including Mount St Helens, Pinatubo, and the Soufriere Hills – risk perception studies have shown that the public have a good understanding of the risk from the volcanoes (Gaillard 2008; Haynes et al. 2007, 2008; Bird et al. 2009; Barberi et al. 2008; Perry and Lindell 2008). They may even have a good understanding of some of the science, and, as mentioned previously, its limitations. However, this does not necessarily lead residents to make the decisions that researchers (or indeed governments) feel that they should make. Individual belief systems play a very important role in controlling behavior, as do relationships, trust, and potential gains. Handling low-probability, high-impact risks raises a variety of philosophical questions: Some scientists, for example, feel that the catastrophic risk potential from volcanoes means that even low risks should be taken more seriously, whereas the public may be more willing to take a risk, particularly if it is convenient or likely to result in gain. This question of “acceptable risk” – if such a thing exists – becomes extremely important and yet intangible.

It is in this context that work by Roeser (2006, 2007, 2009, 2010) is particularly helpful. Moral emotional judgments play a very important role in managing volcanic and seismic crises, because of the high stakes involved. Roeser (2009) argues that the apparent dichotomy between rational and emotional judgments about risk (“dual process theory”) is a false distinction: It is also a distinction that is at the heart of ideas about “acceptable risk”. There is an implied moral element here, one that has been witnessed in debates on Montserrat about the legality and morality of mandatory evacuations. In this particular case, there are two competing moral judgments. The first states that it is wrong to force people to leave their property (and in many situations this includes their livelihoods, particularly in farming communities). This judgment also appeals to ideas of the right to ownership and to take personal responsibility for one’s safety. The second judgment states that if the risk of a catastrophic event is considered to be high, then people should be moved even if this is against their will. The reasoning behind this may vary – it may be based on high levels of uncertainty in the risk assessment, felt or legal accountability of local authorities (as is the case on Montserrat), or the recognition that if a hazardous event occurs it will be too dangerous to send in rescuers – a further moral judgment. In several recent natural disasters, including Hurricane Katrina, mandatory evacuation orders were challenged by residents who wanted to take responsibility for themselves regardless of the risk of death. On Montserrat, the Governor was sued by local residents for forcing them out of their homes for several months during a period of high volcanic activity (Donovan 2010). This case also involved testimony from scientists involved – and several suffered socially as a result of the tensions on the island, because the political decisions were made based on scientific advice. The fact at the time was that the uncertainty was very high and the Governor of the island is personally responsible, under UK law, for the safety of the population.

There are cultural differences in the way that people view the morality of risk judgments. Many of those who objected to the evacuations on Montserrat were from the USA, where there is a more prevalent culture of litigation and of rights to property. There was also a colonial element – a sensitivity to being told what to do by the UK. However, in other countries, objections may vary. For example, the recent eruption of Mount Merapi in Indonesia involved

the evacuation of hundreds of thousands of people. In this case, the refusal to move was based on farming livelihoods and religious beliefs (see also Wilson et al. 2009). However, the vast majority of people evacuated because they could see that the volcano posed a significant threat. The problem on Montserrat – and in other evacuations – was that the threat was less obvious and not realized to the full extent possible. Communicating the fact that in conditions of high uncertainty, an evacuation may be justified even if the feared event does not occur is a major challenge in the management of geophysical hazards – particularly volcanoes, where such evacuations can last for months. Judgments about these issues are highly moralized for many stakeholders – and this is not a purely rational morality. It can be influenced by affect and cognitive biases, and this is at the heart of the fabled notion of “acceptable risk.” It is also the reason that this idea is so disputed, particularly among scientists.

Recent work by Dan Kahan (Kahan et al. 2009; Kahan 2010) has highlighted the role of cultural cognition in risk communication. This broadly reflects studies of the cultural perception of risk, such as those on Mount Merapi (Dove 2008), Montserrat (Haynes et al. 2008; Donovan 2010), and Etna (Chester et al. 2008). In these cases, religion played a very important role in the interpretation of the volcanic events – perhaps suggesting that a “risk society” mentality is in different stages of development in these areas, even as the global risk society looks in. Closely related is the cultural perception of uncertainty. This differs from the perception of risk in that uncertainty is often much less well defined. There can be a significant risk of a volcanic eruption, but considerable uncertainty as to its nature, its magnitude, its acceptability, the responsibility of local officials, population distribution, and so on. Some aspects of this may be quantifiable, others not. Cultural cognition suggests that the ways in which people handle risk and uncertainty are likely to be affected by their personal beliefs and value systems. The formation of groups and networks with similar values is a symptom of this (Beck 1992; Kahan 2010); a key example would be the climate skeptics, who reject the science behind climate change. Cultural cognition tends to relate to authority, equality, community, and individualism (Kahan 2010); these values have important implications for the management of volcanic and seismic crises, and their influence is traceable in the legality and morality discourses noted above. In volcanic crises in particular, the question of authority is extremely important, as is that of national identity (Donovan et al. 2011). The respect not only for local officials involved in decision making, but also for scientists providing advice, is extremely influential in whether or not people will obey an evacuation order. There is a tension between educating a population that there is a high level of uncertainty, and undermining their trust in science – unless uncertainty is adequately explained and represented in the communication of scientific advice (e.g., Hillerbrand and Ghil 2008).

In the case of volcanoes in particular, tourism is an increasing factor in increasing vulnerability (e.g., Bird et al. 2010; Leonard et al. 2008; Erfurt-Cooper and Cooper 2010). On Mount Etna, for example, thousands of tourists ascend the volcano every day in the summer. Educating tourists is rather different from educating resident populations: There is a transience about being a tourist, and the risk is clearly much lower if relatively little time is spent on the volcano. Nevertheless, this can be a major challenge in some areas. On Hekla volcano in Iceland, for example, scientists are relatively confident that they will have a warning around 20–30 min before the volcano erupts. However, Hekla is a popular hiking route in summer and takes around 4 h to climb. Therefore, a logistical problem arises: How to communicate a warning given that people may not have time to escape in any case. This itself may have cultural implications, too: Some nations might be more risk averse and keep people

away at all times, while others would prefer to take the risk in order to maximize the appreciation of natural beauty – and, perhaps most notably on Etna, the economic value of tourism.

## Risk Governance and Policy Making

Several studies of public participation have been carried out on active volcanoes (e.g., Mitchell 2006; Cronin et al. 2004). Donovan (2010) argued that it can be viewed as a form of political empathy: the consultation of local populations in the drawing up of evacuation plans is an opportunity to ensure that they feel listened to, and also to increase their knowledge and perception of the risk. However, the fact that much such consultation has in fact been carried out by researchers and not by governments highlights again the problem of governing low-probability, high-impact risks. The selection of field sites by researchers may not be representative of global risk or societal need. In general, participatory exercises have been well received by local communities. In crisis situations, though, participation cannot realistically be organized. Thus, a prerequisite of participatory governance for natural hazards is that it is preparatory not responsive. The exception would be the management of ongoing volcanic eruptions where particular issues can be dealt with at public meetings.

Recent discussions in scientific governance have concerned the use of the precautionary principle as a key aspect of governing under uncertainty. This adds another spin to the discussion about “acceptable risk”: If a risk is very low, is it reasonable to make decisions based on precaution if the decision will involve major ramifications for stakeholders? This is further complicated in the case of catastrophe risk, where the moral imperative would seem to be on preventing disaster. The problem is that the economic or societal impact of an evacuation may also be disastrous – and the resulting decisions therefore have to weigh lives against livelihoods. The nature of geophysical hazards can be very challenging for policymakers, particularly given the low probability of their occurrence and the paucity of votes involved in preparing for events that have not happened in living memory.

## Summary

This section has attempted to document a very wide range of disciplines in relation to risk research in the geophysical hazards, spanning both social and physical sciences. Risk unites disciplines, but also draws attention to the methodological and philosophical differences between them. In particular, the differences between the epistemology of tradition research (sometimes referred to as “mode 1” science) and research that is driven by societal need (“mode 2”) may be significant, but also blurred: Individual scientists are motivated by different factors, and have differing beliefs about the nature of science and its role in political decision-making. This is also true of social scientists. Coordination of multidisciplinary projects is therefore an important challenge in the current research climate.

Recent history suggests that the number of people adversely affected by volcanic eruptions and earthquakes will continue to increase, and that the impacts will be severe (Huppert and Sparks 2006; Jackson 2006). New research into both scientific and societal methods for prediction and management of geophysical hazards is crucial for protecting populations.

This includes hazard modeling and forecasting, education of policymakers and publics, engineering solutions, and social and political action.

## Further Research

---

This section follows from the previous two sections, and summarizes potential areas for expansion in research in geophysical risks. It deals both with scientific challenges and social scientific challenges, framing them in a philosophical and epistemological context.

### Uncertain Science

---

Both volcanological and seismological communities are currently engaged in a philosophical and epistemological struggle to manage uncertainty in the assessment of risk. An important first step in this process is to define the terms, which have become very confused in both fields. Secondly, it would be helpful to examine the social aspects of the scientific assessments, and particularly the role of expert judgment in providing scientific advice under high levels of uncertainty. This is in part a philosophical and epistemological problem that requires the exploration of new ways of doing science in the social context. Sociologists of Scientific Knowledge have delineated “mode 1” and “mode 2” science as traditional and applied science, respectively (Gibbons et al. 1994). However, this distinction breaks down where science enters the policy sphere in the geophysical hazards, as scientists attempt to retain their traditional methods in order to answer questions that science itself cannot yet answer. Risk assessments routinely challenge the nature of science and ask it to extend its epistemological basis. This has caused some confusion, and a lot of debate, among scientists, as is discussed above.

The management of scientific uncertainty in modeling has been under scrutiny in the climate change debates. This is an extremely important area of research for assessing geophysical hazards. Several types of model are relevant – global models, local models, hazard-specific models, multidisciplinary models – all of which require development. The management and understanding of the different types of uncertainty involved in modeling is also in need of further discussion. Similarly, the use of different kinds of monitoring data in models of particular volcanic systems is worthy of further research, especially in relation to the management of error and uncertainty, which varies extensively between different types of monitoring. Finally, the ongoing acquisition of new data about faultlines and volcanoes is crucial in mapping risks, and in informing models and statistical methods.

The use of subjective probabilistic methods for both hazard and risk assessment is also in need of further review and discussion. This is an important area of interdisciplinarity between social and physical scientists, and the former could take a more proactive role in understanding the social and philosophical implications of particular methods (e.g., De Finetti 1974; Corvalyn 2008), as well as in identifying social factors that could be incorporated into mitigation models. While quantification is necessary for risk management, qualitative methods from the social sciences are important in framing the use of quantitative data and its presentation. Philosophical ideas are also important in understanding the ways in which science is used, progresses, and interacts with the social and political domains. The question of how models, interpretations, and reports handle scientific and societal uncertainty is also a key epistemological challenge for

both physical and social scientists – it relates to the nature of science and its social role. This is a growing area of research in the geophysical hazards, and one with a lot of scope for further development.

## Uncertain Societies

---

Social understanding of risk from geophysical hazards has been shown to be restricted by the low probability of these events, and the consequent focus on everyday issues. Recent research on moral emotions and cultural cognition suggests that new pathways have to be found to represent risk in socially and culturally appropriate ways (Kahan et al. 2009). This requires cultural studies using qualitative methods alongside studies in expression and communication. In particular, the potential for catastrophic impacts as a result of eruptions or earthquakes requires a sensitive approach combining legal, political, cultural, and scientific perspectives to draw up plans that include moral and emotional awareness – for example, concerning attachment to property and livelihoods. In this respect, there are many studies that can be used to illustrate the importance of these aspects in the past, and the power of anecdote in this context should not be underestimated. Personal and societal narratives are a rich source of information about how particular societies handle uncertainty. Chester (2005) demonstrated the importance of religion in understanding the impact of disasters, and in planning for particular events: Local customs and beliefs have a significant impact not only on the way that the disaster itself is perceived, but also on the credibility of different kinds of authority. Thus, on Montserrat, the role of religious leaders in urging the population to listen to the scientists was very significant (Donovan 2010).

There are also questions about the ways in which risk assessments are represented to policymakers and publics. Recent studies by Gigerenzer (Gigerenzer et al. 2005; Gigerenzer 2008) have shown that public and academic understanding of probabilities may be inadequate. Studies of this nature are needed in the geophysical hazards as part of the process of refining the expression of risk assessments. In particular, work with policymakers in this regard would be very significant. It is clear from recent experiences (notably Montserrat) that scientists' understanding of political systems and requirements is important in facilitating the flow of information in a crisis. The "ash crisis," for example, showed that scientists between the UK and Iceland could exchange information relatively easily, but beyond the scientific community, communication became more challenging. The communication process is particularly worthy of consideration in handling uncertainty, because it generates so much uncertainty itself through the misunderstandings of individuals.

One of the key challenges in promoting transboundary risk assessment and management is the coordination of scientific research and policy advice: enabling governments to locate appropriate experts rapidly, and providing experts with advice about their role (e.g., Renn 2008). This could be carried out by an international geophysical organization, perhaps following the paradigm of the World Meteorological Organization. Mapping available expertise, advising scientists on their role, translating research, and facilitating technological support for decision making would be useful functions that are currently lacking (e.g., Sparks 2007). Academic research in its traditional form is rarely accessible for those who might benefit from it. Conversely, scientists and social scientists may not be aware of their rights and

responsibilities when providing advice. There are also philosophical and epistemological considerations, since science can be misused as well as misinterpreted. An important step forward in the management of future geophysical disasters would seem to be an international body to maximize the usefulness of expertise and research for risk reduction.

## Conclusions

This chapter has documented the recent history of volcanic and seismic hazards and risk assessment. It has looked at some key case studies of earthquakes and eruptions that have had significant impacts on the science and social science of risk assessment and management. In particular, it has discussed the growth of uncertainty discourses and the relationship between science and policy in the volcanic and seismic contexts. This is a growing area of research that has great potential for further development in an interdisciplinary framework. Public and political perception of low-probability, high-impact risks is generally marred by preoccupation with matters of daily life (Gaillard 2008). This puts pressure on the research community to expand its efforts into the public sphere through education initiatives – and this is often a major part of the role of volcano observatories, for example. However, in many areas at risk from these hazards, the political channels for scientific advice simply do not exist. Preparedness is often linked to recent history of seismicity or volcanic activity. Given the catastrophic potential of geophysical hazards (e.g., Self 2006; Smil 2008), much further work is required uniting social and physical scientists with policymakers, NGOs, and publics. Communicating the nature of uncertainty is central in this process.

**Abstract:** The aim of this chapter is to provide an overview over decision theory, in particular Bayesian decision theory, to explain its main ideas with some emphasis on risk and to flag the most important controversies about the theory. The paper starts out with the St. Petersburg paradox and motivates the idea that rational agents maximize expected utility. Since “rationality” is ambiguous, the attention is restricted to a core notion of rationality that evaluates an agent’s choices in relation to her desires and beliefs. Accordingly, in Bayesian decision theory, the expected utility arises from utilities and probabilities that measure the strengths of the agent’s desires and beliefs, respectively. This raises two questions: (1) Why do rational agents maximize expected utility? (2) How can the strengths of the agent’s desires and beliefs be measured? Both questions are commonly answered in terms of representation theorems. Such theorems show that the strengths of the agent’s beliefs and desires can be represented in terms of numerical probabilities and utilities if the choices she would take in hypothetical cases fulfill certain conditions. The theorems further entail that an option is preferred to another if and only if it has a higher expected utility than the latter. This chapter covers results by von Neumann–Morgenstern, Ramsey, Savage, and Bolker–Jeffrey. It discusses the consequences for choices that are risky in a nontechnical sense and concludes by pointing out major controversies concerning Bayesian decision theory.

## Introduction

---

If a person is rational, she will choose an option that maximizes what she expects to gain from her choice. This is, in very rough terms, the core of much decision theory, particularly of Bayesian decision theory. In more mathematical terms, it is claimed that a rational agent maximizes her expected utility. The expected utility arises from utilities that express the extent to which various outcomes are desired by the agent and from probabilities. Proponents of Bayesian decision theory – Bayesians, for short – stress that the probabilities express the degrees to which the agent believes certain propositions.

Decision theory is extremely influential in philosophy, economics, in the foundations of statistics (cf. French and Ríos Insua 2000; Robert 2007), and in other fields. It also shapes much thinking about risk, not just because risk is a technical term in decision theory, but also because it suggests advice how we should rationally choose from options that are risky in a nontechnical sense. The aims of this chapter are to unfold the idea that rational agents maximize expected utility, to review the most important results and controversies about this idea, and to discuss its consequences for risk. The emphasis is on Bayesian decision theory, but I will also cover other approaches from what I call *standard decision theory*. This term is my umbrella term for theories that take rational agents to maximize expected utility (see Sugden 2004 for alternatives).

Decision theory is centered on mathematical results and its achievements cannot be appreciated without some mathematics. But the mathematics can get quite involved and cannot be outlined in an chapter like this. I will therefore take a middle course and informally describe the most important mathematical results using examples. My aim is to get across the basic ideas rather than to make mathematically precise statements. I recommend Raiffa (1968), Fishburn (1979), Kreps (1988), Hammond (1998a), Hammond (1998b) and Sugden (2004) for more formal reviews of decision theory; see also Barberà et al (1998, 2004) and Peterson (2009).

The plan of this chapter is as follows: The remainder of the introduction motivates the idea that expected utility is maximized by rational agents. The section about history explains the most

famous related approaches in decision theory. I discuss the implications about risk in the section about current research. A survey of philosophical issues about decision theory is provided in the last section.

To begin, suppose that Peter wants to sell his old car. He can either sell it to a lawyer at a price of \$3,000. There is a chance of 20% that the car will break down in the next year, and to sell the car to the lawyer, Peter has to agree to pay him back \$2,000 in case the car breaks down. Alternatively, Peter can sell the car to his old friend Mary at a price of \$2,000. If she gets the car at this price, she agrees not to claim any money back if the car breaks down. What should Peter do? How should he decide?

One way to give Peter is advice is to consider the money that Peter will gain. Let us do so using a table. Peter has two *options* – selling the car to the lawyer and selling it to Mary. Depending on the *conditions* – whether the car will break down in the next year or not – the options lead to different *outcomes*. In  *Table 15.1*, each row represents an option and each column represents a condition. Accordingly, each box stands for an outcome that arises by combining an option and a condition. In each box, we note the money that Peter gains given an outcome. In the lower half of each box, we additionally put down the probability that the condition corresponding to the outcome obtains. For instance, the upper left box represents the outcome that arises if Peter sells the car to the lawyer and if the car does not break down. Peter will then obtain \$3,000 all in all. The probability of the car not breaking down is .8. Note that the probabilities in each row sum up to 1 – the conditions jointly exhaust the space of possibilities.

In the example, we assume that the probability of the car breaking down is .2, independently of whether the car is sold to the lawyer or to Mary. Accordingly, each box from the same column has the same probability. But the probability that the condition obtains may also depend on the option that Peter chooses. Maybe the car is more likely to break down if it is sold to the lawyer, because he uses the car more often than Mary would do. In this case, the probability in each box would have to be the conditional probability of the condition, given that Peter takes the option corresponding to the box.

Good advice for Peter could focus on the *expected monetary value* of each option. Consider selling the car to the lawyer first. With a chance of 80%, the car will not break down in the next year and Peter will not pay back anything, in which case the monetary value of the option for Peter is \$3,000. With a 20% chance, the car will break down, in which case the monetary value of the option for Peter is  $\$3,000 - \$2,000 = \$1,000$ . Thus, on average, the monetary value of the option for Peter is  $\$3,000 \times .8 + \$1,000 \times .2 = \$2,600$ . This is the expected monetary value of the option. If Peter were faced with the same decision many times and would always take the first option, he would very likely gain \$2,600 on average. Consider now the other option.

 **Table 15.1**  
A simple decision problem

	Car does not break down	Car breaks down
Sell car to lawyer	\$3,000 .8	\$1,000 .2
Sell car to Mary	\$2,000 .8	\$2,000 .2

The expected monetary value of the option is \$2,000 independently on whether the car breaks down or not. Thus, the expected monetary value is \$2,000. This is less than the expected monetary value of the first option. Peter is thus better off if he chooses the first option. It thus seems that Peter should take the first option.

When we generalize this idea, we come up with the following *decision rule*, call it the *maximum expected monetary value-rule* (MEMV):

*MEMV.* An agent should choose the option with the maximum expected monetary value. If several options maximize the expected monetary value, she is permitted to take any of these options.

But is MEMV a sensible rule for making decisions quite generally? Obviously, it is not. One reason is that money is not everything that is important about the options. There may be additional benefits for Peter if he sells his car to his old friend Mary – she will invite him to her famous parties, say. Now we may perhaps take this additional benefit into account by translating it into money too. But this would not get us very far for other reasons. The point is simply that money does not really count what matters to us. Suppose, for instance, that Peter needs additional \$2,000 at the end of next year and that he is in deep trouble if he does not have the money at that time. In this case, Peter should probably choose the second option because it gives him \$2,000 for sure. If he chooses the other option, on the contrary, there is some chance that he does not have the additional \$2,000 at the end of the year and thus runs into deep trouble (Resnik 1987, pp. 85–88; cf. also Lumer 2002, pp. 2–4).

That maximizing the expected monetary value is not a sensible idea can also be made vivid using the so-called *St. Petersburg paradox*. This point was made in a paper that was written by Daniel Bernoulli in 1738 and that is often thought to be the first work in utility theory (Bernoulli 1738/1954, crucial ideas in the paper are due to Gabriel Cramer). Suppose, you can buy a ticket for the St. Petersburg gamble, which is defined as follows. A fair coin is flipped until it lands heads for the first time. If  $n$  is the number of flips needed to produce the first heads, you are given  $\$2^n$ . Thus, you obtain \$2 in case the coin lands heads at the first flip; you obtain \$4 if the coin first lands tails and then heads, and so on. As the coin is fair, the probability to get \$2 is 1/2, the probability to get \$4 is 1/4, and so on. The expected monetary value of the gamble is thus

$$(\$2/2 + 2^2/2^2 + 2^3/2^3 + \dots),$$

which is infinity. The ticket for the gamble has a finite price. You have to decide between buying the ticket or not buying the ticket. If you maximize the expected monetary value, you should buy the ticket whatever price it has. The reason is that the expected monetary value of buying the ticket is infinite; the gamble will on average give you infinitely many \$, which will compensate for the price of the ticket. On the other hand, the expected monetary value of not buying the ticket is zero. The paradox arises because it seems insane to pay much money for a ticket intuitively. It can be shown, for instance, that you will obtain \$4 or less with a probability of 75%.

Bernoulli resolved the paradox by suggesting that the desirability of some amount of money does not increase in the same way as the amount itself increases. Put differently, the value of additional \$1,000 for you depends on the amount of money that you already own. \$1,000 is very valuable to you if you do not have any other money, but it does not make much of a difference if you have already \$1,000,000. This is captured by the *Law of Diminishing Marginal Utility*, which is well-known from economics (e.g., Samuelson and Nordhaus 2001, p. 86).

Bernoulli suggested that the desirability that some amount of money has for you is proportional not to this amount, but rather to its logarithm. That is, the desirability of \$1,000,000 is not just 1,000 times the desirability of \$1,000, but only twice the latter. One can show that, under this assumption, the expected monetary value of the St. Petersburg gamble is finite and that the gamble is not worth any price. The counterintuitive consequences of the St. Petersburg paradox are avoided. To avoid similar counterintuitive consequences concerning gambles that are similar to the St. Petersburg gamble, the desirability of money has to be bounded from above (Menger 1931; see also Resnik 1987, pp. 107–109).

We conclude that MEMV is not a good idea. But it seems easy to amend MEMV. We require that not the expected monetary value, but rather the expected *desirability* of a choice be maximized. Let us assume that the desirability of an outcome can be measured in quantitative terms using *utilities* (more on this shortly). Suppose further that the utilities of our decision problem are as in  [Table 15.2](#). Note that the utility of an outcome is not proportional to the money it affords Peter.

To give advice to Peter, let us calculate the *expected utility* (rather than the expected monetary value) for each option. We obtain an expected utility of  $.8 \times 200 + .2 \times 100 = 180$  for the first option and an expected utility of 190 for the second option. Thus, Peter should sell the car to Mary.

We have now applied the *maximum expected utility-rule (MEU)*:

*MEU*. An agent should choose the option with the maximum expected utility. If several options maximize the expected utility, she is permitted to take any of these options.

Utility maximization avoids some pitfalls of MEMV. But the question is nevertheless

(Q) Is MEU is defensible? Should people really maximize expected utility?

Alternative rules are possible. For instance, the agent could focus on the minimum utility possible under an option and then try to maximize this minimum amongst the options. This is the famous Maximin rule (Resnik 1987, pp. 26–28, see also Rawls 1971, Part I, particularly §26 and Gardiner 2006).

The question whether MEU is defensible (Q) turns on two other questions.

(Qa) Where do the utilities come from? I have said that a utility measures the desirability of an outcome, but what kind of desirability are we talking of? Are we concerned with moral desirability, with desirability for Peter – call this prudential desirability – or with some other desirability? And how is the relevant desirability measured using numbers?

(Qb) Where do the probabilities come from? How do we obtain their values?

 **Table 15.2**  
The decision problem

	Car does not break down	Car breaks down
Sell car to lawyer	200	100
	.8	.2
Sell car to Mary	190	190
	.8	.2

The numbers in the upper halves of the boxes represent the utilities of the outcomes

Clearly, whether MEU is defensible turns on what the utilities and probabilities express and how their values are determined.

We cannot answer the questions (Q), (Qa), and (Qb) unless we decide what the focus our theory should be and what kind of advice we are interested in. Let us first think about *desirability* (Qa). We may decide to understand “desirability” as *moral* desirability. Desirability would then have to be the kind of value that matters for morality, and the utilities would measure it. With such a notion of desirability, MEU would become a moral principle and its “should” would concern the moral rightness of choices. As is well-known, utilitarianism defends something like MEU as the principle of morality (for utilitarianism see e.g., Sen and Williams 1982; Glover 1990; Shaw 1999 and Darwall 2002). If we understand MEU as a candidate for a moral principle, the decisive questions are whether we can quantify moral desirability using utilities (Qa) and whether maximizing moral desirability gives a defensible account of moral rightness (Q).

Alternatively, we may want to develop a theory of *prudential* reason. The utilities would then have to measure how much the outcomes contribute to the well-being of some fixed person (presumably the agent). The decisive questions then are whether the well-being of a person can be measured using utilities (Qa; see Griffin 1989, Part II) and whether maximizing one’s well-being in this sense is a defensible account of prudential reason (Q).

Decision theorists take yet another line. They think of desirability in terms of what the agent desires. An outcome is taken the more desirable, the more it is desired. Decision theorists thus use MEU to judge the agent’s choices by her own lights, i.e., from the standpoint of her own desires. A related judgment concerns the rationality of a choice – a *rational* agent will choose that option that maximally reflects what she wants. Thus, MEU is about what agents should do rationally. The decisive questions then are whether the strengths of a person’s desires can be measured using utilities (Qa) and whether maximizing desirability in this sense is a defensible account of rational choice (Q).

The term “rational” is of course ambiguous. Decision theorists conceive of rationality in a fairly minimal sense. This sense of rationality may be called *means-ends rationality* or *instrumental rationality* (recent philosophical work about means-ends rationality includes Bratman 1987; Kordsgaard 1997; Wallace 2001; Broome 2002; Smith 2004 and Raz 2005). Very roughly, an agent is means-ends rational if and only if (iff, for short) she takes means that she regards to be appropriate to realize her ends or to satisfy her desires. Conversely, we can criticize an agent as not fully means-ends rational if, in a certain situation, only one of her ends is relevant and if she does not take an option that she takes to be necessary and sufficient to realize it. This example is often used to explain instrumental rationality, but the assumption that there is only one relevant aim and that exactly one option is taken to be necessary and sufficient to realize the aim is completely unrealistic in most cases. Typically, there are many things that the agent wants, and each option will make a difference to many things that the agent wants. What then does means-ends rationality require in such a case? MEU is a candidate for spelling out means-ends rationality quite generally. The idea is that a rational agent maximizes the expectation value of what she wants.

Read in this way, MEU is still normative. It is about what one should do in some sense of “should.” There is an alternative way to understand MEU. The idea is that MEU constrains the choices of agents that are rational in a technical sense. I will come back to a related reading of MEU in the last section of this chapter.

Let us now think about the *probabilities* and where they come from (Qb). A theorist faces two basic options. One can either let the probabilities reflect real-world chances. This is particularly

plausible for gambles such as the St. Petersburg gamble. Presumably, each coin has a well-defined objective probability to land heads. The alternative is to say that the probabilities reflect the agent's own expectations. The probabilities will then express how likely the agent takes it to be that an option leads to a specific outcome. In slightly different terms, they measure the extent to which the agent believes that an option leads to a specific outcome. They measure degrees of belief or levels of confidence (see Kyburg and Smokler 1964 for an anthology).

*Bayesian* decision theory opts for the second alternative. That is, Bayesian decision theorists use MEU to judge an agent by her own lights not just as far as the utilities are concerned, but also concerning the probabilities. The choices of the agent are judged in relation to her own desires and beliefs. It is arguable that we are now talking about the centerpiece of rational choice and rational agency. The reason is that we only call a choice irrational if the agent fails by her own lights, i.e., relative to her own desires and beliefs. On the contrary, if an agent does what she *falsely takes* to serve her ends maximally, her choice is not irrational, but rather ineffective (cf. Scanlon 1998, Chap. 1).

Here then is the core of Bayesian decision theory (BDT):

*BDT.* An option is rational to choose iff it maximizes the expected utility of the agent (if several options tie at the maximum expected utility, each of them is rational to choose). The expected utility of an option is the expectation value of the utility of the outcome, given this option. Here the utility of an outcome measures the degree to which the outcome is desired by the agent. The expectation value is formed using probabilities that reflect the degrees of confidence that the agent assigns to an outcome, given that a particular option is chosen.

Three warnings are in order. First, no presumption is made concerning the content that the desires of the agent have. It is neither assumed that the agent only cares about her own good nor that her desires are only directed at her own pleasure. This may or may not be so. As has often been pointed out, it is unfortunate to speak of utilities in decision theory given that hedonic accounts of utility dominated in early utilitarianism.

Second, to form an expectation value of a utility, one has to have probabilities. What is most important for BDT from a conceptual point of view is that the probabilities reflect the agent's own beliefs about the world – otherwise we would not be talking about rationality in the core sense picked by Bayesians. As already indicated, Bayesians take probabilities to measure *degrees of belief*. The basic assumption is that belief comes in degrees. This can be motivated using the preface paradox (Makinson 1965; Foley 1992; Hawthorne and Bovens 1999). The agent's probability for a proposition is then taken to be the degree to which the agent believes the proposition. A proposition that is endorsed as true by the agent has a degree of belief or probability 1. A proposition that is believed to be false or disbelieved has 0 as its degree of belief or probability. Propositions that the agent is not certain about have a degree of belief strictly between 0 and 1 (it is not clear whether there is also a type of belief that does not come in degrees and how it is related to credences that do have degrees). The idea that probabilities measure degrees of belief may also be employed more generally to explain what probabilities are and what probabilistic statements mean. Views that take probabilistic statements to express degrees of belief of the speaker are called subjectivist. The important point to note is that BDT does not entail a subjectivist view for every probability. It is compatible with BDT that some probabilities are objective, for instance, that they reflect propensities (dispositions) of real-world systems. BDT is not meant to yield a general interpretation of probabilities

(for interpretations of probabilities see Fine 1973, Howson 1995, Gillies 2000; Hacking 2001; Mellor 2005 and Hájek 2010; see also Hacking 1975, 1990; Skyrms 1999; Jeffrey 2004 and Howson and Urbach 2006).

Third, BDT has an “if,” and not an “iff.” It claims a necessary condition of rational choice, but we need not think that this is the only constraint of rationality. In the example, Peter may not be fully rational if another possible constraint is violated, e.g., if his utilities would not stand certain reflection. Maybe, the utilities would change and become more rational if Peter tried to imagine what it means to sell the car to Mary. Additionally, Peter may not be rational if his probabilities do not properly reflect his evidence (more on this later). Whether there are such additional constraints of rationality is not at issue when we think about BDT. In particular, the central results of standard decision theory apply to one single choice. They do not constrain how utilities and probabilities (or desires and beliefs) should rationally change (see below for qualifications). We may thus say that BDT is concerned with synchronic aspects of rationality. One reason is that decision theory and BDT in particular have chosen to focus on a narrow core of practical rationality to begin with.

BDT is a development of MEU. We have obtained BDT by determining the focus of the theory. This is a first step to answer our above questions. But we have not yet answered these questions. So is BDT a defensible claim about rationality (Q)? And how can one measure the extent to which something is desired using utilities (Qa)? Finally, how can one measure degrees of belief using probabilities (Qb)?

To answer these questions is the point of much formal decision theory. An answer is often provided in terms of a *representation theorem*. Most representation theorems come in two parts. First, there is an existence claim according to which one can represent the strengths of desires and beliefs using numbers, viz. utilities and probabilities. The representation is such that the rational option to choose maximizes expected utility. Second, there is a uniqueness claim according to which the representation is unique in some sense. Of course, a unique representation is only possible under certain assumptions. These assumptions are a matter of much philosophical discussion.

In the following section, I will present four approaches to obtain a representation theorem. As we will see, some of the approaches do not really get us as far as BDT. I will nevertheless survey them because they are important in decision theory.

## History

---

### The Von Neumann–Morgenstern Representation Theorem

---

The most important step in utility theory after Bernoulli's 1738 paper was presumably the representation theorem by John von Neumann and Oskar Morgenstern (1947) (cf. Fishburn 1989). Their aim was to provide foundations for utility theory, which was at that time already used in economics. It was notoriously unclear though what utilities are. The early hedonic conceptions due to Bentham (1789) and Mill (1863) are problematic for both descriptive and normative purposes. The crucial idea of von Neumann and Morgenstern is to identify the utility of an outcome with the degree to which it is desired. They provide a precise method to obtain numerical utilities. Their theorem does not provide a method to measure degrees of belief though because the probabilities are assumed as given. For similar results see Marschak (1950), Herstein and

Milnor (1953), Hausner (1954) and Luce and Raiffa (1957, Chap. 2). In the following, I will not follow von Neumann and Morgenstern, but rather present a more elegant version of a von Neumann–Morgenstern-style representation theorem due to Jensen (1967) and rely on Hammond (1998a, pp. 152–164).

Let us start from the idea that rational agents maximize expected utility. To calculate the expected utility of an option, we need a utility for each possible outcome. In mathematical terms, each outcome  $a$  has to be mapped to a real number  $u(a)$ , which is called its utility.  $u(a)$  is supposed to *represent* the extent to which the outcome  $a$  is desired. Some outcomes are more strongly desired than others or (*strictly*) *preferred* to them, as I shall also say. Let us introduce some abbreviations and let “ $a \succ b$ ” denote that  $a$  is preferred to  $b$ . That  $a$  is preferred to  $b$  means that the agent will always choose  $a$  if presented with a choice between outcomes  $a$  and  $b$ . Preferences and thus desires are thus connected to hypothetical choices (see Fehige and Wessels 1998 for a collection about preferences).

If the utilities are to represent the extents to which outcomes are desired by the agent, or her preferences, for short, the utility of an outcome  $a$ ,  $u(a)$ , should be larger than that of an outcome  $b$ ,  $u(b)$ , if  $a$  is preferred to  $b$  (i.e., if  $a \succ b$ ). Let us therefore require that

$$u(a) > u(b) \text{ iff } a \succ b. \quad (15.1)$$

Here, the first “ $>$ ” sign denotes the “larger than”-relation among numbers.

As is well-known, one cannot always find a mapping  $u$  that satisfies our requirement. Suppose, for instance, that the agent has cyclic preferences. She prefers  $a$  to  $b$ ,  $b$  to  $c$ , and  $c$  to  $a$ . Any mapping from outcomes into real numbers that respects our requirement of representation would have to obey:

$$u(a) > u(b), \quad u(b) > u(c), \quad u(c) > u(a).$$

But this is impossible for any numbers  $u(a)$ ,  $u(b)$  and  $u(c)$  since it implies  $u(a) > u(a)$ , which is plainly false. The agent must not have any cyclic preferences if a representation is to be possible.

Now to have cyclic preferences is in fact odd. Suppose, Peter prefers a salad to a pizza, a pizza to pasta, and pasta to a salad. What is he to choose if he has to take exactly one of them? If Peter prefers the salad to the pizza, he should be happy to pay a bit of money to get the salad rather than the pizza. If he prefers the pizza to pasta, he should be happy to pay a bit to get the pizza instead of pasta. And if he prefers pasta to the salad, he should be happy to pay a bit to get pasta instead of the salad. It then seems that we can get arbitrary amounts of money from Peter by arguing him through the circle many times (Binmore 2009, pp. 13–14).

Since Peter’s preferences seem odd in this case, we can deem Peter irrational and confine ourselves to rational agents. The hope is that at least the preferences of *rational* agents can be represented in the way envisaged. Let us therefore assume an axiom that constrains the preferences of rational agents. A very efficient way to do so is to adopt the following axiom, which I call vNM1 due to the relation to the von Neumann–Morgenstern utilities (see Kreps 1988, Chap. 2).

*vNM1.* The preferences of a rational agent are asymmetric, i.e., no outcome is preferred to itself (we never have  $a \succ a$ ). The preferences of a rational agent are also negatively transitive, i.e., if  $a$  is preferred to  $b$ , then any outcome  $c$  will either be preferred to  $b$  or else will  $a$  be preferred to  $c$  (i.e., if  $a \succ b$  we have for all  $c$ :  $c \succ b$  or  $a \succ c$ ).

The strategy to confine oneself to *rational* agents and to lay down *axioms* for the preferences of rational agents is standard in decision theory (for simplicity I will often drop the qualification “rational” in “rational agent”). The strategy is to some extent innocuous because BDT is about the choices of rational agents only. The strategy has nevertheless a price because vNM1 is a substantive claim about rational agents. It purports to constrain the preferences of rational agents. That it does so may be denied, and much criticism of standard decision theory is based upon the charge that the theory misinterprets rational choice.

As a consequence, decision theory is really rationality-in rationality-out. It does not provide constraints of rationality for free. It is rather based upon substantive assumptions about rational choice. These assumptions are in a way translated into the maximization of expected utility.

For the following, it is useful to introduce more notations. We will say that outcome  $a$  is no less desired than  $b$ ,  $a \succeq b$  iff it is false that  $b \succ a$ . The agent will be said to be *indifferent* between outcomes  $a$  and  $b$ ,  $a \equiv b$  iff  $a$  is no less desired than  $b$  and  $b$  is no less desired than  $a$ . Our requirement of representation implies that

$$u(a) \geq u(b) \text{ iff } a \succeq b$$

and that

$$u(a) = u(b) \text{ iff } a \equiv b.$$

Assuming vNM1, we can obtain a first, very simple representation theorem, call it ORT (representation theorem with ordinal utilities; Kreps 1988, Chap. 3):

*ORT.* Assume that vNM1 holds and that the number of possible outcomes is finite or countable.

Then there is a mapping  $u$  from the outcomes to the real numbers such that (► 15.1) is satisfied.

ORT grants the existence of a representation. As the preferences of the rational agent impose a certain order on the outcomes, and as this order is preserved using the mapping  $u$ , the latter is called an *ordinal utility function*. Note though that the mapping and thus the representation is not unique. If  $u$  furnishes a representation, so does  $fu$ , the composition of  $u$  with any strictly monotonically increasing function  $f$  from the real numbers to the real numbers (Kreps 1988).

ORT underwrites the maximization of utility. For it is a platitude that rational agents choose what they prefer most (at least if we restrict the notion of rationality suitably). Given our representation, this is equivalent to saying that a rational agent chooses an option with a maximal utility.

All this is still far from BDT. We want to underwrite the maximization of *expected utility* in decisions such as Peter’s. To that end, von Neumann and Morgenstern and their followers introduce a new type of option. Let us start from a set of outcomes  $S$ . The new options are *lotteries*. If the agent chooses a lottery, a gambling device is used, for instance, a coin is flipped, and, depending on the result (heads or tails), a *prize* from  $S$  is realized. Each lottery only gives a finite number of prizes with a nonzero probability. Each outcome  $a$  from  $S$  can itself be regarded as a lottery that gives  $a$  for sure. Clearly, lotteries model options under which the outcomes are not fixed, but chancy.

The set of all lotteries with prizes in  $S$  has a certain structure; it is a mixture space. The essential point is that one can combine two lotteries to form a new lottery in the following way.

Assume that  $\mu$  and  $\lambda$  are lotteries and take  $\alpha$  to be a real number from the interval  $[0,1]$ . Under the new lottery, each outcome  $a$  from  $S$  has a probability of  $\alpha \times p_\lambda(a) + (1 - \alpha) \times p_\mu(a)$  if it has a probability of  $p_\lambda(a)$  under lottery  $\lambda$  and a probability of  $p_\mu(a)$  under lottery  $\mu$ . If the agent does not care how the values of the probabilities for the prizes arise, we can think of the new lottery as a two-stage lottery. In the first stage, a coin is flipped that lands heads with a probability of  $\alpha$ , and tails with a probability of  $(1 - \alpha)$ . If the coin lands heads, lottery  $\lambda$  is played in the second stage, whereas lottery  $\mu$  is played in the second stage if the coin lands tails. The new lottery is called a *compound lottery*; for obvious reasons, it is denoted as  $\alpha \times \lambda + (1 - \alpha) \times \mu$ .

Our question now is: What does it mean to choose rationally between lotteries? How are the preferences over lotteries constrained for rational agents?

It is first natural to assume that the agent's preferences over the lotteries obey the axiom vNM1. But we need two further assumptions to obtain expected utilities. The first is the *independence axiom*.

vNM2. Suppose that  $\lambda$ ,  $\mu$ , and  $\nu$  are lotteries and assume that  $\lambda$  is preferred to  $\mu$  (i.e.,  $\lambda \succ \mu$ ).

Then the compound lottery  $\alpha \times \lambda + (1 - \alpha) \times \nu$  is preferred to the compound lottery  $\alpha \times \mu + (1 - \alpha) \times \nu$ .

The independence axiom is not implausible (but see McClenen 2001). To see this, compare the alternative options  $\alpha \times \lambda + (1 - \alpha) \times \nu$  and  $\alpha \times \mu + (1 - \alpha) \times \nu$ . Let us think of them as two-stage lotteries with the same random process at the first stage. For instance, a coin is flipped that lands heads with a probability of  $\alpha$  and tails with a probability of  $(1 - \alpha)$ . If the coin lands tails, each of our two alternative lotteries gives  $\nu$ , in which case there is no difference between the lotteries. If the coin lands heads, the first lottery gives  $\lambda$ , whereas the second gives  $\mu$ . But  $\lambda$  is preferred to  $\mu$ . So it seems plain that the first lottery should be preferred to the second. The idea is that the ranking between the lotteries only depends on those cases in which the lotteries differ (see Machina 1982 for generalizations of expected utility theory without the independence axiom).

The last axiom is the *continuity axiom*.

vNM3. Suppose that  $\lambda$ ,  $\mu$ , and  $\nu$  are lotteries and assume that  $\lambda$  is preferred to  $\mu$  ( $\lambda \succ \mu$ ) and that  $\mu$  is preferred to  $\nu$  ( $\mu \succ \nu$ ). Then there is a real number  $\alpha$  strictly between 0 and 1 such that the compound lottery  $\alpha \times \lambda + (1 - \alpha) \times \nu$  is preferred to  $\mu$ . Likewise and conversely, there is another real number  $\alpha$  strictly between 0 and 1 such that  $\mu$  is preferred to  $\alpha \times \lambda + (1 - \alpha) \times \nu$ .

This is again not implausible. Suppose that  $\mu$  is ranked between  $\lambda$  and  $\nu$ , as is assumed in vNM3. Consider now compound lotteries of the type  $\alpha \times \lambda + (1 - \alpha) \times \nu$ . All of these lotteries can lead to  $\lambda$  and  $\nu$ ; however, their probabilities for  $\lambda$  and  $\nu$  differ. If  $\alpha = 1$ , the compound lottery coincides with  $\lambda$  and is thus preferred to  $\mu$ . Likewise, if  $\alpha = 0$ , the compound lottery coincides with  $\nu$ , and thus  $\mu$  is preferred to it. Let us now start with  $\alpha = 1$  and decrease  $\alpha$ . Thus, in the compound lottery, the higher ranked  $\lambda$  becomes less likely in favor of the lower ranked  $\nu$ . It is thus plausible to assume that the compound lottery becomes increasingly lower ranked for the agent. It is also plausible to think that, at some point, the compound lottery passes  $\mu$ . What the continuity axiom implies in this intuitive picture is this: There is a value of  $\alpha$  smaller than 1 such that the compound lottery is still preferred to  $\mu$ . Likewise, there is a value of  $\alpha$  larger than 0 such that  $\mu$  is already preferred to the compound lottery.

We can now state the *von Neumann–Morgenstern representation theorem* (vNMRT). Its first part, vNMRT.E, grants the *existence* of a representation:

vNMRT.E. Assume that vNM1 – vNM3 hold for a rational agent. Then there is a mapping  $u$  from the outcomes to the real numbers such that a lottery is preferred to another one iff its expected utility is larger than that of the second lottery.

As before, we obtain the expected utility of a lottery by adding the products of the utilities of the outcomes,  $u(a)$ , with their respective probabilities under the lottery.

vNMRT.E effectively introduces a new type of representation. A lottery is preferred to another iff its *expected* utility is higher. In this way, lotteries are evaluated using not their own utilities, but expected utilities. These derive from the utilities of the prizes and the probabilities. In this way, vNMRT.E underwrites the maximization of expected utility. To the extent that a rational agent conforms to vNM1 – vNM3 and chooses what she prefers most, she maximizes the expected utility.

The second part of the theorem, call it vNMRT.U, is about *uniqueness*.

vNMRT.U. The representation is unique up to affine transformations.

A transformation is affine if it is positive and linear. vNMRT.U implies that, if the utilities  $u(a)$  represent the agent's preferences, so do the utilities  $\alpha \times u(a) + \beta$ , where  $\alpha > 0$  and  $\beta$  are arbitrarily fixed real numbers. But vNMRT.U also grants that there are no other representations than these. Put differently, utilities do not have a zero point nor natural units. However, ratios of utility differences are uniquely fixed. This is necessary if the maximization of expected utility is to make sense. In  Table 15.2, for instance, it matters, not just which utility is larger than which, but also how utility differences compare to each other. It is important for the final choice that the difference between the utilities in the second column ( $100 - 190 = -90$ ) is  $(-9)$  times the difference between the utilities in the first column ( $200 - 190 = 10$ ). If the ratio of the differences were  $(-3)$  instead of  $(-9)$ , maximizing expected utility would favor the first option rather than the second. We have thus to make sense of utility differences being equal or being multiples of each other. This is achieved by the representation theorem by von Neumann and Morgenstern. It yields *cardinal* utilities.

The theory can easily be applied in practice (cf. Luce and Raiffa, Chap. 2; see below for a proviso). Consider Peter's decision with his car once more. There are four outcomes (car not breaking down and sold to the lawyer; car breaking down and sold to lawyer, etc.). As a rational agent, Peter should be able to rank these outcomes. Without loss of generality, he can set the utility of the highest ranked outcome at 1, and the utility of lowest ranked outcome at 0. For each other outcome  $a$ , he has to find a lottery that has only the highest and lowest ranked outcomes as prizes and that is equally ranked with  $a$ . If Peter's preferences satisfy the axioms, it is granted that there is such a lottery for each  $a$ . In this way, Peter will obtain a unique utility for each outcome. To determine what *option* to choose rationally, Peter has to think of the options as lotteries. For instance, the first option may be regarded as a lottery that provides one outcome with a probability of .8 and the other with .2. Peter should then choose the option that maximizes expected utility.

There is, however, a problem about the probabilities. In von Neumann–Morgenstern utility theory, they are simply put in by hand. They arise as parts of the lotteries that are presented as options. The probabilities are supposed to be intelligible (otherwise the lotteries would not be so), and they are assumed to obey the probability calculus. The theory does not say much as to

what the probabilities are and where their values come from. This is not very satisfying from a theoretical point of view.

It is often assumed that the probabilities are objective chances that characterize gambling devices such as roulette wheels. That is, there are mind-independent facts as to what the values of the probabilities are. The objective probabilities may quantify the strength of a disposition or be defined in terms of hypothetical frequencies. Under such an objectivist reading of the probabilities, von Neumann–Morgenstern theory only applies to lotteries that involve gambling devices or other systems for which an objective probability is defined. However, many real-world situations such as Peter's in our example are not like this. Here the probabilities are not objective, but rather reflect the agent's ignorance as to what outcome a choice may produce. We can only apply the von Neumann–Morgenstern theory to such cases if we grant that the axioms of the theory continue to hold for choices in which probabilities reflect the agent's ignorance (cf. Pfanzagl 1967). But can we take this assumption for granted?

Anscombe and Aumann (1963) provide an extension of von Neumann–Morgenstern utility theory to include subjective probabilities. They introduce two kinds of lotteries, viz. roulette lotteries and horse-race lotteries. Whereas the outcomes of the former have objective probabilities, the outcomes of the latter have not. Anscombe and Aumann consider compound lotteries that involve both roulette and horse-race lotteries. They assume that the agent's preferences over roulette lotteries obey the axioms of von Neumann–Morgenstern utility theory (or our axioms from above). Likewise, the agent has preferences over horse-race lotteries that have roulette lotteries as prizes. These preferences obey the axioms of von Neumann–Morgenstern utility theory as well. So we obtain two kinds of rankings and correspondingly two kinds of utilities – one for horse-race lotteries and one for roulette lotteries. Anscombe and Aumann make a few weak assumptions about how the two sorts of preferences are connected. Their main result is that the agent prefers one horse-race lottery to another iff a certain linear combination of the utilities of the prizes is higher. The coefficients that arise in this linear combination take the role that probabilities take in the assessment of roulette lotteries and can thus be interpreted as subjective degrees of belief.

Under Anscombe and Aumann's theory, a rational agent maximizes an expected utility that arises from subjective probabilities. Moreover, the subjective probabilities are not put in by hand, but are instead obtained from the preferences of the agent. So the theoretical problem about probability in the von Neumann–Morgenstern theory is to some extent avoided. However, the subjective probabilities only arise from preferences concerning gambling devices that can be characterized using objective probabilities in turn. In this sense, objective probabilities are conceptually prior. This allows for a certain criticism because the notion of an objective probability is sometimes taken to be problematic. The question then is whether we can do without objective probabilities altogether. The answer is positive and was in fact given prior to von Neumann and Morgenstern by Ramsey.

## Ramsey's Approach

Frank P. Ramsey's approach is contained in his paper "Truth and Probability" (Ramsey 1931), which was written about 1926 and first published in 1931. It did not become influential until much later, but it is no exaggeration to say that it contains the core of Bayesian decision theory.

Ramsey did not elaborate the details, but Suppes (1956) provides a logical reconstruction of Ramsey's proposal (see also Davidson and Suppes 1956; cf. also Bradley 2001).

Ramsey's aim is different from that of von Neumann and Morgenstern and in some way complementary to theirs. The latter want to provide foundations for utility theory, and their main idea is that utility represents the degree to which something is wanted. Ramsey's primary interest is in probability theory. He identifies probabilities (or at least some of them) with degrees of belief. Thus, probabilities *represent* degrees of belief. Each proposition  $q$  about which the agent has views is mapped to its probability  $p(q)$ . We require that  $p(q) > p(r)$  iff the agent is more confident about  $q$  than she is about  $r$ .

But what does it mean to say that one proposition is more strongly believed than another one? And what does it mean that a proposition  $q$  is believed to a degree  $p(q)$ ?

Ramsey's crucial idea is that degrees of beliefs are determined in virtue of the *effects* they would have on action. Note that Ramsey explains degrees of belief not just in terms of *actual* effects that belief states have on *actual* actions, but also using hypothetical effects a belief state would have, provided a rational agent faced a suitable choice.

Suppose, we want to know the degree to which Peter believes that his car will not break down in the next year. To find this out, we can ask him what he would do if he were faced with a choice between the following two options: Either selling the car to the lawyer or selling it to Mary. As things are in the example, the options boil down to something like (obtain \$3,000 from the lawyer if the car does not break down; obtain \$1,000 from him if it does) and (obtain \$2,000 and additional benefits from Mary if the car does not break down; obtain \$2,000 and fewer additional benefits if the car does do so). Peter is thus confronted with two different *bets* on the truth of the proposition that his car does not break down. Assume now that the utilities from  Table 15.2 specify how strongly the various outcomes are desired. Qualitatively, if Peter is almost certain that his car will not break down in the next year, he would give it to the lawyer if he faced the decision. If he is much less confident that his car will not break down, on the contrary, he would choose to give it to Mary. Thus, by confronting Peter with the hypothetical choice, we can constrain the strength of his confidence. As we shall see presently, we can extend this story to obtain quantitative degrees of belief. The more general point is that we can obtain probabilities, when we have a suitable set of outcomes with their utilities and when we consider the hypothetical choices that an agent would make if she were faced with certain bets. De Finetti's definition of subjective probabilities is based upon this idea (de Finetti 1931, 1937). His approach is obviously the counterpart of von Neumann–Morgenstern expected utility theory.

De Finetti's approach suffices to define probabilities, but there is a problem with it if our interest is in decision theory. What Peter would choose in a hypothetical choice is not only a function of his beliefs about the car, but also of the extent to which he desires the outcomes that can arise. We can only obtain probabilities in this way if utilities are provided. But how do we obtain the utilities? So far, we have only von Neumann–Morgenstern utilities, which were derived taking for granted some probabilities, and we are moving in a circle. What we should aim at then is to obtain utilities as measures of strength of desire and probabilities as measures of strength of belief *at the same time*. And the only facts that determine those strengths concern the hypothetical choices an agent would make if faced with suitable sets of options. The problem is that beliefs of various degrees and desires of various degrees cooperate to determine what the agent would choose. To obtain degrees of belief, we have to disentangle them from the

agent's desires with their various strengths. The virtue of Ramsey's approach is that it obtains both utilities and probabilities from hypothetical choices or preferences.

Assume an agent has preferences over a set of *outcomes* such that vNM1 is fulfilled. There are also *propositions* about which the agent has views and to which subjective probabilities will be assigned. Finally, the agent is faced with hypothetical choices between *bet-like options*, under which the outcome is a function of the truth of a proposition. These options need not involve gambling devices – the idea is only that, *given what the agent thinks*, various outcomes are possible for some option.

Ramsey assumes that some propositions are *desire-neutral*. The truth of such a proposition  $q$  makes never a difference as to how much an outcome is wanted. Thus, for any outcome  $a$ , the agent is indifferent between the options “ $a$  is realized and  $q$  (is true)” and “ $a$  is realized and  $q$  is false.” A good candidate for a desire-neutral proposition is the proposition that the number of people at Times Square at noon tomorrow is even. Whether this is so or not will not affect the degrees to which outcomes are desired by most people.

Ramsey's account can now be developed in three steps. The *first step* is to identify propositions that will obtain a degree of belief of .5. Suppose that the agent prefers outcome  $a$  to  $b$ . It thus matters to her whether  $a$  or  $b$  will obtain. Consider now a desire-neutral proposition  $q$ , its negation  $\neg q$  and the following options: “ $a$  if  $q$ ;  $b$  if  $\neg q$ ” and “ $b$  if  $q$ ;  $a$  if  $\neg q$ .” These are bets on the truth of  $q$ , but the bets differ because they connect the outcomes  $a$  and  $b$  to the truth of  $q$  in different ways. Ramsey proposes to say that the agent takes proposition  $q$  and its negation  $\neg q$  to be *equally probable* iff she is indifferent between the bets. In this case, the degrees of belief concerning  $q$  and  $\neg q$  are equal and they obtain the value .5.

This is exactly what an expected utility formalism would imply. If we know that  $p(q) = p(\neg q)$ , the expected utility of the first option is  $p(q) \times u(a) + p(\neg q)u(b) = p(q) \times (u(a) + u(b))$ , and the expected utility of the second option is  $p(q) \times u(b) + p(\neg q) \times u(a) = p(q) \times (u(a) + u(b))$ , which is the same. Since the utilities are identical, the agent is indifferent between the options.

The *second step* is to define when utility differences of two outcomes are equal. Consider the four outcomes  $a$ ,  $b$ ,  $c$ , and  $d$ . We want to say that

$$u(a) - u(b) = u(c) - u(d).$$

Not just is  $a$  preferred to  $b$ , and  $c$  to  $d$ , but also is  $a$  preferred to  $b$  to the same extent that  $c$  is preferred to  $d$ . But what exactly is this supposed to mean? Ramsey proposes the following condition: Let  $q$  be an desire-neutral proposition with  $p(q) = .5$ . The utility differences are identical and the equation holds iff the agent is indifferent between the following choices: “ $a$  if  $q$ ;  $d$  if  $\neg q$ ” and “ $b$  if  $q$ ;  $c$  if  $\neg q$ .”

This condition is again motivated by the idea that the preferences of a rational agent can be represented using expected utilities. If this is so, the agent is indifferent between two options iff the expected utilities are identical. The expected utilities of the options are  $p(q) \times u(a) + p(\neg q) \times u(d)$ , and  $p(q) \times u(b) + p(\neg q) \times u(c)$ , respectively. If they are identical, we have  $p(q) \times u(a) + p(\neg q) \times u(d) = p(q) \times u(b) + p(\neg q) \times u(c)$ . Since proposition  $q$  is desire-neutral, we have  $p(q) = p(\neg q)$ , and it follows that  $u(a) - u(b) = u(c) - u(d)$ , as stated above. Ramsey's condition makes only sense though if it holds for *any* desire-neutral proposition with  $p(q) = p(\neg q)$ . Ramsey introduces this as an assumption.

The *third* step, finally, is to fix the probabilities of arbitrary propositions. According to Ramsey, an agent believes a proposition  $q$  to a degree of  $p(q)$  iff the agent is indifferent between the following two options “ $a$  in any case” and “ $b$  if  $q$ ;  $c$  if  $\neg q$ ,” where the utilities for the outcomes  $a$ ,  $b$ , and  $c$  obey:  $(u(a) - u(c))/(u(b) - u(c)) = p(q)$ . To say this is again no more than reading expected utilities in the choices of the agent. Our agent is indifferent between the options mentioned iff the expected utilities are identical. This is equivalent to  $u(a) = p(q) \times u(b) + p(\neg q) \times u(c) = p(q) \times u(b) + (1 - p(q)) \times u(c)$ , where we assume that  $p(\neg q) = 1 - p(q)$ , as is familiar from the probability calculus. Thus, indifference is equivalent to  $p(q) = (u(a) - u(c))/(u(b) - u(c))$ , which is exactly the condition that Ramsey proposes.

In this way, we obtain probabilities that measure degrees of belief and utilities that measure the degrees to which outcomes are wanted by an agent. One can show that the degrees of belief obey the rules of the probability calculus. One can also obtain a representation theorem, according to which an agent prefers a bet-like option to another iff the expected utility is higher than the other. The representation of degrees of belief turns out to be unique, utilities are determined up to an affine transformation as before.

However, to obtain these results, some assumptions have to be made (see Ramsey 1931, pp. 74–75 and Suppes 1956). For instance, if the account is to work, an agent that prefers outcome  $a$  to  $b$  must prefer ( $a$  if  $q$ , and  $b$  if  $\neg q$ ) to  $a$ . An axiom that requires this may again be introduced as a constraint of rationality. Ramsey also needs a lot of outcomes that are desired to the same extent as are bet-like options. Axioms that guarantee this cannot plausibly be read as constraints of rationality, but rather concern the availability of suitable outcomes. Suppes (1956, p. 66) thus distinguishes *axioms of rationality* from *axioms of structure*. The latter constrain possible outcomes and options. As a consequence, the theory is not only restricted to rational agents but also to decisions for which the axioms of structure hold.

How far does this get us concerning BDT? At first glance, Ramsey reconstructs an agent’s preferences or choices using an expected utility formalism to obtain numerical degrees of beliefs and utilities. From this perspective, expected utility maximization seems an input to his theory (cf. Kaplan 1996, p. 168). Some remarks of Ramsey’s suggest such a reading too. As he puts it, his approach “is based throughout on the idea of mathematical expectation” (p. 70). Even under this interpretation, we have a remarkable achievement because it is not at all obvious that BDT can be used to define degrees of beliefs and to measure utility differences. But Ramsey’s result would not justify BDT. In this spirit, Kaplan (1996, p. 176) complains that Ramsey’s results do not underwrite the idea that rational agents maximize expected utility.

However, there is indeed much more to Ramsey’s results. Forget about the *motivations* for the three steps and take them to be *definitions* of degree of belief and degree to which an outcome is wanted, or of probability and utility. The definitions immediately imply that, in certain simple choices, the agent maximizes expected utility (this is just how the definitions are devised). What Ramsey shows is that probability and utility can always be defined in this way given that some axioms of rationality and of structure hold. It can also be shown from the axioms that expected utility is maximized more generally and not just in those choices that are considered in the definitions. Thus, granted the axioms, it follows that rational agents maximize some expectation value. If Ramsey’s definitions capture our pre-theoretic knowledge about belief, desire, and their degrees, the expectation value reflects the beliefs and desires and their strengths, and BDT is justified.

That BDT follows from assumptions that do not explicitly require the maximization of expected utility is even clearer from Savage’s theory.

## Savage's Theory

Leonard J. Savage's "Foundations of Statistics" (1954/1972) is often regarded as *the* articulation and defense of Bayesian decision theory. Fishburn (1979, p. 191) calls it "[t]he most brilliant axiomatic theory of utility ever developed" (he does not mention the Bolker-Jeffrey theory). Savage's theory draws on work by Ramsey, de Finetti, and von Neumann and Morgenstern (for earlier work by Savage see Friedman and Savage 1948, 1952).

Savage's conceptualization of choices is markedly different from what we have seen so far. The role of the conditions (whether the car will break down or not) is taken by states and events. Each *state* corresponds to a full description of all the objects the agent is concerned with (i.e., of the *world* in Savage's terms). *Events* are sets of states. An event in our example is that the car breaks down in the next year. This is not a state, because it leaves many things open, for instance, whether Peter will be invited to Mary's parties. In Savage's terms, all states in which the car breaks down constitute the event that the car breaks down.

A state in Savage's sense is not the state of the world at the moment of choice, but also encompasses future developments, for instance, whether the car will break down in the next year. The agent does not know what the real state is and whether certain events obtain. Savage's theory will eventually yield a probability function for the events (the probability function is defined on *events* rather than on *states* because there may be so many states that only suitable sets of states have probabilities).

An outcome is called a *consequence* by Savage. This term is a bit misleading because Savage's consequence means a set of consequences in common parlance. Each option is conceptualized as an *act*, which is a function from states to consequences. For instance, if Peter sells his car to Mary, the state "the car does not break down in the next year and Mary hosts many parties next year" is mapped to the consequence "Peter obtains \$2,000, Mary drives the car and Peter is invited to all of Mary's parties"; the state "the car breaks down in the next year and Mary hosts many parties next year" is mapped to the consequence "Peter obtains \$2,000, Mary drives the car for some while, Mary becomes angry with Peter and Peter is only invited to one of Mary's parties"; and so on.

Since acts are functions, an act together with a state fixes the consequence. The probabilities for the events can thus not depend on the act chosen. This may seem problematic. As was suggested above, the probability that the car breaks down may depend on whether it is sold to the lawyer or to Mary. Such a dependence is not possible in Savage's theory. If the car's breaking down is an event, there can only be one probability for it. Nevertheless, Savage's theory can deal with the example if the decision problem is conceptualized using different states. The idea is that each state does not contain information about whether the car will break down, but only information about whether the car will break down *if* Mary owns it, and so on. The event that the car will break down *if* Mary owns it, has as fixed probability, as Savage requires, but choice of the agent will effectively make a difference for the probability that the car breaks down.

The development of Savage's theory is quite different from that of Ramsey's. First, Savage does not need desire-neutral propositions. Second, he obtains utilities *after* probabilities, whereas Ramsey goes the other way round.

Savage starts from *preferences over acts* (where acts correspond to options in our earlier terms). Savage's first assumption (S1) is that vNM1 is satisfied for preferences over acts.

Second, Savage assumes the famous *sure thing axiom*, which is not far from the independence axiom from above (cf. Fishburn and Wakker 1995). Here is a very rough formulation:

S2. If we compare two acts concerning the extent to which they are desired, states on which the acts agree do not matter.

In more detail, suppose that an act  $f$  is preferred to another act  $g$ , but that  $f$  and  $g$  (as functions on the states) coincide for some event. That is, if the event obtains, the acts yield exactly the same consequence. For instance, the acts  $f$  formalizing “buy lottery ticket no. 1 for \$1” and  $g$  formalizing “buy lottery ticket no. 2 for \$1” do not make any difference if both tickets lose. Suppose now that both acts are modified because the regulations for lotteries change, and each customer gets 1 cent back if her ticket loses. We then have new acts  $f'$  and  $g'$ , which still agree on the event that both tickets lose. The *sure thing axiom* requires that  $f'$  is preferred to  $g'$ .

Taking for granted this axiom, Savage can define the notion of “one act being preferred to a second one, *given event B*.” Intuitively, this captures the idea that a certain act is preferred to another *for certain circumstances*. For instance, given that the car breaks down, Peter may prefer selling his car to Mary to selling it to the lawyer.

Savage’s third axiom concerns what he calls *constant acts*. An act is constant iff it has the same consequence for every state. The preferences over acts include preferences over constant acts, and these induce preferences over consequences in a straightforward way. Savage’s third axiom reads as follows.

S3. If a constant act is preferred to another constant act, then it is also preferred to the latter given an arbitrary event.

Intuitively, if one act always has the same consequence  $c_1$ , if another act always has the same consequence  $c_2$ , and if we prefer the first act to the second, this does not change if we acquire new information on the real state of the world. One may object that there are counterexamples. For instance, I may prefer taking the bus to work (constant consequence: pay \$2, 10 min time for getting to work) to walking (constant consequence: pay \$0, 20 min for getting to work) quite generally, but not if I learn that there is rain. However, the counterexample relies on the fact that certain aspects of a walk that matter to me are not taken into account in describing the consequences. If we properly take into account what matters to me, walking to work is not a constant act and the counterexample disappears.

The next step is to think about acts that take the role of bets. I will call an act a bet on an event (with prizes  $c_1$  and  $c_2$ ) if the act maps each state from the event to consequence  $c_1$ , and each state outside the event to another consequence  $c_2$ , where  $c_1$  is preferred to  $c_2$ . Real bets can be conceptualized as bets on events, but other options may be bets too. To obtain any bet on an event, Savage has to assume that

S4. There is some consequence (or some constant act) that is preferred to another consequence.

Savage furthermore assumes the following axiom.

S5. If some bet on event  $A$  with consequences  $c_1$  and  $c_2$  is preferred to some bet on event  $B$  with consequences  $c_1$  and  $c_2$ , then every bet on  $A$  with consequences  $c_3$  and  $c_4$  is preferred to every bet on  $B$  with consequences  $c_3$  and  $c_4$ .

This axiom requires consistency in accepting bets on events. Suppose, I have to choose between the following bets. The first bet pays \$1 if  $A$  occurs, and \$2 if not. The second bet pays

\$1 if  $B$  occurs, and \$2 if not. Suppose, I prefer the first bet to the second. Let us now modify both bets by slightly changing the consequences. A prize of \$1 is consistently replaced by one of \$100, and a prize of \$2 is consistently replaced by one of \$500. According to S5, I should continue to prefer the first to the second bet.

This seems plausible. A rationale may be that my reactions to the bets from the example should only depend on whether  $A$  seems more likely to me than  $B$ . If I take  $A$  to be more likely than  $B$ , it will always be preferable to bet on  $A$  if the prizes do not differ. However, Savage does not yet have the notion of probability. He rather argues the other way round. He uses the axioms S1–S5 to make sense of *qualitative* degrees of belief. A rational agent takes event  $A$  to be more probable than event  $B$  iff she prefers a bet on  $A$  with consequences  $c_1$  and  $c_2$  to a bet on  $B$  with consequences  $c_1$  and  $c_2$ . Axiom S5 implies that this will be so for every pair of consequences  $c_1$  and  $c_2$ . It turns out that the relation “... is taken to be more probable than ...” has many features that one would expect for probabilities.

However, Savage's aim is to derive *quantitative* probabilities. We need a function  $P$  on the events such that  $p(A) > p(B)$  iff  $A$  is taken to be more probable than  $B$  in the sense just defined.

To obtain such a representation that is furthermore unique, Savage introduces another axiom. It is more technical and reads as follows:

S6. If one act is preferred to a second one and if an arbitrary consequence  $c$  is given, the set of states can be partitioned into tiny sets that each have the following property: If the preferred act is slightly modified as to yield  $c$  on the tiny set and otherwise left unaffected, it is still preferred to the second act. An analogous statement holds about the second act.

In Suppes's terms, this is at least in part an axiom of structure. Savage suggests the following strategy to justify S6: Suppose, you prefer climbing to swimming at a particular occasion. Assume furthermore that you do not like a certain pain. Consider now a long series of  $n$  flips of a coin you think to be fair, where  $n$  is a natural number. Modify climbing such that you suffer the pain if one particular series of heads and tails occurs and the consequence of climbing otherwise. Of course, the higher  $n$  is, the less likely will a particular series of heads and tails be regarded. What S6 claims is that there is some number  $n$  such that you would still prefer modified climbing to swimming.

From S1–S6, Savage obtains a unique representation of probabilities. Given a notion of probability, it is not difficult to obtain utilities, as we know from the von Neumann–Morgenstern theory. The crucial step is to introduce acts that are counterparts to lotteries in the von Neumann–Morgenstern framework. A lottery has finitely many prizes (consequences in Savage's terms), but they are now connected to events on which subjective probabilities are defined.

Savage can show that the preferences over such lotteries follow the expectation value of the consequences. To extend this result to arbitrary acts, he needs an additional axiom.

S7. Suppose, every consequence that an act  $f$  yields for event  $A$  is preferred to another act  $g$  given  $A$ , then  $f$  is preferred to  $g$  given  $A$ . (And an analogous statement holds, in which “preferred” is replaced by “is not preferred to”).

Assuming S1–S7, we do not only obtain a unique quantitative probability that represents qualitative probability, but also the existence of a utility function such that one act is preferred to another one iff the expected utility of the consequences is larger for the first act than for the second. That is, rational agents to which S1–S7 apply follow MEU. Their preferences can be represented using expected utilities.

## The Bolker–Jeffrey Theory

---

Although Savage's theory is the most famous version of Bayesian decision theory, there is an interesting alternative, viz. the theory developed by Ethan D. Bolker and Richard C. Jeffrey (Jeffrey 1965a, b; Bolker 1966, 1967). While the main mathematical results upon which the theory is based are due to Bolker, Jeffrey is the most prominent philosophical defender of the theory.

In each of the approaches reviewed so far, probabilities and utilities attach to different kinds of entities. Probabilities are assigned to propositions (Ramsey) or to events (Savage), whereas utilities characterize outcomes or acts. In the Bolker–Jeffrey theory, on the contrary, both probabilities and utilities attach to propositions. The underlying idea is that both belief and desire are *propositional attitudes*, i.e., attitudes with a content that can be expressed using a proposition. That belief is a propositional attitude is uncontroversial, but desires may seem to aim at objects rather than at propositions. For instance, we say that Peter wants a new bike. However, what we really mean by this is that Peter wants to own a new bike or to drive a new bike and this can be expressed using a proposition. Another problem is that we can only desire something that does not yet obtain. Jeffrey does not have a rebuttal to this and suggests that his theory is really about desirability from the agent's point of view. The idea is that some propositions would count as better news to the agent than others (Jeffrey 1965a, p. 72). Actions and options are also conceptualized as propositions, viz. as those propositions that describe the actions or the options.

In Jeffrey's framework, the agent has two attitudes to each proposition: She takes the proposition to be probable to some extent, and she takes the proposition to be desirable to some extent. Let us say that proposition  $q$  is preferred to proposition  $r$  iff the agent takes  $q$  to be more desirable than  $r$ . As before, we want a representation, i.e., a function that maps any proposition  $q$  to a real number  $u(q)$  such that  $q$  is preferred to  $r$  iff  $u(q) > u(r)$ . In the same way, we want a function that maps any proposition  $q$  to a real number  $p(q)$  such that  $q$  is taken to be more likely than  $r$  iff  $p(q) > p(r)$ . Jeffrey assumes that the preferences over the propositions are asymmetric and negatively transitive.

A proposition does not uniquely fix the state of the world. The proposition  $q$  that Peter sells the car to Mary is compatible both with the car breaking down and with the car not breaking down in the next year. Obviously, the desirability of  $q$  should be responsive to the desirabilities of both possibilities. If both the propositions  $q_1$  (that Peter sells the car to Mary and that the car breaks down) and the proposition  $q_2$  (that Peter sells the car to Mary and the car does not break down) are not very desirable,  $q$  cannot be either. But the desirability of  $q$  should also depend on how likely  $q_1$  and  $q_2$  are taken to be. If  $q_1$  is very desirable but regarded very unlikely, then it should not have a large impact on the desirability of  $q$ . This suggests the following formula:

$$u(q) = \frac{u(q_1) \times p(q_1) + u(q_2) \times p(q_2)}{p(q_1) + p(q_2)}$$

Here we assume that  $q_1$  and  $q_2$  are incompatible, but jointly exhaust  $q$ . According to the formula,  $u(q)$  is a *conditional expectation value*. It equals the expectation value of the desirability of the various possibilities compatible with  $q$ , given that  $q$  is true. The less likely a possibility is given  $q$ , the smaller is its contribution to the desirability of  $q$ .

This may seem plausible, but the question is again how we can justify the formula. Here is where Bolker's mathematical results step in. We have the following representation theorem:

Suppose, an agent has preferences on a set of propositions with a certain structure. Assume furthermore that the preferences are asymmetric and negatively transitive and that they obey further constraints that I will not list here. Then there is a utility function  $u()$  on the propositions that represents desirability as required. Furthermore, there is a probability function on the propositions such that, for every proposition  $q$ ,  $u(q)$  can be expressed as the conditional expectation value of the utility, given  $q$ . The representation is unique up to some transformations. Interestingly, these are not just affine transformations of the utilities, and the probabilities are not uniquely fixed (see Bradley 1998 and Joyce 1999, Chap. 4 for attempts to restore the uniqueness of the probabilities in the Bolker–Jeffrey framework).

The Bolker–Jeffrey theory has some advantages over Savage's (see e.g., Eells 1982, pp. 82–86). For instance, the probabilities for various outcomes can now depend on the action chosen. This is so because the *conditional* expectation value is taken. It is also interesting that the difference between utility and expected utility disappears in the theory – each utility can be written as a conditional expectation value.

## Current Research: Bayesian Decision Theory and Risk

Standard decision theory of any brand seems to give unequivocal advice for risky choices. The advice is of course to maximize expected utility. This advice is justified by representation theorems according to which rational agents maximize expected utility. To be sure, since decision theory only captures a narrow notion of rationality, its theorems themselves do not ground a *moral* evaluation. But it is plausible to assume that moral preferences and moral choices should respect the constraints from decision theory too (see Dreier 2004 and Lumer 2010 for the relation between decision theory and morality).

However, intuitively, it does not always seem rational to maximize expected utility. Consider a choice between the options represented in  [Table 15.3](#).

The numbers in the upper halves of the boxes specify the utilities, whereas the numbers in the lower halves denote the probabilities as before. Let us grant that there cannot be any doubts about the probabilities – they may be objective probabilities over outcomes of gambling devices, or subjective probabilities based upon the available evidence. We observe that option  $O_2$  has a slightly higher expected utility (160) than  $O_1$  has (150) and that  $O_2$  is thus recommended as rational by standard decision theory. But many people will prefer  $O_1$  to  $O_2$  because  $O_2$  seems too risky.  $O_2$  has a higher expected utility than  $O_1$ , but only because an

 **Table 15.3**  
Another decision problem

	$q$	$\neg q$
$O_1$	200	100
	.8	.2
$O_2$	0	16,000
	.99	.01

The numbers in the upper halves of the boxes denote utilities

outcome with an extremely high utility has a tiny probability. If  $O_1$  is chosen, by contrast, there will at least be a utility of 100 for sure. Is it really irrational to prefer  $O_1$  to  $O_2$ ?

One can, of course, simply deny this by rejecting standard and particularly Bayesian decision theory. I will turn to related criticism of the theory in the next section. In this section, my question is only what Bayesians themselves can say.

Before discussing our question, it is useful to mention that, in decision theory, “risk” has often a technical meaning that does not reflect ordinary usage (cf. Hansson 2011). First, decisions are said to be under risk iff probabilities are available to the agent. This is contrasted to decisions in which the agent has no probabilities for the outcomes. The terminology dates back to Knight (1921).

Second, in the literature, expected utility is sometimes multiplied with a minus sign and called risk. In these terms, Bayesian decision theory implies that rational agents minimize risk (e.g., Berger 1980, p. 8). The pertinent meaning of “risk” is at odds with much common usage of “risk,” where risk is either quantified as the probability of some bad event provided a specific option is chosen, or as the expected harm that a choice produces (where potential benefits are not taken into account, see Hansson 2011).

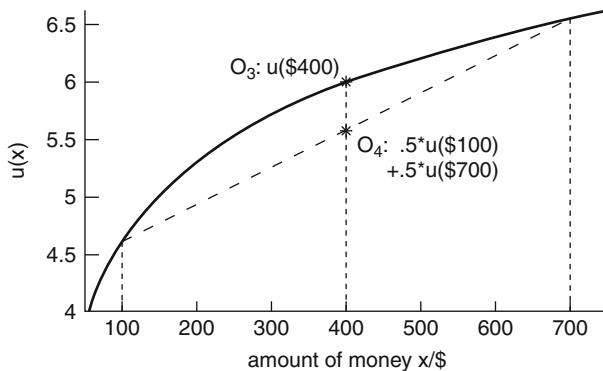

Finally, there is a technical notion of risk aversity to which we will turn presently (see Friedman and Savage 1952; Pratt 1964; Arrow 1970).

In our example, Bayesians will certainly insist that it is not rational to prefer  $O_1$  to  $O_2$  if the utilities and probabilities are as in [Table 15.3](#). To prefer  $O_1$  to  $O_2$  is to have preferences that do not obey the axioms of the theory. The axioms are partly axioms of structure, partly axioms of rationality. If axioms of structure are violated, nothing is wrong with preferring  $O_1$  to  $O_2$ , but it is unlikely that axioms of structure are violated (see below). So presumably, axioms of rationality are flouted and  $O_1$  cannot be the rational option to choose.

If an agent insists on preferring  $O_1$  to  $O_2$ , one can doubt that the utilities in the boxes properly reflect the agent’s utilities to begin with. In decision theory, the utilities are constructed from the agent’s preferences. If  $O_1$  is preferred to  $O_2$  and if the axioms are obeyed, we will never obtain utilities as in the boxes of the table.

Proponents of standard decision theory have additional resources to explain why we might want to prefer  $O_1$  to  $O_2$  in the example, while not rejecting the axioms of decision theory. The fault may simply be that we do not properly interpret the utilities from the table. We tend to “translate” the utilities in something homely by using some good as a proxy. For instance, in the example, we identify a utility of 100 with \$100, a utility of \$10,000 with \$10,000 and so on. But this is a mistake because the utility of money is in fact not a linear function of the amount of money. This is the main upshot of the St. Petersburg paradox. Since the utility of additional \$100 decreases, as the amount of money increases, we underestimate a utility of 10,000. We compare it to the utility of \$10,000, which is maybe not 100 times the utility of \$100, but only two times that utility.

In other words, if the numbers in the table do not reflect utilities, but rather some other good (e.g., money), an expected utility formalism may well imply that we should rationally choose the option that looks less risky. To see this, assume that the utility  $u(x)$  of some money  $x$  is a concave function of the amount of money  $x$ . That is, the utility increments for an additional \$1 decrease, as the amount of money grows (we still assume that the utility is a monotonically increasing function of the amount of money). The logarithm is an example of a concave function (cf. [Fig. 15.1](#)). Compare now the following two options ([Table 15.4](#)): The first option ( $O_3$ ) gives the agent \$400 for sure, the other ( $O_4$ ) is a gamble between \$100 and \$700.

**Fig. 15.1**

**Utility as a function of the amount of money.** The function is concave and thus illustrates risk aversity

**Table 15.4**

#### A yet other decision problem

	p	$\neg p$
$O_3$	\$400	\$400
	.8	.2
$O_4$	\$100	\$700
	.5	.5

Intuitively,  $O_4$  is more risky, but its *expected monetary value* is the same as that of  $O_3$ . Consider now the *expected utilities* of the options. We obtain for  $O_3$

$$u(\$400)$$

and for  $O_4$

$$.5 \times u(\$100) + .5 \times (\$700).$$

As  $u(x)$  is a concave function (see Fig. 15.1), the expected utility for  $O_4$  is less than that for  $O_3$ . Consequently, the agent should prefer  $O_3$ , which is the less risky option.

In this way, standard decision theory can rationalize preferences for less risky options. Utility functions that are concave (in some domain) as is  $u()$  in our example are said to capture *risk aversity* (in that domain). Many utility functions for goods are presumably concave in a large domain and thus encapsulate risk aversity. However, standard decision theory can only underwrite the choice of less risky options if risk is assessed in terms of other goods (e.g., money). An agent can never be risk averse concerning utilities (see Pratt 1964 and Arrow 1970, particularly Chap. 3, for risk aversity).

It may be objected that some people do not like (or, alternatively, enjoy) the uncertainty associated with real lotteries. This suggests that some prefer a *utility* of 400 for sure to a gamble with prizes of utilities 100 and 700, respectively (or the other way round). However, if the uncertainty of

an outcome is perceived to be bad or good in itself by the agent, the decision problem has to be redescribed. In this way, a contradiction with standard decision theory can be avoided.

Nevertheless, some ways of handling risk that do not seem irrational cannot be described in an expected utility framework. This is so when somebody applies the Maximin Rule, while having probabilities for each outcome given an option. See Kahneman/Tversky (1979), Kavka (1980), Ayres/Sandilya (1986), and Ekenberg et al. (2001) for further discussion.

## Further Research

---

To conclude, I will flag the most controversial issues raised by standard decision theory. I focus on more philosophical issues and do not review purely formal work in decision theory (see Fishburn 1979, 1982; Hammond 1998a, b; Sugden 2004).

1. *Is the maximization of expected utility a necessary condition of rational choice?* The main claim of standard decision theory is that rational agents maximize expected utility. As the maximization of expected utility can be derived from axioms, the question boils down to whether the axioms put down necessary conditions of rational choice and whether the axioms of structure are applicable. The standard view about the axioms of structure is that they may be fulfilled in most cases of interest at least by suitably redescribing the choice under consideration. The main issue then is whether the axioms of rationality reflect genuine constraints of rationality. This is the subject of much controversy (see e.g., Sugden 1985). Many objections against standard decision theory are cast in terms of paradoxes (e.g., Allais 1953; Ellsberg 1961). The paradoxes present choices between options. The choices that are intuitively judged to be rational by most people violate the requirement of maximizing expected utility. The paradoxes are discussed in [Chap. 19, Paradoxes of Rational Choice Theory](#), in this volume. Other criticism against standard decision theory grows out of empirical research (see below).

There are also attempts to justify some constraints of rationality from standard decision theory. So-called Dutch Book-arguments are most famous in this respect. They show that an agent who violates certain requirements is committed to accept sets of bets under which she will lose no matter what events materialize. There are well-known “Dutch-Book” arguments for the axioms of the probability calculus (Ramsey 1931, see also Gillies 2000, Chap. 4). It is controversial though whether agents that would accept Dutch books are irrational (see Kadane 1996 for a critical perspective).

2. *Is the maximization of expected utility a sufficient condition of rational choice?* As I have stressed above, standard decision theory focuses on a single choice and concentrates on a core notion of rationality to start with. Thus, other constraints of rationality seem possible. However, since the formalism of standard decision theory is thought to be extremely powerful, some may feel tempted to say that every requirement of rationality should be of the kind we have seen in developing the theory. If this is right, then maximizing expected utility may be sufficient for rational choice.

It is nevertheless very plausible that there are additional constraints of *epistemic/theoretical* rationality on the *probabilities* or the beliefs of the agent. As we have seen, the axioms of Bayesian decision theory (Ramsey, Savage, and Jeffrey) imply that the probabilities of an agent fulfill the axioms of the probability calculus. These axioms do not fix the

values of most probabilities though and only constrain combinations of them. But probabilities should also reflect the available evidence. If a coin has landed heads in about 50% of its flips so far, we should assign it a probability close to .5. Proponents of Bayesian decision theory reconstruct this by requiring that rational agents update their beliefs using empirical evidence. When data  $d$  are observed, the agent's probability for proposition  $q$ ,  $p(q)$ , should be replaced by the *posterior* probability  $p'(q) = p(q|d)$ , i.e., the probability for  $q$ , given the data. This is called *Bayesian conditionalization*. The posterior probability  $p(q|d)$  equals  $p(d|q)p(q)/p(d)$  via Bayes' Theorem. Bayesian conditionalization is sometimes justified by a "Dutch Book"-argument (Teller 1973; Lewis 1997), which is, however, very controversial (e.g., Howson 1995, pp. 8–10). Bayesian conditionalization is generalized to cases in which the data are uncertain via Jeffrey conditionalization (e.g., Jeffrey 1965a, Chap. 11).

As is manifest from Bayes' Theorem, Bayesian updating makes the posterior probability depend on the *prior* probability  $p(q)$ . This dependence is often "washed out" due to conditionalization. Under certain restrictions, the posteriors of agents with different priors, but with the same *likelihoods*  $p(q|d)$  converge, as the agents update their beliefs using the same data (Savage 1954/1972, pp. 46–50, Blackwell and Dubins 1962). It remains true though that finite data do not uniquely fix the values of the probabilities in this framework. This is often thought to be a problem since there seem to be cases in which some value of a probability seems eminently more reasonable than others.

*Objective Bayesians* claim that there are additional constraints on the values of probabilities (Williamson 2009, 2010). They typically demand that the priors obey the *Principle of Insufficient Reason* (or the Principle of Indifference; see Keynes 1921, p. 42 for a statement). Consider a set of mutually inconsistent, but jointly exhaustive propositions. According to the principle, each proposition should receive the same probability unless there are any reasons that speak in favor of one proposition rather than its rivals. This principle is generalized by the MAX-ENT principle by E. T. Jaynes (1957, 1968, 1979). However, the Principle is fraught with difficulties. The problem is that there are often many alternative ways to partition the space of possibilities, and various partitions will lead to different probability assignments. In such situations, the Principle cannot be applied unless one partition can be shown to be the right one (Gillies 2000, pp. 37–49).

To sum up, it is agreed among Bayesians that there is at least one other constraint of rationality (Bayesian updating). It affects degrees of belief only, but it is arguable that a choice is irrational in a broader sense if it draws on probabilities that have not been updated properly (see Earman 1992 for Bayesian updating and the implications for the philosophy of science).

3. *Can the maximization of expected utility guide choices?* As presented, decision theory is normative, since it constrains the choices of rational agents and since rationality is a normative notion. Now some normative principles such as moral principles can *guide choices*. That is, they give substantive answers to the practical question "What shall I do?" when it is asked from a first-person perspective. The question then is whether the maximization of utility can function in the same way. This is unlikely, because expected utility maximization is empty, unless utilities and probabilities are given, and because Bayesians only obtain utilities and probabilities from the agent's own preferences and choices. We cannot expect that these preferences are already given to an agent who deliberates what to do. Consequently, maximization of expected utility cannot guide choices

(see Peterson 2008, Chap. 2 for a recent version of this criticism, cf. also Bermúdez 2009, see also [Chap. 16, A Philosophical Assessment of Decision Theory](#)).

Bayesians have two kinds of replies. One reply is that guiding action is not an aim of the theory. As said above, the maximization of expected utility is a development of means-ends rationality, and means-ends-reasoning does not guide choices if the agent has not yet decided about her preferences. On this view, Bayesian decision theory expounds requirements of consistency on preferences. The second reply is that Bayesian decision theory can guide actions if combined with additional assumptions. For instance, if we assume a function for the utility of money, we can obtain more substantial advice. On this view, Bayesian decision theory would resemble the axioms of Newtonian mechanics. The latter have only observable consequences if they are combined with empirical hypotheses concerning forces.

4. *When should standard decision theory be applied? And are Bayesians committed to think that every decision is a decision under risk in Knightian terms* (Knight 1921)? Decision theory, as it has been presented, is concerned with one single decision. One can however apply the theory to a series of decisions. The basic idea is to regard a series of “small” decisions as one “big” decision. The options of this big decision are plans how to decide in the series of the little decisions. The plans may be conditional on information that only becomes available as the plans are carried out. Savage (1954/1972) famously restricts this strategy to what he called small worlds. Roughly, small worlds are such that we prefer the principle “Look before you leap” to the principle “You can cross that bridge when you come to it” (Savage 1954/1972, 16). Binmore (2009) makes a proposal on how to extend the scope of Bayesian decision theory to “bigger” worlds.

When we focus on a single choice, there is a very simple answer to the question when standard decision theory applies. It applies to those kinds of situations in which the axioms of structure hold. It is sometimes suggested that Bayesians take every decision problem to be one under risk in the terms of Knight and that they always recommend the maximization of expected utility. What is right about this is that Bayesians need not assume there to be objective probabilities to maximize expected utility. However, if the axioms of structure do not hold (or if the other axioms do not impose necessary conditions on rationality in the case at hand), then Bayesians are not committed to maximizing expected utility.

5. *Can one use Bayesian decision theory for descriptive tasks?* Although we have hitherto characterized decision theory as normative, the theory may also be used for descriptive purposes. If we assume that some agents are indeed rational in the sense of the axioms, their choices can be described using MEU. Whether agents are indeed rational is a matter of contingent fact. Empirical research is often taken to speak against the hypothesis that real-world agents maximize expected utility (see e.g., Kahneman/Tversky 1979 and Tversky/Kahneman 1981; consult Camerer 1995 for an overview; see also [Chap. 21, Real-Life Decisions and Decision Theory](#)). Related claims have to be taken with care though because standard decision theory is difficult to falsify. Typically, additional assumptions have to be made to obtain testable predictions from decision theory.

The normative claims from standard decision theory are, of course, not falsified if real people do not maximize expected utility. We cannot infer what we should do by looking at what people do in fact do. It would, however, be strange if most people were not rational for most of the time. Empirical results have thus some indirect impact on the fate of standard decision theory as a normative theory and they have in fact inspired alternatives (see e.g., Loomes and Sugden 1982 and Weirich 2004).

When decision theory is applied for descriptive purposes, rationality effectively drops out of the picture. It is immaterial for descriptive purposes whether a set of axioms are in fact constraints of rationality or not. The only question is whether the axioms are fulfilled for real-world agents. This is the basis for a more pragmatic approach to decision theory. The idea is that the axioms *define* a technical notion of rationality and that the theory can be applied to those agents that are rational in the technical sense (cf. Kreps 1988, pp. 4–6).

6. *What does Bayesian decision theory imply about human motivation?* Theories of motivation provide a framework for explaining actions and choices. According to the Humean theory of motivation (Smith 1987), actions are properly explained in terms of belief-desire pairs. Humean explanations in terms of beliefs and desires rationalize an action in a minimal sense (Davidson 1963). Anti-Humeans often claim that at least some actions are more appropriately explained using beliefs only (for instance, moral beliefs; cf. Nagel 1970). There is some affinity between Bayesian decision theory and the Humean theory of motivation because the former is often cast in terms of beliefs and desires and because many Bayesians are in fact committed to something like the Humean theory of motivation. Humeans, on the contrary, need a clear-cut distinction between beliefs and desires and may resort to standard decision theory to this end. However, Bayesian decision theory does not provide an independent argument for the Humean theory of motivation. It is also compatible with other views. It is arguable that the axioms do not properly apply to desire, but rather to other states (e.g., judgments of desirability or moral preferences; see Lewis 1988, 1996 and Price 1989 for discussion).
7. *What kind of probabilities ground rational action?* This chapter has concentrated on *evidential* decision theory in which the expected utilities arise from conditional probabilities in the most general case (think of the example in the introductory section and of the Bolker–Jeffrey theory for the moment). Proponents of *causal* decision theory, on the contrary, claim that the probabilities should not be conditional ones, but rather reflect causal knowledge. See Gibbard/Harper (1981), Lewis (1981), Eells (1982), Sobel (1994), and Joyce (1999).

Responding to some real or perceived problems of standard and particularly Bayesian decision theory, economists, philosophers, and others have developed variants (e.g., Kaplan 1996; Peterson 2008) or alternatives (e.g., Kahneman/Tversky 1979; Loomes and Sugden 1982). The discussion about Bayesian decision theory is alive as ever.

**Abstract:** The significance of decision theory consists of giving an account of rational decision making under circumstances of uncertainty. This question is important both from the point of view of what is in our personal interest and from the point of view of what is ethically right. But decision theory is often poorly understood and its significance only sparsely discussed in the literature.

In a short history of decision theory, it is demonstrated how modern axiomatic decision theory works differently from classical decision theory, but also how it is confused with it. Further, it is explained how modern axiomatic decision theory is an instance of fundamental measurement theory. This is then followed by a thorough introduction to Savage's version of modern axiomatic decision theory.

Turning to the interpretation of the theory, the maxim "maximize expected utility," which stems from classical decision theory, is shown to misrepresent the structure of modern axiomatic decision theory. Whereas the classical theory *assumes a value assignment to outcomes and derives preferences over uncertain acts*, the modern axiomatic approach *assumes preferences over uncertain acts and derives the utility assignments*. In the modern approach, the action guidance is to conform to the axioms.

Analyzing decision theory as a theory of good, the maxim "maximize expected goodness" repeats the misunderstanding. Moreover, it implies risk neutrality about good and a cardinal measure of good, and both are problematic. Only an ordering of uncertain acts that conforms to the axioms allows for risk aversion about good. If there were an independent cardinal measure of the goodness of outcomes, utility would be an increasing, strictly concave transform of good.

The Principle of Personal Good states the idea that the ordering of uncertain acts according to general betterness should be determined by how good the uncertain acts are for individuals. It sounds like a reasonable idea, and a widely used way of valuing life is based on it. But it is certainly not uncontroversial because it conceals conflicts of interest between individuals in final outcomes. In the context of decision theory for general and individual betterness, the Principle of Personal Good holds if, and only if, general utility is the sum of individual utilities.

The chapter concludes with suggestions for future research.

---

## Introduction

The significance of decision theory consists of giving an account of rational decision making under circumstances of uncertainty. This is clearly an issue of great practical importance. Almost any decision one can think of is taken in a context in which the decision maker has only limited information. Therefore, the decision maker is faced with more or less uncertainty about what the actual outcome of the decision will be. This again means that he is faced with the risk that the outcome might be different from the one he intends, possibly with worse consequences. How should we deal with this uncertainty and the risks it involves? This question is important both from the point of view of what is in our personal interest and from the point of view of what is ethically right.

Decision theory is supposed to enable us to deal rationally with uncertainty. It tells us how to model the uncertainty of a decision situation and thereby how to structure a decision problem. It is, moreover, supposed to guide us by explaining how the rational decision maker ought to choose in the face of uncertainty (I will only be concerned with decision theory as

a normative theory). However, even though many are familiar with the maxim “maximize expected utility,” there is, perhaps surprisingly, great confusion about what the actual message of decision theory really is.

On the face of it the confusion stems from the fact that the term “utility” is used with many different meanings, which are often not made clear and, moreover, often confused with one another. The core of modern axiomatic decision theory is a pair of formal theorems. In the standard interpretation, they state that if the decision maker’s preferences fulfill certain axioms (requirements of rationality), then these preferences can be represented by an expected utility function, and this function is *cardinal* (I shall explain later what all this means). This meaning of “utility” (a cardinal function representing preferences) is often poorly understood by people not fully acquainted with the formal content of decision theory. And it is often used alongside and confused with “utility” referring to what is “good for an individual,” in one sense or another, or to other forms of substantial value.

Of course, the confusion of meanings is unhelpful. But there is also a substantial problem lying underneath this surface. As a pure formal theory, decision theory does not offer us any guidance. The formal apparatus needs interpretation in order to be of any help. But once we look for a plausible interpretation that could guide us prudentially as well as morally, the question of how the technical apparatus of decision theory should be combined with relevant theories of prudential and ethical value emerges. This again raises the question of how the formal notion of “utility” relates to substantial values.

Whereas the axioms of decision theory, and other aspects of the formalization, are a matter of some controversy, which has been discussed at length in the literature (much of which is described elsewhere in this book), the question about what can be learned from decision theory in the context of prudential and ethical value has, on the contrary, only been briefly addressed. However, this has profound implications for our understanding of how to deal with risk. Hence, in this chapter, I shall take decision theory and its axioms for granted and attempt to identify a plausible interpretation of the theory, as applied to what is good for an individual and what is generally good.

An additional source of confusion is that there are several versions of decision theory. I shall be concerned with what I call *axiomatic expected utility theory*. The notion of expected utility involves probabilities. Some versions of decision theory do not have the expected utility form, because they are concerned with situations in which no probabilities are available (a condition often called “ignorance”).

Among expected utility theories, there is a distinction between classical and modern theories. Classical theories established an objective (which later came to be called “utility”), which a rational individual ought to maximize. Modern theories work in a different way. They establish axioms about the structure of preferences and claim that a rational individual should have preferences that satisfy them. The theories show that if an individual does satisfy the axioms, then “utilities” can be constructed such that the individual maximizes his expected utility (I shall say much more on this difference below).

Different modern theories have different axioms. However, what I would like to call the conventional theories, are sufficiently similar to allow me to speak generally about “decision theory.” There are some unconventional theories as well, which deviate from the general picture (e.g., Jeffrey 1983), or even take a non-expectational form (e.g., Machina 1982), but I shall leave these aside. I shall use Leonard Savage’s theory (Savage 1972) as representative of “decision theory” in my discussion, because I consider it to be the most general statement of the ideas underlying conventional decision theory.

The chapter first gives a short account of the history of decision theory in order to locate the origins of the different meanings of “utility” and to explain the development from the classical theories to the modern axiomatic approach. Savage’s theory is presented in some detail, concentrating on the aspects of importance for rest of the chapter. The structure of the theory is explained and contrasted with a widespread misrepresentation.

Next, decision theory is examined as a theory of what is good for an individual and what is ethically good in the face of uncertainty. Concerning the latter, a specific discussion of how the ethical attitude toward uncertainty should reflect what is good for individuals in the face of uncertainty is presented. The chapter concludes by outlining questions for further research.

Decision theory is a formal theory, and many issues relating to it involve further formal complications. A few formal issues are important for the main argument of the chapter. The ideas behind these issues are explained such that they should be intuitively accessible, even for readers with a limited background in mathematics.

In some cases, I shall also mention formal issues related to decision theory, but I will not go into the details. Some readers will be acquainted with these details, while others will not. However, readers unfamiliar with the complexities can safely skip these instances of “name dropping” without causing problems for their understanding.

John Broome’s writings play a prominent role in this chapter, because he, more than anyone else, has discussed the philosophical aspects of decision theory. I am very grateful to the Swedish Science Council who supported part of the research underlying this chapter.

---

## A Short History of Decision Theory and the Notion of Utility

---

### Bernoulli’s Hypothesis

---

The first developments of relevance for this chapter date back to the seventeenth century when the theory of probability was founded. These early theorists were largely concerned with the question of how to evaluate gambles of money. They concluded with the maxim that the gamble with the greatest expected winnings was the most advantageous. This maxim, known as the *Principle of Expected Value* or the *Principle of Mathematical Expectation*, states that we should evaluate a gamble according to the sum of its possible winnings or losses, each weighted with its probability.

The Principle of Expected Value involves risk neutrality about money. *Risk neutrality about money* means that if two gambles have the same expected monetary value, then they are always equally good. But in some cases, it seems reasonable to prefer avoiding the risk of losing. *Risk aversion about money* means that if two gambles have the same expected monetary value, the less risky is always better. Daniel Bernoulli (1738) was the first to question the Principle of Expected Value (translated in Bernoulli (1954), quoted from Page (1968), p. 200):

- ▶ Somehow a very poor fellow obtains a lottery ticket that will yield with equal probability either nothing or twenty thousand ducats. Will this man evaluate his chance of winning at ten thousand ducats? he asks. Would he not be ill-advised to sell this lottery ticket for nine thousand ducats?

Bernoulli thinks the answer is “no.” On the other hand, a rich man might be more prone to risk. Bernoulli draws the conclusion that the value of an item to an individual should not be

based on its monetary price. Rather, it should be based on what Bernoulli calls *emolumentum*. The *emolumentum* of a gamble is not the same for all individuals; it depends on the individual's wealth. A gain of 1,000 ducats is more significant to the poor man than it is to the rich man.

In the translation of Bernoulli's paper in *Econometrica* from 1954, *emolumentum* was translated as "utility." This translation may be one of the sources of the confusion of Bernoulli's theory with modern axiomatic utility theory. *Emolumentum* means something like *advantage* or *benefit*. The value to an individual of an item is thus the degree to which it is in his interest, or how good it is for him. Bernoulli suggests the maxim that an individual should evaluate a gamble by its *emolumentum medium*, i.e., its expected goodness to him. John Broome (1991b) has dubbed this maxim *Bernoulli's Hypothesis*.

Gabriel Cramer, whom Bernoulli quotes in French in his paper and who appears to be the one who first presented these ideas, used the expression *Esperance Morale* (moral expectation) for what Bernoulli calls *emolumentum medium*. Because of this, the translation "moral worth" is sometimes used instead of the translation "utility." Cramer stressed the moral character of the question of how to measure the true value of an item to an individual. He further identified the moral expectation of a certain gain with the pleasure one hopes to derive from it and, correspondingly, the moral expectation of a loss with the pain caused by it.

To summarize Bernoulli's theory: In the face of risk, an individual should be concerned with his own good. Money has diminishing marginal goodness to an individual. Therefore, an individual has reason to be risk averse concerning money; the poorer he is, the more he has reason to prefer money for sure to gambles with a risk of losing. To this, Cramer adds the idea that the goodness of an item for an individual is the pleasure one can derive from it.

Bernoulli used his theory to solve the so-called St. Petersburg Paradox, which had been presented to him by his cousin Nicolas Bernoulli (quoted from Page (1968), p. 209):

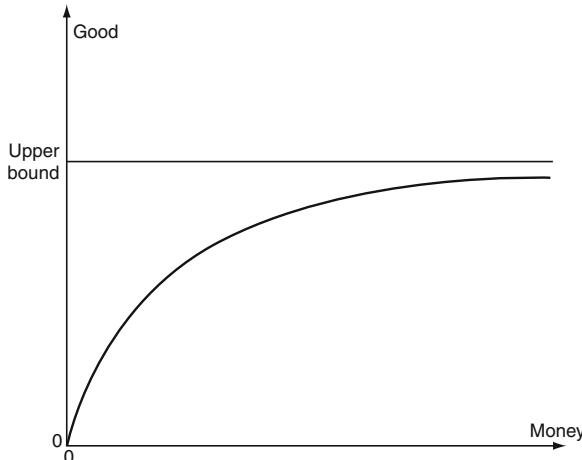

- Peter tosses a coin and continues to do so until it should land "heads" when it comes to the ground. He agrees to give Paul one ducat if he gets "heads" on the very first throw, two ducats if he gets it on the second, four ducats if on the third, eight if on the fourth, and so on, so that with each additional throw the number of ducats he must pay is doubled.

How should we evaluate this gamble? Notice that the expected value of the gamble is infinitely high:

$$\frac{1}{2} \cdot 1 + \frac{1}{4} \cdot 2 + \frac{1}{8} \cdot 4 + \dots = \frac{1}{2} + \frac{1}{2} + \frac{1}{2} + \dots = \sum_{n=1}^{\infty} \left(\frac{1}{2}\right)^n \cdot 2^{n-1} \rightarrow \infty$$

The "paradox" is that according to the Principle of Expected Value, Paul should be willing to pay any finite sum for this gamble. However, no one would pay more than a small price (Bernoulli suggests 20 ducats). The solution hinted at by Bernoulli, and more clearly stated by Cramer, consists of the claim that money has diminishing marginal goodness or moral worth to an individual, which moreover has an upper bound when one's wealth grows toward infinity. This solution has been widely accepted (e.g., Savage (1972) and Arrow (1970)), although whether it really answers the problem of the paradoxically high expected value of this kind of gamble, is still contested. However, we shall not pursue this question any further.

The diminishing marginal goodness of money implies that goodness as a function of money is an increasing strictly concave function. The graph of an increasing strictly concave function has a characteristic downward curvature. Cramer further assumed that the function has an upper bound, see Fig. 16.1.

**Fig. 16.1**  
The goodness of money

### Bentham and the Utilitarian Economists

Economists adopted the notion of “utility” for choices under certainty. Savage (1972, p. 95) suggests that Bernoulli’s paper might have been the principal source for the introduction of the notion of “utility” in economics. At any rate, the utilitarian philosopher Jeremy Bentham (1789) connected the classical economists’ use of “utility” with the neoclassical economists’ use by saying that (p. 2):

- ▶ By utility is meant that property in any object, whereby it tends to produce benefit, advantage, pleasure, good, or happiness, (all this in the present case comes to the same thing) or (what comes again to the same thing) to prevent the happening of mischief, pain, evil, or unhappiness to the party whose interest is considered.

In other words, an object has utility to the extent that it promotes what is in an individual’s interest, or what is good for the individual. Bentham goes on to determine what is good for an individual more specifically as, “pleasure” (philosophers call this account of an individual’s good *hedonism*). A pleasure can be measured (at least in theory) by its intensity and duration, and amounts of pleasure can be added up and compared across people. Bentham’s theory was adapted by W. S. Jevons in his *Theory of Political Economy* (1873). Commenting on Bentham’s definition of “utility,” Jevons (1873/1970, p. 46) said: “This perfectly expresses the meaning of the term in Economy”.

After this, the meaning of “utility” in economics gradually changed from the tendency of an object to produce good to the good itself. An individual’s “utility” is an individual’s own good. This change is documented in Broome (1991a), reprinted in Broome (1999), pp. 19–28. Since an individual’s good was identified with “pleasure,” utility was considered a mental entity, the amount of which could be measured and compared across people.

A *rational* individual should prefer the outcome that provides him with the highest utility, i.e., the greatest (expected) balance of pleasure over pain. The “law of diminishing marginal

utility” was widely accepted, not just for money as in Bernoulli’s case, but for all goods. As a consequence, economists claimed that a transfer of income from a rich person to a poor person would increase the total utility of society, other things being equal, and therefore represent a better overall outcome.

## The Axiomatic Turn

---

During the 1920s, economists became increasingly skeptical about the notion of utility as a mental entity which could be measured. For one thing, the measurement of mental entities was never made operational. But perhaps more important was the dawning insight into utility functions. An individual’s utility function was supposed to measure the balance of pleasure over pain for the various available alternatives and if the individual was rational, he should form his preferences accordingly. However, it was discovered that for a function representing an individual’s preferences over outcomes, only the *ordering* of the outcomes is significant. Any function preserving the same order represents these preferences equally well. This is called an *ordinal* utility function.

Since the basic economic theorems could be proved on the basis of ordinal utility functions alone, the notion of utility as a measurable mental entity became theoretically superfluous for explaining an individual’s preferences. The preferences could simply be considered basic in the theory. This development is complete in Hicks and Allen (1934).

Moreover, there was also skepticism concerning the comparison of utility as pleasure across individuals. Many economists considered such comparisons meaningless, because they did not believe there was any fact of the matter. Or if such comparisons were accepted as meaningful, they were deemed *value judgments* that belonged to the realm of ethics and not the realm of economic science – again because they appeared not to be factual statements (see, e.g., the discussion in Robbins (1935)). This explains the prominence of the notion of a *Pareto Improvement* in economics ever since, which only applies when everyone prefers one state to another or is indifferent between them, and at least one individual definitely prefers it. Such comparisons of states are not dependent on interpersonal comparisons.

Through this development, “utility” came to mean the value of a function representing an individual’s preferences. “Represents” in this sense simply means that one outcome has a higher utility than another if, and only if, it is preferred to it. Consider the weak preference relation “– is weakly preferred to –” (i.e. “– is preferred or indifferent to –”). A utility function for the case of a finite, or infinite but countable, set of outcomes exists if, and only if, an individual’s weak preference relation for outcomes are transitive and complete. The proof of this dates back to Cantor (1895). For an uncountable set of outcomes, a further continuity condition is needed Debreu (1959).

A weak preference relation is *transitive* if, and only if, for all triples of outcomes  $A$ ,  $B$ , and  $C$ , if  $A$  is weakly preferred to  $B$ , and  $B$  is weakly preferred to  $C$ , then  $A$  is weakly preferred to  $C$ . Transitivity is widely considered a rational requirement of consistency.

A weak preference relation is *complete* if, and only if, for all pairs of outcomes  $A$  and  $B$ , either  $A$  is weakly preferred or indifferent to  $B$ , or  $B$  is weakly preferred or indifferent to  $A$ . Completeness implies that all outcomes are comparable; either one outcome is preferred to another, or the other way round, or there is indifference between them – no other possibilities are allowed.

It is implicit in this change that a *rational* individual is now defined as a person whose preferences are transitive and complete. Whereas before, a rational individual's utility function (measuring the total pleasure) was given and his preferences derived from it, preferences are now given as primitives, from which the utility function (now understood as numbers representing these preferences) is derived.

The modern definition of "utility" is thus *the value of a function which represents a person's preferences*. This is a purely technical definition of "utility"; there is no logical connection to an individual's good. However, economists very often assume a connection of this sort. That is, they assume *The Preference Satisfaction Theory* about an individual's good: An outcome is better for an individual than another if, and only if, it is preferred. This theory implies that an outcome is better for an individual if, and only if, it has a higher utility. Thereby, the new meaning of utility is confused with the old meaning, which refers to an individual's good.

The Preference Satisfaction Theory only mentions an individual's preferences. Either the preferred outcome obtains or it does not. No reference is made to any mental entity such as "pleasure." However, the Preference Satisfaction Theory about an individual's good is often confused with the old hedonistic theory about an individual's good when the discussion uses expressions like *experienced* or *felt satisfaction* (i.e., a mental state) of the preferred outcome. The confusion about "utility" is thereby doubled.

### **Interlude: Measurement Theory**

---

The formal content of the axiomatic utility theory belongs to fundamental measurement theory (Krantz et al. 1971), which investigates the conditions under which empirical comparisons of properties of objects can be faithfully transformed into measurement scales. Examples of empirical relations are "longer than," "hotter than," or as in our case, "is weakly preferred to."

Given an empirical relation on a set of objects, a *representation theorem* asserts that *if* the empirical relation satisfies certain axioms, *then* a *numerical representation* can be constructed, i.e., a real-valued function that assigns numbers to the objects in such a way that the size of the numbers preserves the empirical ordering of the objects. In our case, a numerical representation can be constructed, if the weak preference relation satisfies the axioms of transitivity and completeness.

A *uniqueness theorem* states what is unique about this numerical representation. It says that *if* a certain function is a representation of the empirical relation in question, *then* another function represents the same empirical relation if, and only if, it is a certain transformation of the first. Hence, the uniqueness of a numerical representation is determined by all and only the kind of transformations that preserve the representation of the empirical relation. The uniqueness of the representation, in turn, defines the kind of measurement scale involved in the representation.

For an *ordinal scale*, only the order of the numbers is unique, anything but the order is arbitrary. An ordinal scale is *unique up to increasing transformation*, i.e., a function represents the same empirical structure as another if, and only if, it is an increasing transform of it. An increasing transformation  $f$  of a function  $u(x)$  has the form  $f(u(x))$ , where  $f$  is an increasing function. An increasing transformation can change everything except the order of the numbers (an example would be if  $u(x) = 1$ ,  $u(y) = 2$ ,  $u(z) = 3$  were transformed to  $f(u(x)) = 10$ ,  $f(u(y)) = 100$ ,  $f(u(z)) = 101$ ).

For an *interval scale*, the choice of unit and zero is arbitrary, but ratios of intervals are uniquely determined. An interval scale is *unique up to increasing linear transformation*, i.e., a function represents the same empirical structure as another if, and only if, it is an increasing linear transform of it. An increasing linear transform of a function  $u(x)$  has the form  $au(x)+b$ , in which  $a$  is a positive number. A linear transform implies that the zero and the unit are changed, but the ratio between intervals remains constant (an example would be switching from the Fahrenheit to the Celsius temperature scale), so:

$${}^{\circ}\text{C} = \frac{5}{9}({}^{\circ}\text{F} - 32).$$

Finally, for a *ratio scale*, the zero is also uniquely determined. A ratio scale is *unique up to similarity transformation*, i.e., a function represents the same empirical structure as another if, and only if, it is a similarity transform of it. A similarity transformation of a function  $u(x)$  has the form  $au(x)$ , where  $a$  is a positive number. A similarity transform implies that the unit is changed, but ratios of numbers remain constant (an example would be switching from centimeters to inches).

In our case, the utility function representing the weak preference relation is an ordinal scale. Interval and ratio scales are both called *cardinal scales*. We shall see examples of cardinal utility scales below.

## Von Neumann–Morgenstern Utility

---

In 1944, John von Neumann and Oskar Morgenstern published the seminal *Theory of Games and Economic Behaviour*. Roughly, games are situations of mutual interdependence, in which the outcome of an individual's choice is dependent on how the others choose to act. Each player is assumed to have a payoff function, defined on all possible outcomes of the game; and each player is further assumed to have full knowledge of the payoff functions of all players. Thus, there is no doubt about what the players prefer in terms of final outcomes. However, the best strategy for a player remains to be determined, because there is uncertainty about the other players' moves. Each player knows that the others will try to maximize their payoff, and they have to consider the likely moves of others when choosing their own. The task for game theory is thus to find the best strategy for players in different types of games.

I shall not be concerned with game theory per se. However, as a side issue, von Neumann and Morgenstern made an important contribution to decision theory. In their game theory, they assumed that a payoff function was based on the players' preferences over outcomes. But they also assumed that this function, which they also called a "utility function," not just preserved the preference ordering, but in fact – as they unfortunately described it – was an instance of "measurable utility." To justify this assumption, they presented a new form of axiomatic utility theory (the proof of which they did not give until the second edition in 1947).

The axiomatic utility theory in economics discussed above belongs to what we might call decision making under certainty. In this case, there is no distinction between an act and the outcome it leads to. Von Neumann and Morgenstern considered preferences over *risky acts*. A risky act is one in which the decision maker does not know the outcome with certainty. He knows that the act has a number of possible outcomes, each of which can occur with a known probability. Such risky acts are often called *lotteries*.

As in the case of decision making under certainty, von Neumann and Morgenstern wanted to represent the decision maker's preferences by a function. But they did not just require that an act had a higher utility if, and only if, it was preferred, they also required that the utility  $u$  of an act, which gave outcome  $A$  with probability  $p$  and outcome  $B$  with probability  $(1-p)$ , should be expressed as  $pu(A)+(1-p)u(B)$ , i.e., as the expected utility of the act.

In other words, the domain on which the utility function was defined had a richer structure than in the case of decision making under certainty. It contained the operation of adding up the utilities of each possible outcome, weighted by their probabilities, to give the utility of the risky act. Von Neumann and Morgenstern could then prove that if a utility function, which satisfies both these conditions exists then it is determined up to linear transformation; i.e., another utility function only represents the same preferences by fulfilling the two requirements if, and only if, it is a linear transformation of the first function. And this makes utility a “measurable entity,” not in the sense of measuring a mental entity such as pleasure, but in the sense of a cardinal utility function that represents preferences.

In an appendix to the second edition, von Neumann and Morgenstern then showed the axioms for preferences over risky acts that are necessary and sufficient to prove the existence of an expected utility function. I shall not give an account of the axioms here. Instead, I will present the axioms of Savage's more general decision theory below.

There has been much confusion about von Neumann and Morgenstern's utility theory. It is clearly an axiomatic utility theory, which states that if given preferences over risky acts satisfy certain axioms, they can be represented by an expected utility function. However, their reference to “measurable utility” made many economists believe that they had attempted to reintroduce utility as a measurable mental entity, which the decision maker aims to maximize.

Savage (1972), who presented the axiomatic decision theory I shall be turning to later on, added to the confusion by stating that von Neumann and Morgenstern gave “strong intuitive grounds for accepting the Bernoullian utility hypothesis as a consequence of well-accepted maxims of behavior” (p. 97). However, Bernoulli meant “an individual's good” by “utility,” whereas von Neumann and Morgenstern meant the value of a function representing preferences over risky acts. In fact, somewhat ironically, von Neumann and Morgenstern (1944/2004, p. 8) assumed that agents maximize their monetary outcome, which they – contrary to Bernoulli – considered “identical, even in the quantitative sense, with whatever ‘satisfaction’ or ‘utility’ is desired by each participant”; in other words, they assumed risk neutrality about money. Clearly, this did not make use of the full potential of their decision theory and – as we shall see below – probably added to the widespread confusion in the area. (Note also that von Neumann and Morgenstern spoke of “desired utility,” which they identified with “desired satisfaction,” another indication of the high degree of confusion in this area.)

---

## Early Modern Decision Theory

Von Neumann and Morgenstern's decision theory assumed preferences over risky acts as basic. But in game theory, they wanted to calculate preferences over acts, given the players' payoff functions for outcomes. And the next developments in decision theory were modeled on game theory. Thus, in a few places (e.g., pp. 32, 85–86), von Neumann and Morgenstern (1944/2004) hint at the idea of a *one person statistical game*, in which the decision maker aims to maximize his payback function in a choice between a number of risky acts.

Abraham Wald adapted this idea in his *Statistical Decision Functions* (1950). Wald's idea was that the concept of game against "nature" (a "player" who does not aim to maximize "his" outcome, but who "chooses" according to a certain probability distribution for outcomes) could serve as a new foundation for statistics. In statistics, the testing of hypotheses and point estimation are treated as separate issues. Wald suggested that they could be seen as instances of the more general problem of choosing a good decision strategy. But note that Wald assumed that the decision maker (the statistician) had a payoff function, which was defined on outcomes.

Von Neumann and Morgenstern's decision theory is often described as being concerned with decision making under risk, because it assumed known probabilities for each possible outcome. In the 1950s, decision theory for decisions under uncertainty was founded. Uncertainty was understood as a situation in which probabilities for "nature's choices" (often called *states of nature*) are unknown, and perhaps do not even exist. Again, game theory was the model. The decision maker has complete preferences over outcomes and he looks for the strategy (i.e., preferences over uncertain *acts*), which is likely to best satisfy these preferences. The first strategy to be examined was the *minimax strategy* (an agent chooses the act so that maximal loss – from the worst possible outcome – is minimized) – a strategy which was in fact adapted from the study of zero-sum games in game theory.

However, this is not the form of decision theory I shall be concerned with here. In 1954, Leonard Savage presented his *The Foundations of Statistics*, which was another form of decision theory for decisions under uncertainty. Savage built on Wald's idea of statistical decision theory, but he took preferences over uncertain acts to be basic. In contrast to the earlier decision theory for decisions under uncertainty, he added the idea of subjective probabilities (and his theory is often called *Bayesian decision theory*). This means that in situations where objective probabilities are unknown or do not exist, the decision maker can still (and according to the theory should) form beliefs about the likelihoods of the various states of nature. Insofar as a consistent measure for subjective probabilities can be construed, decision making under uncertainty can be reduced to a form similar to decision making under risk.

Similar ideas had actually been put forward by Frank Ramsey as early as 1926, but his paper was not published until 1931 after his death, and it did not have much impact at that time. Savage's theory is more general. His account of subjective probabilities was largely inspired by a paper by Bruno de Finetti (1937), translated in de Finetti (1964).

Decision theorists who believe that subjective probabilities are arbitrary in cases where there is no evidence whatsoever have continued to develop strategies in the tradition of the early theories of decision making under uncertainty. They now call these situations *ignorance*. For more on such theories see, e.g., Luce and Raiffa (1957, pp. 275–326). I shall now introduce what I shall use as the paradigm of modern axiomatic decision theory for the rest of this chapter.

## Savage's Decision Theory

### The Basic Concepts

Savage (1972) models uncertainty in the following way: The individual in a decision situation is concerned with some object (called the *world*) because the outcome of the acts, he has to choose between, is determined by the state of this world, but he does not know which of several

possible states is the true state. A *state* is thus a full description of the relevant aspect of the world resolving all uncertainty. The *true state* is the state that does in fact obtain. An *event* is a set of states.

An *act* is defined as a function that attaches an outcome to each state of the world. An *outcome* is a description of what finally matters to the decision maker, i.e., how his life and well-being are affected (Savage uses the term “consequence,” but I shall use the term “outcome”). An act is thus exclusively determined by its possible outcomes, it does not have any properties that do not show up in some outcome.

Savage provides this example to illustrate the concepts (pp. 13–14):

- ▶ Your wife has just broken five good eggs into a bowl when you come in and volunteer to finish making the omelet. A sixth egg, which for some reason must either be used for the omelet or wasted altogether, lies unbroken beside the bowl.

The uncertainty in this case is about whether the sixth egg is good or rotten. Savage suggests that you must decide among three acts, namely, to break it into the bowl with the other five, to break it into a saucer for inspection, or to throw it away without inspection. Depending on the state of the egg, each of these acts will have some consequence for you, as outlined in this decision matrix (❷ *Table 16.1*).

There are some important assumptions underlying this model of uncertainty. States are assumed to be mutually exclusive, and the specification of states is assumed to be exhaustive. This ensures that one and only one state obtains. Also, the acts are assumed to be mutually exclusive. And finally, states are assumed to be causally independent of acts. Richard Jeffrey (1983) suggested a decision theory without this latter restriction, which might therefore be considered more general. However, it also involves some complications which I do not want to go into here.

There are no further rules for the specification of a decision problem. The specification of a decision problem is relative to the description of states. A description of a state cannot cover all aspects. Hence, there will be further uncertainties under the surface of a description resolving the uncertainty in focus. Savage says that any small world state is an act in a larger world, which means that further uncertainties can be analyzed as the possible outcomes in a finer-grained description of states.

I shall now present the important details of Savage’s theory. Suppose there are  $n$  acts and  $s$  states of the world. Each act  $A$  assigns an outcome to each state  $(a_1, a_2, \dots, a_s)$ . The theory is

❷ **Table 16.1**

An example illustrating the basic concepts

States Acts	6th egg is good	6th egg is rotten
Break 6th egg into bowl	Six-egg omelet	No omelet, and five good eggs destroyed
Break 6th egg into saucer for inspection	Six-egg omelet, and a saucer to wash	Five-egg omelet, and a saucer to wash
Throw 6th egg away	Five-egg omelet, and one good egg destroyed	Five-egg omelet

divided into two parts. One part is concerned with the existence of a probability measure that assigns unique probabilities  $p_1, p_2, \dots, p_s$  to each state that sum to one. The other part is concerned with assigning utilities to outcomes such that, given the probabilities for states, the utility of an act  $A$  is its expected utility:

$$u(A) = p_1 u(a_1) + p_2 u(a_2) + \dots + p_s u(a_s)$$

Given the probability measure, this latter part is almost identical to von Neumann and Morgenstern's theory for decisions under risk.

Savage now goes on to assume that the decision maker has a weak preference relation defined on all pairs of acts. The *first axiom* states that the weak preference relation for acts is *transitive* and *complete*. We recognize this requirement from axiomatic decision theory for decisions under certainty described above. It ensures a complete ordering of all acts.

## The Sure-Thing Principle

---

Next, Savage defines the notion of one act being weakly preferred to another *given some event*. Remember that there are  $s$  states and that an event is a subset of states. Consider a subset of states  $X$ , e.g.,  $s_1$  and  $s_3$  (the event that either  $s_1$  or  $s_3$  obtains). Consider further two acts  $A$  and  $B$ , which have the same outcomes in the event that  $X$  does not obtain ( $\sim X$ ), i.e., in all other states  $s_2, s_4, s_5, \dots, s_s$ .  $A$  is weakly preferred to  $B$  given  $X$  if, and only if,  $A$  is weakly preferred to  $B$ .

The *second axiom* is called the *Sure-thing Principle*. Suppose we have four acts  $A, B, C$ , and  $D$ . For a fixed set of states,  $A$  and  $B$  have identical outcomes, but they differ in their outcomes for the remaining states. For the same fixed states,  $C$  and  $D$  likewise have identical outcomes, but not necessarily the same as  $A$  and  $B$ . For the rest of the states,  $C$  has outcomes that are identical with  $A$ 's in these states, and  $D$  has outcomes that are identical with  $B$ 's outcomes in these states. The Sure-thing Principle now states that if  $A$  is weakly preferred to  $B$ , then  $C$  is weakly preferred to  $D$ .

This can also be expressed thus: if one act is weakly preferred to another, given some event  $X$ , then this preference holds, whatever (identical) outcomes occur in the event  $\sim X$ . The essence of the Sure-thing principle is that, when comparing two acts given some set of states, the evaluation can be done independently of what happens in the remaining states. Thus, the reasons for preferring  $A$  to  $B$  must come from the set of states, where they differ in outcomes. The same can be said about  $C$  and  $D$ . And since the reasons for preferring  $A$  to  $B$  are the same as the reasons for preferring  $C$  to  $D$ , it follows that if an individual prefers  $A$  to  $B$ , he/she should also prefer  $C$  to  $D$ .

In order to see what this excludes, consider the famous counter-example given by Maurice Allais (1953), translated in Allais (1979). You have to decide your preferences among the following lotteries, in which one out of a hundred numbered tickets is drawn randomly, and you receive a prize determined by the number of the ticket (☞ [Table 16.2](#)).

Allais prefers  $A$  to  $B$  and so do many other people as several empirical studies have shown. Their reason is that  $A$  gives €1 million with certainty, whereas  $B$  involves a small risk of getting 0. Since  $A$  and  $B$  have identical outcomes for states 12–100, we can say that they prefer  $A$  to  $B$  given states 1–11. But  $C$  and  $D$  likewise have identical outcomes for states 12–100; and given states 1–11,  $A$  is identical with  $C$ , and  $B$  is identical with  $D$ ; therefore, the Sure-thing Principle

■ **Table 16.2**  
Allais' example

Lottery A			Lottery C		
States			States		
Ticket 1	Tickets 2–11	Tickets 12–100	Ticket 1	Tickets 2–11	Tickets 12–100
€1 million	€1 million	€1 million	€1 million	€1 million	0
Lottery B			Lottery D		
States			States		
Ticket 1	Tickets 2–11	Tickets 12–100	Ticket 1	Tickets 2–11	Tickets 12–100
0	€5 million	€1 million	€0 million	€5 million	0

implies that they should also prefer *C* to *D*. But Allais (and many others besides him) prefers *D* to *C*. For him, since there is an 89% chance of getting 0 anyway, the 10% chance of getting €5 million outweighs the extra 1% risk of getting 0. So this preference violates the Sure-thing Principle.

The Sure-thing Principle implies that what happens in one state can be evaluated separately from what happens in the others. There can be no interaction between states in the evaluation. A way to justify this principle is to point out that only one state can obtain. When we evaluate a state, we should imagine what it would be like if that state obtains. And if it does, no other state will occur. Therefore, how could what never happens possibly affect the value of what does happen?

But Allais suggested that there can be interactions: The reason to prefer *A* to *B* is that *A* gives €1 million *with certainty*, and certainty is something that does not show up in any state separately, it results from what happens in all states taken together.

Decision theorists feeling pressed by Allais' or similar examples do have a maneuver in response. If there is something special about certainty, it should show up as part of some outcome. For instance, it has been suggested that if you get 0 in *B*, you would feel very disappointed. But then this disappointment should be part of the outcome. And if the outcome in *B* for state ticket 1 is "0 and feeling very disappointed," there is no longer any threat to the Sure-thing Principle. The problem with this maneuver is that it should not be ad hoc. We would like to have some nonarbitrary, independent principles for when more fine-grained descriptions of outcomes are allowed.

It is not the task of this chapter to take a stand for or against the Sure-thing Principle. It is rather to explore the consequences of accepting the Sure-thing Principle. I shall just point out that the Sure-thing Principle and the idea of giving special weight to certainty are very different ways to model uncertainty. The Sure-thing Principle allows no interaction between states in the evaluation of acts. In effect, this means that the evaluation of an outcome is independent of how probable it is. And the Sure-thing Principle is a necessary condition for representing preferences by an expected utility function.

The idea that certainty has a special status, and more generally that the evaluation of an outcome may depend on how probable it is, is a violation of the Sure-thing Principle, because the evaluation of an outcome in one state depends on what happens in other states. Therefore, if uncertainty is modeled based on these features, then preferences cannot be represented by an expected utility function.

Savage next defines *weak preference among outcomes*: outcome  $a$  is weakly preferred to outcome  $b$  if, and only if, act  $A$ , having  $a$  as the outcome in every state, is weakly preferred to act  $B$ , having  $b$  as the outcome in every state. Moreover, an event is impossible if it does not influence the preference among any acts.

*Axiom 3* says that if  $A$  is an act, which has the outcome  $a$  in every state, and  $B$  is an act, which has the outcome  $b$  in every state, and  $X$  is not an impossible event, then  $A$  is weakly preferred to  $B$  given  $X$  if, and only if,  $a$  is preferred to  $b$ .

This means that knowledge of an event  $X$  cannot change a preference among outcomes. In other words, if an act has the same outcome in every state, the outcome should be certain in the sense that it is independent of which state obtains. The description of an outcome should thus contain all relevant information leaving no uncertainty for the decision maker. If the evaluation of some proposed outcome turns out not to be independent of whichever state obtains, it should be regarded as an act, not an outcome.

## Qualitative and Quantitative Subjective Probability

The remaining axioms are concerned with probabilities (with the exception that axiom 6 also has implications for the evaluation of outcomes). Since I am not concerned with probabilities per se, I shall only present the axioms briefly. First some definitions:

A person is offered a *prize* in case  $X$  obtains, if he is offered an act of which he prefers the outcome given  $X$  obtains to the outcome given  $X$  does not obtain.

Consider the following situation, where  $a$  is preferred to  $a'$  and  $b$  is preferred to  $b'$  (☞ [Table 16.3](#)).

Now a definition of *qualitative subjective probability*:  $X$  is at least as probable as  $Y$  if, and only if,  $A_X$  is weakly preferred to  $A_Y$ . The decision maker prefers  $a$  to  $a'$ , and he therefore prefers the act which is more likely to result in  $a$ , rather than  $a'$ . In other words, he considers  $X$  more probable than  $Y$ .

*Axiom 4* mirrors the Sure-thing Principle for qualitative probability. It says that if  $A_X$  is weakly preferred to  $A_Y$ , then  $B_X$  is weakly preferred to  $B_Y$ . Hence, this axiom states that the evaluation of probabilities of states is independent of the prizes offered. The Sure-thing Principle is an independence requirement for the evaluation of outcomes (outcomes can be evaluated independently from the probabilities of states), and this is an independence requirement for the evaluation of probabilities (probabilities of states can be evaluated independently from the outcomes in states).

*Axiom 5* is the rather innocuous assumption that there is at least one pair of outcomes,  $a$  and  $b$ , such that  $a$  is preferred to  $b$ . If axiom 5 were false, then the relation – is more probable than – would be empty.

☞ [Table 16.3](#)

Illustration of qualitative probability and axiom 4

	$X$	$\sim X$		$Y$	$\sim Y$
$A_X$	$a$	$a'$	$A_Y$	$a$	$a'$
$B_X$	$b$	$b'$	$B_Y$	$b$	$b'$

*Axiom 6* says that if  $A$  is preferred to  $B$ , and  $x$  is any outcome, then there exists a partition of the set of states such that, if  $A$  is modified in any event of the partition to take the value  $x$  in all states there, other outcomes being the same, then modified  $A$  remains preferred to  $B$ ; if  $B$  is modified in any event of the partition to take the value  $x$  in all states there, other outcomes being the same, then  $A$  remains preferred to modified  $B$ .

Consider first the case in which  $A$  is modified.  $A$  is modified in some subset of states by replacing the original outcomes in these states by the outcome  $x$ . The axiom requires that modified  $A$  remains preferred to  $B$ . If  $x$  is a better outcome than the original unmodified outcomes, this is trivially fulfilled. Thus, the axiom only has teeth in the case when  $x$  makes  $A$  worse. In this case, the axiom implies that no matter how bad an outcome  $x$  is, there exists a partition of the set of states into events that are sufficiently fine grained to make the probability of any of them so close to zero that if  $A$  is modified with  $x$  in any of them, modified  $A$  is still preferred to  $B$ . And similarly, no matter how good an outcome  $x$  is, a partition of the set of states into events exists such that if  $B$  is modified with  $x$  in any of them,  $A$  is still preferred to modified  $B$ .

This is a quite strong assumption. Firstly, it ensures that one can always find an event, which corresponds to each probability number, such that the probability measure is unique. Secondly, it is also serves as a continuity condition. In measurement theory, such conditions are often called *Archimedean* conditions, because they correspond to the *Archimedean* property of real numbers: for any number  $x$ , no matter how small, and any number  $y$ , no matter how large, there is an integer  $n$  such that  $nx \geq y$ , i.e., the ratio between any two numbers is always finite. Axiom 6 excludes outcomes, which are “infinitely” good or bad. If there was an infinitely bad outcome  $x$ , modified  $A$  would not remain preferred to  $B$ , regardless of how low the probability of  $x$  occurring; and  $x$  would have to be assigned an infinitely low utility; if there were an infinitely good outcome  $x$ ,  $A$  would not remain preferred to modified  $B$ ; and  $x$  would have to be assigned an infinitely high utility. Thus, axiom 6 ensures that any outcome can be assigned a real-value utility number (i.e., utility fulfills the *Archimedean* property of real numbers).

## The Representation and Uniqueness Theorems

---

From the 6 axioms follows the conclusion:

There exists a probability measure  $p_i(s_i)$  assigning probabilities to states that sum to one, and a real-valued utility function  $u(a_i)$  assigning utilities to outcomes

$$u(A) = p_1 u(a_1) + p_2 u(a_2) + \dots + p_s u(a_s) \text{ such that}$$

$A$  is weakly preferred to  $B$  if, and only if,

$$p_1 u(a_1) + p_2 u(a_2) + \dots + p_s u(a_s) \geq p_1 u(b_1) + p_2 u(b_2) + \dots + p_s u(b_s); \text{ and}$$

the probability measure is unique, and the utility function is unique up to linear transformation.

I shall not present a proof. Savage's own proof is quite complicated. A more accessible proof is probably Fishburn (1970, pp. 191–214).

## The Maxim “Maximize Expected Utility”

---

Many expositions of decision theory are summarized in the maxim that the decision maker should maximize expected utility. Gärdenfors and Sahlin (1988, pp. 1–5) is a telling example. Introducing Savage’s decision theory, they say that the assumption is that the decision maker *evaluates the possible outcomes by assigning a utility measure to them*, and that he possesses probability measures of the likelihood of each state. He is then supposed to *compute the expected utility* of the various alternative acts and choose the one with the maximum expected utility. Gärdenfors and Sahlin claim that Savage’s representation and uniqueness theorems provide the foundation for these assumptions and the principle of maximizing expected utility.

Although popular, it should by now be clear that this is a misunderstanding of the theory. It is true that Savage’s theorems provide the decision maker with a cardinal utility measure for outcomes and a unique probability measure for the likelihood of states. It is also true that a decision maker, who has a cardinal utility measure for outcomes and a unique probability measure as given, and who forms his preferences according to a computation of the expected utility of acts, trivially satisfies Savage’s axioms. Still, Gärdenfors and Sahlin put things upside down; they begin with numerical evaluations of outcomes (called “utilities”) and probabilities and let the preferences over acts be the result of a calculation of the expected utility of the alternative acts. But theory starts out from the assumption that the decision maker has *preferences over pairs of acts*. It then proves that if these preferences over acts conform to the axioms, they can be represented by a function with an expected utility form. Preferences over acts are the primitives of the theory, from which the numerical representation of outcomes is deduced.

Utility is a theoretical construct that summarizes the information already given by the preferences. To say that an individual maximizes his expected utility is just to repeat that he chooses according to his preferences. As it is often carefully expressed, if the decision maker’s preferences satisfy the axioms, his choices can be described *as if* he maximized (the theoretical construct) utility (e.g., Luce and Raiffa (1957, p. 31)). But utility is *not* defined as a substantial objective; it is not assumed to play any role in the decision maker’s deliberations as something he aims to maximize. The decision maker does not prefer one act to another *because* it has a higher utility, he simply prefers it and therefore it has a higher utility.

The difference is not only about the role of utility in deliberation, it is also about the decision maker’s attitude to risk: If the decision maker assigns “utility” to an outcome according to the *value* for him of the outcome occurring, maximizing expected utility implies *risk neutrality about this value*. Preferences based on this calculation therefore ignore the question of risk. If utility, on the other hand, is derived from basic preferences over acts, these preferences are defined to take risk into account, and utility therefore embodies the considerations of risk. The utility of an outcome cannot be identified with the value for the decision maker of the outcome.

Hence, the central misunderstandings are, firstly, not to recognize that *preferences over acts are assumed by the theory* and not derived from it; moreover, not to recognize that *utility is defined to represent these assumed preferences over acts* and, even though the theory assigns utilities to outcomes, these utilities are derived from the basic preferences over acts and thus reflect the decision maker’s attitude to risk. I stress these points because they form a recurrent theme in this chapter.

## The Problem of Action Guidance

---

However, if decision theory simply assumes that the decision maker has a complete preference ordering for acts, then he already knows what to do. It seems a reasonable expectation that decision theory should guide us in dealing with uncertainty. Now we are told that it simply assumes that we already know what to do. What is the use of a theory of this kind? The first step in answering this question is to make the message of decision theory clear. What does it recommend?

Well, taken literally, it does not recommend anything. The theory consists of a representation theorem and a uniqueness theorem, which are two statements of the “if . . . , then . . . ” form. It does not contain any prescriptions. However, the standard interpretation of theory assumes it to have normative implications.

Decision theory (in Savage's version) is born with the following interpretation: the empirical relation is the decision maker's weak preference relation, and it is defined on a set of objects which is the product set of the alternative acts and the set of the possible states; more precisely, the preferences are defined on the rows of this product set, i.e., on acts understood as uncertain prospects, consisting of the outcome in each possible state ( $a_1, a_2, \dots, a_s$ ). The numerical representation assigns nonnegative numbers that sum to 1 to the states (called “probabilities”) and real numbers (called “utilities”) to outcomes in such a way that one act is preferred to another if, and only if, it has a higher expected utility.

On this standard interpretation, the axioms are understood as requirements of rationality for choice behavior. These requirements are only formal. They are not about the content of preferences, but about consistency requirements between them. The claim that it is rational to conform to the axioms has been backed up by additional theorems aiming to show that a decision maker, who violates the axioms, risks ending up with less preferred outcomes than he could have achieved. He may thus fare worse by his own standards than he could have, and to end up choosing a less preferred outcome when a more preferred outcome could have been obtained is clearly not rational.

One such theorem says that an individual who violates transitivity may be exploited by a so-called money pump. A violation of transitivity implies cyclical preferences (e.g.,  $A$  is preferred to  $B$ , which is preferred to  $C$ , which is preferred to  $A$ , and so on). Assume that you are willing to pay a small amount for obtaining a more preferred outcome. If you have cyclical preferences, then, at some stage, you will end up with the outcome with which you started, but this time with less money (Davidson et al. 1955). Another theorem says that an individual who violates the laws of probability (which are implied by the axioms) may be exploited by a so-called Dutch Book. A Dutch Book is a combination of bets that is certain to lead to a loss. For instance, if your probabilities, in a given case, do not sum to 1, this fact can be exploited by setting up bets you will be likely to accept because of your probabilities, but which taken together will lead to a loss for sure (Kemeny 1955; Lehman 1955; Shimony 1955).

The strength of this kind of justification for the axioms (often called *pragmatic arguments*) is contested (Schick 1986; Rabinowicz 1995). Also, axioms like completeness or the Sure-thing Principle are in need of another kind of justification. The Sure-thing Principle was discussed briefly above. And why should completeness be a requirement of rationality? Or axiom 6 for that sake? However, again I shall not pursue these questions any further, because the interest here is to take the axioms for granted and to ask what we can learn from them with regard to decision making under uncertainty.

Hence, if we take the message of decision theory to be that preferences should conform to the axioms, we shall have to take a closer look at the axioms to get a grip on what is recommended. The axioms are conditions for the structure of preferences. They do not tell us what preferences to have, but once we have some preferences, they constrain the additional preferences we could rationally have together with them.

The most important axiom for decision theory's handling of uncertainty is no doubt the Sure-thing Principle. It tells us that, when comparing two acts, we should compare them state-by-state and then weigh up the differences between the possible outcomes in such a way that they can be weighted with any kind of probability. Utility assignments embody this weighing up. Consider  [Table 16.4](#) below (taken from Broome (1991b, p. 146)), the numbers represent income per week for some individual.

It follows from the theory that  $A$  is preferred to  $B$  if, and only if,  $u(A) > u(B)$ , i.e., if  $\frac{1}{2}u(100) + \frac{1}{2}u(200) > \frac{1}{2}u(20) + \frac{1}{2}u(320)$ , which again is equivalent to  $u(100) - u(20) > u(320) - u(200)$ . These utility differences tell us how much the difference between these outcomes counts. The risk of getting €20 instead of €100 counts for more than the chance of getting €320 instead of €200. Had it been the other way round,  $B$  would have been preferred to  $A$ .

Weighing up these differences *determines the attitude to risk*, and the *considerations concerning risk are embodied in the utility assigned to each possible outcome*. Note that the utility assigned to an outcome is independent of probabilities. The weighting embodied in the utility assigned to outcomes is supposed to work for any probability distribution over the states. In the example, the states are equally probable, but the same weighting should cover all possible unequal distributions as well.

Remember that Bernoulli coupled the claim about risk aversion about money with the claim that money has diminishing marginal value. However, as pointed out by Hansson (1988), the diminishing marginal value of money and risk aversion about money gambles are conceptually two different things. So, if the decision maker is risk averse about money gambles, the utility of an outcome is not just the value for him of the outcome, but rather an increasing strictly concave transform of the value for him of money. I return to this point below.

To summarize, decision theory tells us to have preferences that conform to the axioms. From the structure these axioms impose on preferences, we can derive some recommendations. Most importantly, the Sure-thing Principle tells us to form preferences by comparing differences between outcomes state by state. Likewise, recommendations for forming subjective probabilities can be derived, but I shall leave them aside here.

 **Table 16.4**  
Weighing outcomes in the face of risk

Prospect A		Prospect B	
State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$	State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$
€100	€200	€20	€320

## Decision Theory as a Theory of Good

### External Reasons

According to the standard interpretation, the rationality requirements are purely formal. The content of the decision maker's beliefs about probabilities, and his preferences over acts, seems to be exempted from the requirements of rationality. To put it another way, the theory does not tell us how we should form our beliefs and preferences; it only sets up some restrictions for this formation process. However, even though it is not part of the theory itself, the standard interpretation will typically refer to *Bayes' Theorem*. This theorem shows, roughly, how we can revise initial probabilities in the light of new information (again, I cannot go into details here, but see Peterson (2009, pp. 125–130) for an introduction and Mellor (2005) for a further discussion). This indicates that, even on the standard interpretation of decision theory, there is some interest in justifying beliefs by reasons that are external to the theory.

Conventional Bayesian decision theorists will, of course, insist that an agent is free to believe and prefer whatever he wishes, as long as he fulfills the formal rationality requirements. However, others have advocated some form of combination of the formal apparatus of decision theory with substantial external theories about what to believe and prefer. For one thing, it is possible to combine decision theory with a more objective approach to probabilities (Broome 1991b). For the rest of this chapter, I shall assume such an approach without being specific about it. I shall simply assume that there is one “best” set of probabilities, which applies to all individuals.

My main concern will be with another concept: the idea that some external substantial theory guides us when determining what is good for an individual, or good overall. It is a reasonable assumption that a theory about what is good for an individual in the face of uncertainty, or a theory about what is good overall in the face of uncertainty, should satisfy the rationality requirements of decision theory, and this is the idea I shall investigate further. The substantial content should come from a theory about what is good for an individual, or from a theory about what is good overall.

In this vein, John Broome (1991b) has suggested an interpretation of decision theory as a theory about good. He assumes the existence of a weak betterness relation for each individual (— is at least as good for individual  $i$  as —) and a weak general betterness relation (— is at least as good as —) defined over acts (i.e., uncertain prospects). It is understood that theories about self interest and ethics determine how the individual relations and the general relation order the acts. On this interpretation, decision theory implies that, if a weak betterness relation (be it personal or general, I shall often discuss these cases together) satisfies the axioms, then it can be represented by an expected utility function.

On the face of it, decision theory is here connected to axiology, i.e., the study of values – more precisely the study of what is good for individual and what is generally good. However, for Broome, the general betterness relation is directly connected to ethics, i.e., the study of what is right to do. Broome defines *teleological ethics* by the claim that the right act is determined by an ordering according to betterness. Standard teleology has a *maximizing structure*: it says that if one act is higher in the ordering then that act is right, and all other acts are wrong.

To see matters this way is rather rare among philosophers. It is more common among economists who do similar things in welfare economics under uncertainty. However,

economists, unlike philosophers, are not used to the concept of goodness. They generally prefer to talk about individual preferences and social preferences. John Broome was originally an economist, but he became a philosopher; and he has thereby been able to bridge the two traditions. A specific point for Broome has been to avoid certain problems with subjective probabilities in welfare economics or social choices by a more objective approach (see more below).

Among philosophers, it is much more common to refer to the maxim “maximize expected goodness.” Derek Parfit (1984) says: “What we ought subjectively to do is the act whose outcome has the greatest *expected* goodness” (p. 25). Michael Zimmerman (2008) advises people to do the act which is *prospectively better*, and “prospectively best” is to be understood in terms of expectable value for the agent” (p. 126).

The widespread opinion among philosophers is that decision theory *implies* the maxim of maximizing expected goodness. Some moral theory provides us with an ordering of outcomes according to their moral goodness. And decision theory supposedly tells us to choose the act, which leads to the highest expectation of goodness. Frank Jackson (1991) says (pp. 463–464):

- ▶ Generalizing, the proposal is to recover what an agent ought to do at a time according to consequentialism from consequentialism’s value function – an assignment of value that goes by total consequent happiness, average consequent preference satisfaction, or whatever it may be in some particular version of consequentialism – together with the agent’s subjective probability function at the time in question in the way familiar in decision theory, with the difference that the agent’s preference function that figures in decision theory is replaced by the value function of consequentialism. That is to say, the rule of action is to maximize  $\sum_i Pr(O_i/A_j) \times V(O_i)$ , where  $Pr$  is the agent’s probability function at the time,  $V$  is consequentialism’s value function,  $O_i$  are the possible outcomes, and  $A_j$  are the possible actions.

For Jackson, “the agent’s preference function” is the agent’s ranking of states of affairs, and it is supposed to be replaced by consequentialism’s ranking. But, as we have seen, decision theory does not advocate the maxim of maximizing expected goodness. However, apart from the mistaken reference to decision theory, philosophers might have other reasons for seeing things this way.

First, Broome’s interpretation of decision theory presented here considers the goodness (or rather betterness) of uncertain acts basic. But when we determine whether one uncertain act is better than another, we do it relative to the available probabilities. This sort of probability-relative betterness appears as an interim sort of goodness. What ultimately matters is what actually happens, once the uncertainty is resolved. Hence, it could be argued that goodness is truly a property of final outcomes and not a notion that can be applied on the basis of probabilities. Most ethical theories have in fact discussed goodness as a property of outcomes with no uncertainty involved, i.e., they assume the ideal situation of choice under certainty. Secondly, the maxim “maximize expected goodness” might be considered more action guiding than simply assuming a complete ordering of acts.

However, both of these ideas have serious problems of their own when it comes to dealing with uncertainty. Ironically, these problems arise exactly because the idea of goodness as a property of final outcomes and the connected maxim of maximizing expected goodness overlook the central insight of decision theory.

## Probability-Relative Goodness

---

Consider first the former claim. Everybody seems to agree that if there is uncertainty at the time when the decision is to be made (and decision theorists would insist that there is *always* uncertainty), the decision maker has to base his decision on the available probabilities. On the other hand, everybody also agrees that what ultimately matters is the final outcome.

Often, it is put in the way that *subjectively* (cf. the Parfit quote above) we ought to do the act whose outcome has the greatest expected goodness. But later on, this act can turn out to be *objectively* wrong. The challenge is: How can we say that one act is better than another on the basis of probabilities when later on, once the uncertainty has been resolved, the act may not turn out to be better after all? What is really the right thing?

Philosophers have struggled with this question. G. E. Moore was perhaps the most firm advocate of the view that goodness is a property of final outcomes. He drew the conclusion that, in the face of uncertainty, you can never know what is the right thing to do (Moore 1903, p. 199). But this would imply that ethics has nothing to say about how to act under conditions of uncertainty.

Using an example set up by Frank Jackson (1991, pp. 462–463), Michael Zimmerman has argued that there are cases in which Moore's view does not imply a lack of knowledge about what is right under conditions of uncertainty, but actually leads to the wrong conclusion:

- ▶ Jill is a physician who has to decide on the correct treatment for her patient, John, who has a minor but not trivial skin complaint. She has three drugs to choose from: drug A, drug B and drug C. Careful consideration of the literature has led her to the following opinions. Drug A is very likely to relieve the condition but will not completely cure it. One of the drugs B and C will completely cure the skin condition; the other though will kill the patient, and there is no way she can tell which of the two is the perfect cure and which is the killer drug. What should Jill do?

(In Zimmerman's account, A is called *B*, and B is called *A*). A decision theoretic analysis of the case looks like  [Table 16.5](#).

In this case, Moore knows that A results in an outcome which is *not* the best. He is therefore forced to say that this act is wrong. But that seems clearly to be the wrong conclusion (Zimmerman 2008, p. 18). B and C are too risky, and Moore's view does not seem to be able to take risk into account.

 **Table 16.5**  
**The Jackson case**

Acts \ States	B completely cures the condition C kills the patient $p = \frac{1}{2}$	C completely cures the condition B kills the patient $p = \frac{1}{2}$
Drug A	Partial cure	Partial cure
Drug B	Complete cure	Patient dies
Drug C	Patient dies	Complete cure

Clearly, the subjective view that whatever the decision maker believes is right (i.e., whatever subjective probabilities he has) is actually right will not do either. It is of course still the case that what ultimately matters is what actually happens. The way to deal with this fact is to make a distinction between probabilities of different status (Broome 1991b, pp. 126–131). Objective probabilities (if they exist) have a higher status than subjective probabilities. Probabilities based on more evidence have higher status than probabilities based on less. At the limit, what would actually happen has the highest status. I cannot present a detailed account of the status of probabilities here, but I hope the idea at least seems intuitively plausible.

You ought to base your judgment on the best available probabilities. Looking at the Jackson Case, we know that *A* does not lead to the best possible outcome, but either *B* or *C* does. Given the best available probabilities, it would be too risky to choose one of these acts. It is better to choose *A*. The certain knowledge we have in this case does not influence the evaluation of the acts (given the available probabilities).

There is a thorough discussion of these questions in Zimmerman (2008). He advocates what he calls the Prospective View, according to which, very roughly, we ought to evaluate the acts on the basis of the best available probabilities. The details of Zimmerman's theory about uncertainty are rather complex, and in some ways they are at odds with decision theory according to Savage's version; however, I cannot go into these details here. One thing worth mentioning, though, is that Zimmerman still believes goodness to be a property of final outcomes, and he understands the Prospective View in terms of the maxim "maximize expected goodness." This prevents him from fully acknowledging the insights of decision theory, with regard to dealing with uncertainty.

## Problems for the Maxim of Maximizing Expected Goodness

---

The maxim of "maximizing expected goodness" faces two severe problems. The first problem is a problem of measurement. We know that the operation of forming the mathematical expectation of some quantity requires that the quantity is cardinally measurable, i.e., it must be determined uniquely, at least up to linear transformation. But it is doubtful whether the goodness of outcomes can be measured with so much numerical structure. The standard assumption in ethical theory is that there is an ordering of outcomes in terms of their goodness. And the lesson from economics was exactly that a simple ordering of outcomes can only be represented by an ordinal scale.

It might be thought that decision theory supplies us with a cardinal measure of the goodness of outcomes. But this is not true. Decision theory provides us with a cardinal measure of the *utility* of outcomes. To identify utility with goodness is a mistake. "Utility" is defined as a function, which represents the betterness relation. In doing so, it assigns numbers (utilities) to outcomes in possible states in such a way that one act is at least as good as another if, and only if, it has at least a high expected utility.

The utility of an outcome reflects its weight in the comparison of uncertain *acts* in terms of betterness. There is no direct way to separate out the *goodness of the outcome* in itself, so to speak. In fact, it is difficult to specify what the goodness of an outcome in itself means. The measurement of goodness is determined by some context. The context of decision theory is the comparison of acts in terms of betterness. Perhaps goodness is measured by the comparison of pure outcomes in a context with no uncertainty? But comparing outcomes in terms of betterness in a context of certainty can only lead to ordinal measurement of goodness.

At any rate, the utility of outcomes is not an entity which it makes sense to use for calculations of expected utility, because it is already defined as that which the decision maker maximizes the expectation of. There is a complete ordering of acts, and utility represents this ordering. To calculate expected utility is just to repeat what we already know.

The challenge for the maxim of maximizing expected goodness is therefore to find a cardinal measure of the goodness of outcomes, which is independent of decision theory, but which at the same time orders outcomes in the same way. The only way to obtain this is through modeling the domain of outcomes with a richer structure that would allow numerical representation by a cardinal scale. This might not be impossible. However, the best known suggestions of this sort depend on strong premises and are considered controversial (there is an example in Peterson (2004); see also the discussion in Broome (1991b); Jensen (1995); Ellingsen (1994)).

But suppose for a moment that the goodness of outcomes could be measured cardinally (independent of decision theory). The second problem is then that the maxim of maximizing expected goodness implies *risk neutrality about good*. Only the expectation of goodness counts, it has no value to avoid risk. This appears rather implausible. Consider a choice between 100 units of goodness for sure, and an option that will lead, with equal probability, to either no units, or 200. These options have the same expectation of goodness, but it seems clearly better to play safe and avoid the risk of getting nothing at all.

At any rate, the maxim of maximizing expected goodness assumes risk neutrality about goodness by definition, so to say, as if it was a direct implication of decision theory. Remember that Bernoulli advocated risk aversion about money, but *Bernoulli's Hypothesis* was exactly to maximize the expectation of goodness, and this implies risk neutrality about good. This may be the reason why many people believe that decision theory implies risk neutrality about good. Also on this point, a fundamental insight of decision theory is overlooked, because decision theory allows us to keep the question about the attitude toward uncertainty about goodness open, simply by recognizing that utility is *not* identical to goodness with certainty.

On the face of it, risk aversion about goodness appears very reasonable. Indeed, if there is reason to be risk averse concerning money, as many people are, there is so much more reason to be risk averse about goodness. It certainly requires an argument to justify risk neutrality about goodness.

It is clear that decision theory and the goodness measure should agree on the *ordering* of outcomes. If utility, as determined by decision theory, happened to be a linear transform of goodness, decision theory would imply risk neutrality about goodness. However, since some form of risk aversion is more plausible, utility is likely to be an increasing nonlinear transform of goodness, more precisely an increasing concave transform of goodness (see ➤ Fig. 16.2).

---

## Bernoulli's Hypothesis

Broome (1991b) puts forward the proposal that we consider utility as a measure of goodness (pp. 142–148, 213–222; see also Jensen (1995)). This would answer both problems: There is now a cardinal measure of the goodness of outcomes, and since utility is defined as that which the decision maker maximizes, risk neutrality about good follows automatically. Broome claims that this would amount to a modern version of *Bernoulli's Hypothesis*: an individual ought to maximize the expectation of his good.

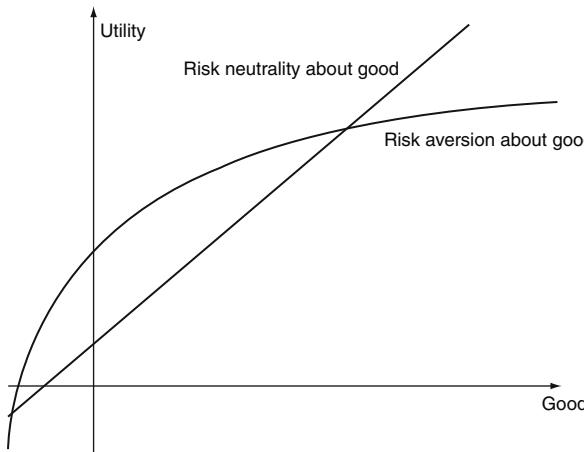

Fig. 16.2

### Utility as a transform of goodness

Broome's suggestion is that a distinction between good and utility (i.e., how much good counts in decision making) appears empty. "Utility" is simply the most plausible candidate to provide the notion of a cardinal measure of the goodness of outcomes with meaning.

But this reasoning seems dubious. The standard meaning of the goodness of an outcome is its value as a certain outcome for the individual. The utility of an outcome, on the other hand, is the strength of the reason in favor the occurrence of this outcome has in decision making under uncertainty, regardless of the probability with which it occurs. Utility summarizes all relevant information about the attitude to risk, whereas the goodness of an outcome contains no reference to risk. These are clearly different concepts.

Hence, Broome's suggestion does not capture the standard meaning of goodness. So when he says that his modern version of *Bernoulli's Hypothesis* implies "risk neutrality about good," this is not risk neutrality about good in the ordinary sense. The question of whether an individual should be risk neutral about good in the ordinary sense remains controversial. But Broome is of course right that the context in which goodness can be measured cardinally remains unclear.

To summarize, the maxim of maximizing expected goodness leaves no room for risk aversion about goodness. Only a betterness relation defined on uncertain acts leaves room for a choice between risk neutrality and risk aversion about goodness. Or rather, a betterness relation defined on acts leads to a utility function, which embodies considerations of goodness and risk simultaneously, where there is no direct way to separate these considerations. This is why I call it a core insight of decision theory to consider the ordering of acts as basic rather than the ordering of outcomes.

## General Good and Individual Good

I shall now move on to the realm of ethics and consider the weak general betterness relation. More specifically, I shall be concerned with how the weak general betterness relation relates to the individual weak betterness relation. The weak general betterness relation implies some

attitude to risk for general betterness. It may seem a natural suggestion that attitude to risk implied by general betterness' should be a function of the individual betterness relations and the attitude to risk implied by them. In other words, I shall examine the idea that general betterness should reflect how uncertain acts look from the personal perspective.

## Equalizing Risk

First, I shall examine the idea that there should be a concern for equality in the prospects people face. Peter Diamond (1967) has demonstrated that the Sure-thing Principle has consequences for general betterness, which once again makes it a controversial axiom, because it is in conflict with this concern. Consider Diamond's example in [Table 16.6](#). There is a kidney available for transplantation and two people  $P$  and  $Q$  who need a kidney in order to survive. The choice is between  $A$ , tossing a coin to decide who is to get the kidney, or  $B$ , giving it directly to  $P$ .

Note that this is a boiled-down version of the more general question about risk distribution: Knowing that one individual is going to die, is it better that two individuals have an equal chance of dying, rather than one individual dying for sure? Or if 100 people will die, is it better to have 10 million people exposed to a 1 in 10,000 chance of dying, than to have 10,000 exposed to a 1 in 100 chance?

The Sure-thing Principle for general betterness implies that we should judge what happens in one state, given fixed outcomes in the other, independently of what these other outcomes are. Suppose we judge it better in state Heads that  $P$  lives and  $Q$  dies, given that in state Tails,  $P$  dies and  $Q$  lives. According to the Sure-thing Principle we should retain this judgment of what happens in state Heads, also given that in state Tails,  $P$  was to live and  $Q$  was to die. If we do, then  $A$  and  $B$  are equally good. But if we believe that people should have equally good prospects, then we should deny this implication. Hence, equalizing risks violates the Sure-thing Principle for general betterness.

Clearly, at least as long as there is nothing to discriminate between these individuals, it appears very unfair to simply pick out one of them to die. The trouble is that two different conclusions can be drawn from this intuition. One is to opt for the general view that there is value in equalizing the prospects people face. This option involves giving up the Sure-thing Principle for general betterness. In this option, the unfairness is not located in any particular outcome. The unfairness is only visible when we compare what happens in one state with what happens in another. Allais wanted to give special weight to certainty about some preferred outcome. Diamond wants to give special weight to avoid the certainty of a bad outcome, and more generally, to equalize the prospects people face.

**Table 16.6**  
Diamond's case

	Act A		Act B	
	State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$	State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$
Individual $P$	Lives	Dies	Lives	Lives
Individual $Q$	Dies	Lives	Dies	Dies

The other option, however, is to say that if there is value in avoiding unfairness, this value should be located in some outcome. Hence, it could be said that the unfairness is indeed done to individual Q in act *B*; and therefore it should be located as part of the outcome in both states here: “dies and treated unfairly.” This is the line John Broome (1991b, pp. 110–115) takes. It avoids violating the Sure-thing Principle, because there is now a difference between the outcomes for Q in the two prospects.

More generally, Broome rejects the idea that there is any merit in equalizing the prospects people face. The reason is simply that if equality is valuable, it is equality in the final outcome that matters, not equality in the prospects people face. This is compatible with the observation that if there is not enough of some indivisible good to treat all people equally, such as the kidney in Diamond’s example above, we owe people equal chances.

## The Principle of Personal Good

---

Assume now that general betterness and individual betterness satisfy the axioms of decision theory. Next, I shall discuss the general idea that the attitude to risk in general betterness should reflect what is good for individuals in the face of uncertainty.

The *Pareto Principle* connects general good (which economists call “social preferences”) with individual preferences: Two acts are socially indifferent if everyone is indifferent between them; and if everyone weakly prefers one act to another, and at least one strictly prefers it, then it is socially preferred. Applied to uncertain acts and allowing for subjective probabilities, the Pareto Principle conflicts with Savage’s axiom 4 for “social preferences.” I cannot go into details here (they are explained in Broome (1991b, pp. 152–163), but it should be intuitively understandable that if people disagree about probabilities, it will be impossible to determine “social probabilities” for “social preferences.”

In the face of this conflict, some economists stick to the Pareto Principle and give up decision theory for “social preferences”; this is called the *ex ante* approach to the aggregation of preferences. But since the task here is to examine the consequences of accepting decision theory, I shall look in another direction. The *ex post* approach to the aggregation of preferences sticks to decision theory and instead abandons the Pareto Principle for acts (but retains it for outcomes). This approach builds on a distinction between preferences over acts, which involves beliefs about probabilities, and preferences over outcomes which presumably does not. The *ex post* approach wants to skip the former and use “social probabilities” instead, but keep the latter as the basis for aggregation.

But this is a misleading distinction. In decision theory, preferences over acts are basic, and they depend on beliefs about probabilities. Preferences over outcomes are derived from these preferences over acts. Hence, there is no way to find pure preferences over outcomes that are independent of beliefs.

Instead, Broome (1991b) has suggested what he calls the *Principle of Personal Good* for uncertain acts. This principle assumes that the same probabilities apply for all individuals, as well as for general good. This is in line with the *ex post* approach. But it is more objective in the sense that it frees the evaluation of an individual’s good from his preferences (which are based on his subjective beliefs).

- ▶ *The Principle of Personal Good:* Two alternatives are equally good if they are equally good for each person. And if one alternative is at least as good as another for everyone, and definitely better for someone, it is better.

The idea underlying the Principle of Personal Good is that general betterness should be responsive to the betterness of an individual. Thus, it is more in spirit with the original Pareto Principle insofar as it insists on the perspective on uncertainty from a personal point of view as being fundamental for the aggregation of betterness across individuals. But the Principle of Personal Good is only sparsely discussed in the literature.

The Principle of Personal Good is defined for uncertain acts and thus implies a notion of probability-relative good. Hence, it implies that general betterness should be responsive to the betterness of individuals, given the available probabilities. But this may lead to a conflict with the concern that general betterness should be responsive to the betterness of individuals in final outcomes.

Consider the following example (☞ *Table 16.7*) set up by Broome (1991b, pp. 170). The states are equally probable. The figures in the table stand for the income of two individuals. Assume that the good for these two individuals is determined by their income only, and assume that it is good for both individuals to avoid risk to their income.

For both individuals, the two acts have the same expectation of income, but *B* is risky, whereas *A* is not. Given the assumptions, *A* is better for both individuals, and the Principle of Personal Good therefore implies that *A* is generally better.

These judgments are relative to the available probabilities. However, we know for sure that whatever state occurs, one or the other individual will end up worse under *A* than he/she would have been under *B*. Relative to what actually happens, *A* is *not* better than *B* for both people. The question is whether we can trust the Principle of Personal Good under these circumstances and declare *A* to be generally better than *B*, given the probabilities.

Broome has raised this question. Initially, he thought the answer was “no, we cannot trust the Principle of Personal Good” (Broome 1978). However, later Broome (1991b) came to believe that there was a defense of the probability-relative Principle of Personal Good. He says (p. 172):

- *A* is better for *P* than *B* because *A* is less risky, and I assumed it is good for *P* to avoid risk. In expected utility theory, the goodness of avoiding risk appears in the form of weights attached to gains and losses. Here it gives the difference between 2 and 1 more weight than the difference between 3 and 2. [...]

[...] the fact that it is good for *P* to avoid risk is something that must contribute to determining the general goodness of alternatives. Since this goodness appears in the weighting of reasons, the weighting must be preserved in determining which alternative is generally better. This is why *A* is generally better than *B*. The benefit of risk-avoidance to the two people must appear in general good.

■ **Table 16.7**  
A problem for the Principle of Personal Good?

	Act A		Act B	
	State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$	State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$
Individual <i>P</i>	2	2	1	3
Individual <i>Q</i>	4	4	5	3

The trouble is that this defense does not work as it stands. From the point of view of general betterness, in order to evaluate  $A$  and  $B$ , we have to compare them state by state. In state Heads,  $P$  gets 2 in  $A$  and 1 in  $B$ , whereas  $Q$  gets 4 in  $A$  and 5 in  $B$ , i.e.,  $A$  is better for  $P$  and  $B$  is better for  $Q$ . In state Tails,  $P$  gets 2 in  $A$  and 3 in  $B$ , and  $Q$  gets 4 in  $A$  and 3 in  $B$ , i.e.,  $A$  is better for  $Q$  and  $B$  is better for  $P$ . There is a conflict of interest between  $P$  and  $Q$  in both states.

How should general betterness take risk into account? Risk neutrality about good seems as implausible for general betterness, as for individual betterness. The utility of an outcome should reflect the attitude to uncertainty in general betterness. Broome also assumes that the Principle of Personal Good applies for outcomes. It seems to follow that general utility for an outcome should be an increasing function of what is good for the individual in the face of uncertainty (as measured by the individual's utility function). And Broome actually suggests that we should use the weights derived from the individual betterness relations, i.e., utilities, when taking the benefit of risk avoidance for the individuals into account in general betterness.

Given the assumption that it is good for the individuals to avoid risk to income (and goodness), their utility functions will be increasing and strictly concave. However, an increasing, strictly concave transformation of the incomes in [Table 16.7](#) does not resolve the conflict of interest between  $P$  and  $Q$  in both states. As long as we do not know how to compare betterness across individuals, we cannot resolve the conflict and say whether  $A$  is generally better than  $B$ , or the other way round. Hence, the fact that  $A$  is better for both individuals is *not* a sufficient reason to say that  $A$  is generally better.

The Principle of Personal Good applied to uncertain acts seems a natural way to deal with risk to general betterness. However, risk to individuals can be taken into account by letting the betterness of outcomes be an increasing function of individual utilities in these outcomes. Also, looking at risk from the point of view of individuals conceals that there is a conflict of interest in both states. This is not to say that the Principle of Personal Good for uncertain acts cannot be justified, but the justification requires stronger assumptions than the mere point that considerations of risk to individuals should appear in general good. I shall point out three important implications of this discussion.

## Valuing Life

The first is about valuing life. Before presenting the case above, Broome (1978), reprinted in Broome (1991, pp. 177–182), in another context, had cast a widespread procedure for valuing the life of individuals in doubt. Suppose that some public project is up for consideration. Apart from bringing some benefits, the project will increase the probability of dying for everyone. Further, assume that in the end one individual will definitely die. The procedure is now to compensate people for the increased risk of death in such a way that everyone, at the time when the project is considered under conditions of uncertainty, accepts that they are better off with the project and compensation, than without. See [Table 16.8](#).

If acceptance is granted as evidence for people actually being better off (under the uncertain conditions), then the Principle of Personal Good applies, and the project judged in advance is better than the status quo. However, later on, when the uncertainty is resolved and one specific

individual is dying, he will not be better off, because in the face of certain death, the compensation will appear hopelessly inadequate. Broome says (1978, p. 94):

- ▶ If the justification for accepting a project [...] is that compensation can be arranged so that nobody is harmed, then the justification cannot possibly apply when, after the project has been carried out and the utmost has been done by way of compensation, somebody palpably has been harmed, namely the person who has died.

Later, after presenting his defense of the Principle of Personal Good quoted above, Broome (1991b) withdrew this remark (p. 171, note 4). But if the defense does not work, and the Principle of Personal Good requires stronger arguments, the procedure cannot be justified by reference to this principle. From the point of view of general betterness, we shall have to compare the options state-by-state. Assuming that the case is completely symmetrical, this comparison is the same for all states: The procedure is only justified if the (individual utilities of) benefits and compensation to the  $n-1$  people are sufficient to accept the (individual (dis) utility of) loss of one life, and this is *not* ensured by the fact that every individual is willing to run the risk in advance. The judgment from general betterness involves comparisons of betterness *across* individuals.

## The Interpersonal Addition Theorem

However, the next point is that it is possible to state precisely the condition under which the Principle of Personal Good does not conflict with general betterness. This can be inferred from the implications of accepting the Principle of Personal Good. Consider the *Interpersonal Addition Theorem* (Broome 1991b):

There are  $s$  states and  $h$  individuals. Assume individual weak betterness relations and a weak general betterness relation. The theorem says:

- (P1) Each of the  $h$  individual weak betterness relations satisfies the axioms of decision.
- (P2) The general betterness relation satisfies the axioms of decision theory.

Table 16.8

Evaluation of a project causing the statistical death of one out  $n$  individuals

	Project with compensation				No project			
	$p = 1/n$	$p = 1/n$	...	$p = 1/n$	$p = 1/n$	$p = 1/n$	...	$p = 1/n$
Individual 1	Dies	Benefits and compensation	...	Benefits and compensation	Status quo	Status quo	...	Status quo
Individual 2	Benefits and compensation	Dies	...	Benefits and compensation	Status quo	Status quo	...	Status quo
...	...	...	...	...	...	...	...	...
Individual n	Benefits and compensation	Benefits and compensation	...	Dies	Status quo	Status quo	...	Status quo

## (P3) The Principle of Personal Good:

- (a) Two alternatives are equally good if they are equally good for each individual.
- (b) If one alternative is at least as good as another for everyone and definitely better for someone, it is better.

From these premises follows the conclusion:

- (C) The general weak betterness relation can be represented by an expectational utility function that is the sum of expectational utility functions representing the weak betterness relations of individuals.

Two remarks: The first is that this is Broome's reinterpretation of a famous theorem by John Harsanyi (1955), reprinted in Harsanyi (1976, pp. 6–23). Harsanyi's theorem was stated in terms of individual and social preferences. As I said above, Broome uses betterness relations because (1) the same probabilities apply for all, and (2) he does not want to commit himself to the *Preference Satisfaction Theory* about an individual's good. The second remark is that several authors have pointed out that the premises only allow the conclusion that the general utility function can be written as a *weighted sum* of individual utilities. In order to reach the conclusion (C), i.e., that the weights are all one, an explicit premise about interpersonal comparisons is also needed (e.g., Vallentyne (1993)).

Now we turn to the implication of accepting the Principle of Personal Good along with the axioms of decision theory for the betterness relations. Each alternative will be an uncertain prospect:

$$\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_s),$$

specifying for each of  $s$  states the outcome for each of  $h$  individuals. For each individual  $i$  there is an expectational utility function. We can write the utility values in each state of nature for all individuals in a grid like  [Table 16.9](#).

The Sure-thing Principle for general betterness implies that we compare one alternative with another, state by state. For each outcome, we aggregate utilities across individuals, and then we aggregate across states to reach the final judgment. In the discussion above, it was assumed that in aggregating across individuals in an outcome, the Principle of Personal Good applies to outcomes. Hence, general utility in a state is an increasing function of individual utilities. It was also assumed that general betterness deals with risk by taking individual utilities (reflecting the good of risk avoidance for individuals). If there is no risk aversion over and above the risk aversion for individuals, the general utility of an alternative will be its expected utility, given by the sum of general utility for each state, weighted by the probability of the state; and the general utility of a state is an increasing function of individual utilities for that state.

 **Table 16.9**

Individual utilities for the outcomes in all states

	State 1	State 2	...	State $s$
Individual 1	$u_1(\mathbf{x}_1)$	$u_1(\mathbf{x}_2)$	...	$u_1(\mathbf{x}_s)$
Individual 2	$u_2(\mathbf{x}_1)$	$u_2(\mathbf{x}_2)$	...	$u_2(\mathbf{x}_s)$
...	...	...	...	...
Individual $h$	$u_h(\mathbf{x}_1)$	$u_h(\mathbf{x}_2)$	...	$u_h(\mathbf{x}_s)$

Once the Principle of Personal Good is accepted, we learn from the Interpersonal Addition Theorem that it is possible to reach the general utility of an alternative in two ways with the same result. On the one hand we can add up the individual utilities for each state of nature, and then form the general expected utility. But we can also, for each individual, form the expected utility, and then add up across individuals. Hence, an implication of the theorem is that the order of aggregation does not matter.

Under the assumptions of the Interpersonal Addition Theorem, it follows that if the Principle of Personal Good holds, then the general utility of an outcome can be written as the sum of individual utilities. And if the general utility of an outcome can be written as the sum of individual utilities, then the Principle of Personal Good holds. Hence, we can trust the Principle of Personal Good *if, and only if, the general utility of an outcome can be written as a sum of individual utilities*. This is quite a strong condition for the aggregation of individual utilities.

In the case of valuing life, it follows that the ex ante willingness of all individuals to accept the increased risk of death is a reason to accept the project only if, in each state, the sum of the individual utilities of benefits and compensation is larger than the (dis)utility of the death of one individual. In other words, it is not only necessary, for all persons, that the  $(n-1)/n$  chance of receiving benefits and compensation outweighs the  $1/n$  chance of death; it is also necessary that benefits and compensations for  $(n-1)$  individuals outweighs the actual death of one individual. Again, this is not to say that the Principle of Personal Good cannot be justified; but it clearly illustrates that strong premises are needed.

## Equality in Outcomes

It follows directly that the Principle of Personal Good conflicts with egalitarianism, as it is commonly understood, namely, that inequality in the distribution of good among individuals has negative value. John Broome (1991b, p. 185) has introduced the following (☞ [Table 16.10](#)).

Interpret the figures as standing for people's good. The idea is to demonstrate a conflict between the Principle of Personal Good and egalitarianism. The two alternatives are equally good for both individuals (and this is so regardless of the attitude to risk, because the risk is the same for both in both alternatives). Hence, the Principle of Personal Good implies that they are equally good. However, an egalitarian would prefer A, because it is certain to lead to an equal outcome. So an egalitarian is forced to deny the Principle of Personal Good.

▣ **Table 16.10**  
**Equality under uncertainty**

	Act A		Act B	
	State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$	State heads $p = \frac{1}{2}$	State tails $p = \frac{1}{2}$
Individual P	2	1	2	1
Individual Q	2	1	1	2

However, there is the possibility that inequality could be considered a personal harm. If the negative value of inequality is part of an individual's good, there is no conflict with the Principle of Personal Good. Broome (1991b, pp. 192–196; see also Broome (1990–1991), reprinted in Broome (1999, pp. 111–122)) has argued that this maneuver is not ad hoc, but actually captures the essence of the concern for fairness. But this view has not been discussed in detail in the literature.

The Interpersonal Addition Theorem states aggregation across individuals in terms of utility. Harsanyi believed that his original theorem supported utilitarianism. But once we consider the complex relation between an individual's utility and his good, it is clear that the sum of individual utilities does not represent utilitarianism, as it is ordinarily understood. Rather, it is equivalent with some form of the priority view. I say "equivalent" for the following reason: If we assume that personal utility is an increasing strictly concave transform of personal good, this weighting function is determined by considerations of risk, and the priority view is concerned with giving more weight to those who are worse off for moral reasons. But for each form of risk weighting function, there will be an identical moral weighting function, such that the sum of personal utilities is equivalent to the version of the priority view having a moral weighting function of the same form.

## Further Research

---

Ethical theories about the distribution of good across individuals, such as egalitarianism, utilitarianism or the priority view, are typically stated in terms of goodness in situations with no uncertainty. As we have seen, decision theory seems to imply that the ordering of uncertain acts is more basic, because it is possible to take the value of avoiding risk to good into account. But then the ethical question becomes how to aggregate individual utilities in an outcome taking uncertainty into account, rather than goodness with no uncertainty. And this would appear to change the focus of ethical theory considerably.

I see three general directions for future research. One is to try to examine the relations of the two approaches by determining how an individual's utility relates to his good. A way to do this would be to model how goodness and considerations of risk each contribute to overall utility. Technically, this could be done by using what is known as a model for conjoint measurement, i.e., a form of measurement, in which the contribution of two or more factors to some overall magnitude can be measured simultaneously (Krantz et al. 1971, pp. 245–368). Bengt Hansson (1988) has hinted at this idea.

The other line is to simply abandon the traditional certainty approach and examine the implications of an approach inspired by decision theory in more detail. This raises questions such as: How should the concern for equality be stated in terms of individual utilities? Is there an important difference between utilitarianism and the priority view, if utilitarianism is stated in terms of individual utilities?

The third line is to abandon decision theory and to develop an alternative model for decision making under uncertainty and examine its implications for our understanding of individual and general betterness. For instance, it would be very interesting to have a model for uncertainty which does not build on the Sure-thing Principle, and then examine its implication for the ethics of uncertain decisions.

In all cases, there is a lot of work to be done.

**Abstract:** Tsunamis, volcanic ash clouds, financial crashes, and oil blowouts are recent disasters that have caught us by surprise and dominated world headlines. It seems that we are just not very good at predicting such risks or dealing with their consequences. This chapter looks at one reason this might be so – that we are not measuring risk appropriately, either in how we assess a risk or how we then make decisions about risk-related problems. Our measurements are conditioned by expectations of precision and simplicity which, we will argue, are too often lacking in the real world.

In assessing a risk we can miss potential outcomes, especially when a system changes over time. We can treat our theories as true irrespective of empirical support, and we can set impractical thresholds of acceptable risk. When we do measure the risk, we may not have enough data of sufficient quality, or behavioral responses may reduce the measured risk yet increase risk that is not measured. In short, our current assessments of risk are too blinkered.

The associated blunders in decision-making are also all too familiar – disregarding a risk because the model says the chance of the event occurring is low even though we have little confidence in the model; conversely, taking an unduly “precautionary” approach to avoid risks when the potential for harm is negligible; worst of all, perhaps, missing the wider decision-making context needed for a sound judgment.

Put together, these factors mean that simple measures of risk can be a poor guide for decision-makers. This chapter advocates five extensions to current methods in order to avoid these pitfalls in the future. In risk assessment, we need to:

1. Estimate *unknown unknown risk*
2. Quantify *model risk*
3. Use *multiple measures and thresholds*; and in decision support
4. Balance *risk and reward*; and
5. Examine *ROB* (Risk Outside the Box)

We will describe examples where, had certain measures of risk been in place, disasters might have been averted. We will then show how each of the extended methods may be applied. Two particular applications of the proposed approach will be provided – “RAG” statuses in project and risk management, and Solvency II in the insurance industry.

## Introduction

---

Worrying about risk has become a defining neurosis of our age (Beck 1992). The news is full of disasters and reports on what was not done in the past and recommendations about what needs to be done in the future. On the one hand, we are safer than ever before in our daily lives yet, on the other, our interdependent and technologically powerful society has increased the potential for major disasters. Controls cost money and constrain freedom, yet accepting known risks, however small, is increasingly politically unacceptable.

The purpose of this chapter is to show how we might plot a course through the conflicting demands of risk and control.

Many of the vagaries of life that were once just part and parcel of existence can now be anticipated and avoided or, at worst, managed if they do occur. Despite our efforts things still keep going seriously wrong, and, when they do, the subsequent investigation invariably concludes that warnings had been ignored and precautions not taken. Whether we are looking

at signaling systems on the railways, health hazards from asbestos, levees in New Orleans, the debt bubble from subprime lending, or deep water drilling for oil, we are wise after the event about how foolish we were before.

It is not just about miserly shortsightedness, though. Where we do invest effort and money, typically in complex computerized models, we often still get it wrong. “Useless Arithmetic” by Orin and Linda Pilkey (Pilkey and Pilkey-Jones 2006) is one of several recent accounts that gives examples of erroneous models, joined recently by accounts of the 2008 credit crisis such as “Fool’s Gold” by Gillian Tett (2009) which exposes the misjudgments in the banking sector and government.

Many reasons are given for such failures. Hubris, conspiracy, incompetence, greed; they all play a part, no doubt. This chapter will argue, however, that a deeper malaise underlies the mishandling of extreme risks – an inability to measure risk appropriately. We think we know more than we do; we believe we are safer than we really are; we seek oversimplification of a complex world. We would like risk to be binary – we either have it or we do not – whereas for most problems we have levels of knowledge and degrees of uncertainty. What we have not done is to feed the uncertainty back into the process. Instead, we prefer to believe our own publicity, a trap which has echoed down the centuries.

The philosopher David Hume touched on it while reflecting on the problem of induction (Hume 1748):

- ▶ The forming of general maxims from particular observation is a very nice operation; and nothing is more usual, from haste or a narrowness of mind, which sees not on all sides, than to commit mistakes in this particular.

The psychiatrist Henry Maudsley described the fallacy in the nineteenth century (Maudsley 1867):

- ▶ (we have) A sufficiently strong propensity not only to make divisions in knowledge where there are none in nature, and then to impose the divisions on nature, making the reality thus conformable to the idea, but to go further, and to convert the generalizations made from observation into positive entities, permitting for the further these artificial creations to tyrannise over the understanding.

From the twentieth century, the physicist Erwin Schrödinger (1935), reflecting on quantum mechanics, said:

- ▶ Reality resists imitation through a model.

and, coming right up to date, business is recognizing the danger of computer models as expressed by Tad Montross, CEO of General Re Corporation (Montross 2010):

- ▶ Understanding the models, particularly their limitations and sensitivity to assumptions, is the new task we face. Many of the banking and financial institution problems and failures of the past decade can be directly tied to model failure or overly optimistic judgements in the setting of assumptions or the parameterization of a model.

We may have lost the mechanistic certainties of traditional science, but our way of thinking is still primarily reductionist in that we presume we can explain the behavior of systems in terms of the behaviors of their component parts. Fundamental physics, founded on the precept of a mathematical theory that describes the way the world works, has been wondrously

successful. Yet its success has set in us an expectation that all problems can be reduced to equations from which we can compute answers to any problem. In practice, though, we have to use approximations and simplifications which we term *models*. Such simplifications can be known to be inaccurate or wrong yet the illusion of a fundamental theory remains which, supported by mathematical apparatus and computer calculations, makes it all too easy for us to believe that the model is the reality it claims to describe. Such *reification* can lead to serious misjudgments as most systems are too complex for fundamental theories to be used without simplification, approximation, or entirely remodeling. The inherent complexity of biological (e.g., Noble 2008) and economic (e.g., Beinhocker 2006) systems show that they are not adequately described by deterministic or traditional probabilistic models. Yet the siren call of models is seductive and too easily they take on the status of false gods.

The good news is that delusory false accuracy from the reification of models can in many important cases be addressed through explicitly recognizing *model risk*, which is the risk that the model is inappropriate to the problem. The bad news is that this is generally difficult and time-consuming, requires an element of subjective judgment, and meets resistance as it challenges preconceptions and vested interests.

A further twist is whether the various models allow for all potential outcomes. In one sense, of course, they never can and we end up assigning a *catch-all probability* to the set of unforeseen outcomes. The problem with this device is how to set the values for the catch-all probability and, even more so, how to estimate its development over time as circumstances change in our complex world. It is interesting to reflect on how well and poorly the future has been foreseen. For instance, leading American figures were polled in December 1900 ([http://www.yorktownhistory.org/homepages/1900\\_predictions.htm](http://www.yorktownhistory.org/homepages/1900_predictions.htm)) and asked to make predictions for the year 2000. In some cases, such as television, the predictions were remarkably prescient. Others, such as missing aeroplanes by concentrating on airships, reflected the technology of that time. Many, though, such as computers, nuclear power, and genetic engineering, were missed completely. With the current increased pace of technological change, we can anticipate the next 20 years to have as many changes as the last 100.

Recent disasters have reawakened awareness of unforeseen outcomes with Donald Rumsfeld's *unknown unknowns* (Rumsfeld 2002) and Nassim Taleb's *black swans* (Taleb 2007). *Unknown unknowns* are those outcomes we neither knew nor could have known "the ones we don't know we don't know" as Rumsfeld described them, and *black swans* are exceptional and extreme occurrences falling outside the set of expected outcomes based on the problem of induction, and illustrated by the inductive conjecture that all swans are white. Taleb, in particular, sees a false parallel, which he terms the *Ludic Fallacy*, between real-world risk with its unknown outcomes and games of chance with their fixed outcomes.

Even if we allow for as-yet unknown outcomes and we estimate model risk, the most important job remains outstanding – judging what constitutes *acceptable* risk. This is rarely a one-sided judgment, as decisions involve considerations of benefits and costs, social and political norms, and ethics. While an assessment of benefits and costs – or risk-reward – can be quantified, setting their levels of acceptability within society and embracing ethical considerations makes this a judgment with a rational basis and not just a computation.

The choice of measures and thresholds alone may not allow the risk to be adequately measured. For example, a regulator may set one measure of risk to protect the public, whereas a company may use quite another measure of risk to decide their appetite for risk in order to make profit. Both are measures of risk but for different purposes.

Still this is not the end of the story, as the very measurement of the risk can affect behavior which in turn affects the risk. The “law of unintended consequences” is familiar in many areas where the vague is made precise, and changes to improve performance against one measure can cause adverse effects elsewhere in the system. Where this is done deliberately to manipulate the system we term it “gaming.”

In summary, then, there are factors over and above those in place today which can lead to the mismeasure of risk: unknown unknowns, model risk, thresholds for acceptable levels of risk, trade-offs of risk against rewards, and the inadequacy of single measures. Finally, there is an element of judgment to reflect factors outside the models which may increase risk.

The title of this chapter echoes Stephen Jay Gould's 1985 book “The Mismeasure of Man” in which he argued that the use of a single number, the IQ, as a measure of man's capability was a misguided simplification. As with models of risk, Gould identified as culprit the fallacy of reification (Gould 1985):

- ▶ The spirit of Plato dies hard. We have been unable to escape the philosophical tradition that what we can see and measure in the world is merely the superficial and imperfect representation of an underlying reality.

We will show how this fallacy of reification identified by Gould applies also to measures of risk, with similar consequences of incorrect judgment and action. Note, though, that in the past 30 years many of the criticisms made by Gould concerning IQ were themselves questioned because it turned out that the single number of IQ, when appropriately measured without cultural bias, was, after all, an accurate predictor of general intelligence. So it might well be with what one might see as the financial risk counterpart of IQ once we understand how to balance its measurement with other assessments. Just as IQ measures intelligence relative to a particular set of tests, so a measure called *VaR* (*Value at Risk*) measures financial risk relative to a particular model. VaR is currently under criticism following the banking crisis, yet may turn out to be a sound measure.

The main body of the chapter is divided into four sections. The first explains what we mean by *Risk*, the second works through some illustrative examples, the third sets out a constructive proposal on how to measure the risk of infrequent extreme events, and the fourth looks at two applications of the proposal – “RAG” statuses used in project and risk management, and the measure of risk used for Solvency II in the insurance industry within the EU.

## Risk

---

Risk applies to most aspects of our lives. We talk about the risks of rain tomorrow, of breaking our leg when playing a football match, of the collapse of a bank, of losing an election, of damage to our children's health from watching too much television, of an earthquake, or of a core meltdown in a nuclear power plant. We have financial markets dedicated to calculating and profiting from risk. In society we seem obsessed with attempting to eliminate risk through health and safety regulations, laws against smoking, and the seeming omnipresence of CCTV.

But what might such uses of the word *risk* have in common?

They share a feeling of uncertainty and harm – there might be some (possibly very severe) harm caused by our actions or nonactions or by certain events, but whether it will occur or how severe it may be, we do not precisely know.

At first glance, uncertain outcomes seem to call for a mathematical treatment in terms of probability theory. Indeed, the simplest mathematical notion of risk is “Probability times Harm” which is often still taken as a rational standard for risk assessment. Authorities like the Royal Society promote this notion of risk (Royal Society 1992) as:

- ▶ The probability that a particular adverse event occurs during a stated period of time, or results from a particular challenge

This sounds seductively like just one number, the probability, but in most cases this simple concept is not able adequately to capture the complexity of real-world risks. To the question “What is the risk of X?” we cannot sensibly expect to get back a single number as an answer unless X is a binary outcome. More generally, we should expect “there is so-and-so chance of this, and such-and-such chance of that, and . . .”; that is, there are multiple chance/harm potentialities. As these chance/harm combinations refer to some period of time, we end up describing risk in (at least) a three-dimensional risk space – *chance, harm, and time*. Decisions about risk will extend this definition further to a five-dimensional risk-decision space – *chance, harm, time, reward, and judgment*.

## Chance

---

Theories of chance have a long history of practical success yet interpretational difficulty. Chance can be about something that might happen (termed *aleatory*) such as “the chance of throwing a six is one sixth.” It can also be about what has happened but we do not know the answer (termed *epistemic*) such as “the chance of a six for a die that has already been thrown, but the outcome of which I do not yet know, is one sixth.” Chance and probability are largely interchangeable in normal usage, though in this chapter the term probability will be used to describe both the theory of chances of possible outcomes as well as the chance of individual outcomes themselves.

Put simplistically, there are two schools of thought about the meaning of chance. Some, termed *Frequentists*, view chance in terms of the statistical outcome of repeated actions. Others, termed *Bayesians*, think of chance in terms of our beliefs about the possible outcomes. Generally, we will view chance through Bayesian eyes as statements of belief, whether about a prediction or an as-yet unknown fact. The choice does not matter in practice as we will argue below that all our probabilistic statements are relative to models of reality, but it is easier to fall into the *reification* trap of thinking the model statements actually are the reality with the Frequentist view than it is with the explicitly subjective Bayesian view.

Whatever our interpretation, probability in its mathematical sense is a mapping of outcomes to numbers between 0 and 1, or in terms of percentages, between 0% and 100%. For instance, the outcomes of a fair die are the faces appearing up with values 1 through 6, and each with a chance of one-sixth. It also has some rules of additivity so that the chance of an actual outcome within a set of possible outcomes is the sum of chances of the discrete outcomes. For example, the chance of throwing a die value greater than 3 is 50% (3 out of 6). This sounds reasonable for a game of chance like dice, but the specification of individual probabilities seems overly precise for more general circumstances such as the chance of getting run over on the way home. In these scenarios, it is more natural to say we think there’s a so-and-so chance but with a such-and-such level of confidence.

For instance, we might say based on statistics of road accidents for those traveling home from Oxford that we reckon that the chance of getting run over tonight, all things being equal, is between 1 in a million and one in ten million. We might then say that our confidence that all things will be equal is only 50% as there is a major project to complete which requires late working. We can now envisage another scenario – having to stay in the office overnight. The chance of getting run over tonight if staying at the office is zero, so given the odds of staying in the office are 50% then the effective chance of getting run over tonight is reduced to between one in 2 million and one in 20 million. Another way of looking at this is that the first set of outcomes ignored the case of staying in the office. By including the chance of staying in the office, and assigning a chance to that higher-level outcome, we recover the probability of all outcomes even though they are now different from the “all things being equal” scenario. The advantage of the two-level response to the question shows that we have based and can explain our calculation on two levels of thinking: the chance of an outcome given that a model is assumed true, and the chance that the model itself is valid.

So *chance* really seems to mean both *primary probabilities* – “here’s a set of outcomes and their probabilities for a particular view” – and *secondary probabilities* – “here are the probabilities of the various views being right.” We can then combine these together to yield a net set of *effective probabilities* or, simply, *probabilities*!

Looking at this problem more generally, the calculus of probability assigns, in the technical sense of a *measure*, a chance to any collection of outcomes. It is not so clear how probability theory deals with ranges of precision about its assignments of chance. The range might be expressed as a range of uncertainties about the outcomes, or as ranges of uncertainties about the chance of given outcomes, or, more generally, as the probability distribution of sets of outcomes (Kaplan and Garrick 1981). Either way, we can always reexpress the outcome as another – *effective* – probability measure over the space of outcomes. But hold on, you might say, surely the second-level probability itself is subject to uncertainty? Should not there be a third-level probability and fourth-level probability and so on ad infinitum? Indeed, there should, and this infinite regress (see Atkinson and Peijnenburg 2006) bedevils the theory of probability. We do not propose any resolution to it in this chapter other than to say we can terminate the hierarchy with a statement of belief (which is essentially the solution offered by Kaplan and Garrick). What is material, then, is that the expression of the problem in terms of both first-level *and* second-level probabilities has more information and may thereby be more persuasive than simply the effective probability distribution.

Taking another example, we may think it highly likely that Everton will beat Tranmere Rovers in the football match tomorrow. They are local rivals, which can be expected to heighten motivation. The match might not happen, the Everton team might all have a bad day, Tranmere Rovers might play out of their skins; yet, despite these uncertainties, we still make statements about the chance of outcomes. We also make such statements in formal risk assessments where we use qualitative categories of likelihood and adversity – there’s a “HIGH” chance of some (harmful) outcome.

It may seem from this that “chance” cannot be expressed as probabilities after all. Yet, even in the case of the football match, we can get some numbers. After all, we might like to bet on the outcome and need some odds. It is not that odds cannot be set, as this regularly happens at visits to the bookmaker. The question should be rather, “how can this be done?” Well, implicitly in this case, explicitly in others, we create a model of the way football teams’ results depend on variables such as team member skills, recent form, condition of the pitch, position in the league table,

opinion of the pundits, content of the respective managers' mothers' dustbins for all we know. On the basis of that model, we can then calculate the risk. We could create multiple models. We could create many versions or parameterizations of any one of the models. Each would make different predictions. If we can test the models against some real-life data, we can start to gain confidence in adjusted combinations of models and their parameterizations. So the message here is that to construct chances, we necessarily employ a model or models of the situation.

## Harm

---

What constitutes harm? Harms might not be easy to compare. Is a bad cold worth something? Is a broken leg worth more? Even when we leave aside the interpersonal comparability between the harm as experienced by different people, it seems odd to assign some value to a broken leg, and another value to a cold. We do not as a matter of course say "I would rate a cold with 3, while a broken leg is worth 14 points on some scale that quantifies harm," rather we say: "I prefer having a cold to breaking my leg."

However, in order to be able to use quantitative risk tools, it does not suffice to have some ordered relationship between various harms; we need to assign actual values to them. For financial services, the simplest expression is monetary value and insurance, for instance, does put values on compensation for injuries, even going as far as government-approved tables such as the Ogden tables (see, for example, The Stationery Office 2007).

However callous it may seem, financial guidelines on the value of life and injuries are commonly used in economic assessments, with bodies such as the Judicial Services Board providing guidelines for personal injury insurance awards (JSB 2010).

While the most commonly used metric for harm is monetary value equivalent, mortality is also used, as in the Danish government's assessment of acceptable risk described below, and proxies for harm such as tons of emitted greenhouse gases are used to set policies on climate change.

As with estimates of chance, harms come with their own uncertainties and, as with probabilities, have second-order estimates of confidence in their values. These can be represented by harms having their own probability distributions, as in the range of damage to a specific building type for a given magnitude of catastrophic event. As with secondary probabilities, these estimates of confidence can be folded into the primary probability distribution to yield an effective probability distribution.

## Time

---

The importance of the time dimension to risk is often overlooked, yet is crucial to any validation or assessment of consequences. The timescales can influence which type of model might make the most robust predictions, and even whether it is possible to model the risk in any quantitative sense able to give predictive results. This is true both for the chance and the harm components of risk.

For short periods of time, there is often little change in either the range of possible outcomes or in our definition of what constitutes harm. Even better, over short periods of time we have become accustomed to being able to make predictions based on models. Indeed, we have grown so pleased with ourselves that we almost believe the models are the reality or believe they approach a "perfect model." Neither, though, seems to be justified in most practical assessments of risk.

Time is often overlooked in risk assessments on the grounds presumably that the world is fixed. We have seen, though, that time is one of the primary causes of *unknown unknown* uncertainty. There is one discipline where the time dependence of outcomes is of primary concern and that is *project management*. In project management one is balancing the factors of scope, resources (and cost), and timelines. One crucial factor in project management is assessing the chances of completing steps, tasks, projects, and programs on time. This is, perhaps, the most important part of project management as scope shifts and resource burns can often be a function of running over schedule.

## Uncertainty in Outcomes

---

The outcomes and their expected harm can be highly uncertain. The time factor magnifies the problem of uncertainty as probabilities can – and in most cases do – change over time; future generations, whom we might put at risk with today's actions or events, may have other preferences and experience harm differently.

How can we know there is not an outcome or state of a system we have not anticipated? And even if we think we know all possible outcomes, if it is a really complex problem, how can we have any idea at all of the chances of these outcomes? With many real-life problems being so vague, a consensus grew up that there are cases where uncertainty is different from probability (or risk). Keynes stated this explicitly in his theory of probability (Keynes 1937):

- ▶ The game of roulette is not subject . . . to uncertainty. The sense in which I am using the term [uncertain] is that in which . . . there is no scientific basis on which to form a calculable probability whatever.

Knight (1921) also famously defined risk as randomness that could be quantified as probability, and uncertainty, now often termed Knightian Uncertainty, as that which could not. Shackle (Shackle 1961) similarly pronounced that:

- ▶ Decision is not choice amongst the delimited and prescribed moves in a game with fixed rules and a known list of outcomes of any move or sequence of moves.

Nassim Taleb takes a particularly militant line against Knightian Uncertainty (Taleb 2006):

- ▶ In real life you do not know the odds, you need to discover them, and the sources of uncertainty are not defined. Economists . . . draw an artificial distinction between Knightian risks (which you can compute) and Knightian uncertainty (which you cannot compute) after one Frank Knight . . . Had he taken economic or financial risks he would have realised that these “computable” risks are largely absent from real life! They are mostly laboratory contraptions

There's certainly something odd going on with probability when it comes to decision-making under uncertainty. The *Ellsberg Paradox* (Ellsberg 1961) offers a compelling illustration of our preference for epistemic over aleatory uncertainty which might also be thought of as a preference for probability over uncertainty. (In a simple version of the Ellsberg paradox there is an urn with 90 balls, 30 of which are red and the other 60 may be either yellow or black, we do not know the mix. The question is would you prefer to accept the offer of \$100 on a random pick being a red or \$100 on it being a black? Most people choose the first option.)

There are many explanations given for the Ellsberg paradox. One such is that we make an overriding qualitative *judgment* about the risk based on our belief in the fairness of the offer, and in the case of the already chosen ball we subliminally anticipate the potential for fraud, as the asker could know the answer since the event has already happened.

Following Hubbard (Hubbard 2009) and Taleb, we shall not make the *Knightian uncertainty* distinction and have already argued that uncertainties can be subjectively quantified. However, when it comes to making a decision, we will propose that allowance of wider considerations – termed “Risks Outside the Box” or *ROB* factors – can adjust the importance assigned to a risk from purely quantitative considerations.

## Thresholds and the Relativity of Risk

---

In a recent talk at the Royal Society on the subject of uncertainty (Smith 2010), Lenny Smith announced “Solvency II is the gift of financial services to the physical sciences”! Could our derided financial systems actually be capable of teaching science something? He was talking about the importance of setting a threshold for unacceptable risk – in this case, the bar being set by regulators of insurance companies is that they must have sufficient capital to be 99.5% certain of paying claims within a 1-year period. This is as part of the Solvency II EU regulations for insurers which we discuss later in the chapter.

This amounts to saying that risk is relative to some standard of (un)acceptability and finding an appropriate measure and threshold is the most critical challenge in formulating a practical risk assessment.

Simple enough, then – all we have to do is set a threshold of unacceptable risk. Would we, for example, think it acceptable, had we the choice, to have people handling asbestos with a chance of asbestosis, or conducting experiments in Oxfordshire with a very small chance of a thermonuclear explosion, or developing new biological weapons with a chance of a harmful biological agent escaping? Sometimes the law enforces behaviors. For instance, it is not nowadays considered acceptable to drive a car without a seatbelt on, or ride a motor scooter without a helmet, or play cricket at school without a helmet. Only a few years ago smoking carriages were the norm on London tube trains, yet would now be treated as an affront to human rights. The science has not changed and there are no strong reasons to suppose the intrinsic risk has changed either. What has changed, instead, is our attitude to the acceptability of those actions that give rise to risk.

Another example is society’s attitude to cholesterol, where although the scientific evidence is equivocal (e.g., Kendrick 2008), beliefs in causal links between eggs and cholesterol and cholesterol in blood to heart disease are used to justify a wide range of diets and drug treatments.

It is clear from these examples that acceptability of risk is relative to society’s views and needs to be explicated in order for a risk to be a “risk” we bother with. And it may be that we set the threshold too low compared to the evidential harm – as was the case originally with asbestos – or too high – as was the case with the recent atmospheric volcanic ash – and when better evidence or methods of measurement or even just a change in social attitudes arrives, we change the threshold.

## The Interrelation of Risk Metrics, Behavior, and Risk

To illustrate how the choice of measure can affect behavior, consider the exposure that insurers have to catastrophe losses. Regulators such as Lloyd's of London, and rating agencies such as Best's, use catastrophe scenarios to probe the sufficiency of capital of an insurer. These are sometimes called *Realistic Disaster Scenarios*. Let's consider one such scenario – a US Florida hurricane making landfall in Miami and causing an insured damage of the order of \$100 billion. The existence of the scenario test can then influence insurers to take on individual risks outside the track of the chosen hurricane event. Whether deliberate or unintentional, the result is a low estimated loss for the test scenario, but high risk to the untested hurricane scenarios with different tracks. The risk to the (irresponsible) insurer's balance sheet is therefore understated by the test.

One response to the potential mismeasure of risk is to repeat the process for many conceivable scenarios, with a chance being assigned to each scenario. This allows the estimation of the probability of an insurer experiencing a certain loss or higher and is termed *probabilistic loss modeling*. Commercial suppliers such as RMS, AIR, and EQECAT produce models to assist underwriters and regulators to assess risk in this way.

From such a range of losses and chances, a simple probabilistic criterion can then be set to measure the amount of money associated to a given chance of loss in any 1 year – the amount or more that could be lost for a stated percentage of years. This measure is called *Value at Risk* or *VaR* and is used throughout finance. For insurers under the new Solvency II regime, the chance will be set to 99.5% in a year, so that the amount of money represents the threshold of what could be lost 1 year in 200.

*VaR* has been criticized in recent years as a blunt instrument made even less effective when operating in a regime about which we have little knowledge and few proven models. The risk of mismeasuring risk due to a lack of scenario models has thus been transmuted into the risk that the probabilistic loss model misrepresents the expected losses for the little understood experience of 1 in 200 year losses. To confound this new measure of risk further, the extreme *VaR* choice is not a measure that underwriters would use for trading which would instead be a view of profit and loss at a timescale of the order of a few tens rather than hundreds of years. This then creates a further conflict as there are multiple measures of risk relating to the differing objectives of the regulator (to ensure sufficient capital to pay policyholders or investors) and the business (to maximize profit).

There are further views possible on behavioral responses to risks. For example, Wilde ((Wilde 1994), see also (Adams 1995)) argues for *risk homeostasis* where risk is assumed in line with the benefits derived, so that the forces of risk of harm and potentiality of benefit will in most cases come to a dynamic equilibrium (*homeostasis*) somewhat akin to a regulator or thermostat. In this way, minimizing a risk in one area displaces the risk to another.

Another, more sinister, take on behavioral response is *moral hazard* whereby one action that attempts to reduce risk can so insulate a party from the direct consequences of that risk that they increase their risky behavior. An example is where drivers become more reckless, or make an expensive choice of garage to repair damage after an accident, because they are protected from the financial consequences by insurance.

## Risk and Reward

In financial circles, *risk* is expressed in terms as financial loss. If loss relates to risk, then what does profit relate to? *Positive risk* of course! This is shown in Fig. 17.1 below where the negative x axis represents loss (or negative profit) and the positive x axis profit (or negative loss).

What we see here explicitly is that we could look at the downside (the “risk”) but it would be foolish to do so commercially in the absence of considering the upside (the “profit”). In this example, the profit is marginal relative to its volatility, so one might well be concerned whether this would be a successful business.

It is worth commenting further on the shape of this curve, as it will vary significantly according to the problem. Fig. 17.1 illustrates a portfolio of risk rather than individual- or catastrophe-exposed accounts, which have a more singular and bounded form. It also does not reflect the most important aspect of managing risk, which is to find ways to offset the downsides. One of the primary methods of dealing with this is, of course, insurance (or reinsurance if you are an insurer). We will return to this point in response to risk.

This assessment of upside as well as downside is sometimes termed *Risk–Reward* or *Cost–Benefit*, and the tolerance for downside risk is termed the *Risk Appetite*. We will return to these concepts as they apply to finance later in the chapter. For now, though, our personal experiences confirm that decisions concerning risk are not just about acceptability levels, they are also about whether an action that incurs risk has benefits, and how we balance these against each other. For instance, is the damage caused to the environment from bovine flatulence outweighed by the benefit from humans eating beef – what is the risk appetite for beef (!)?

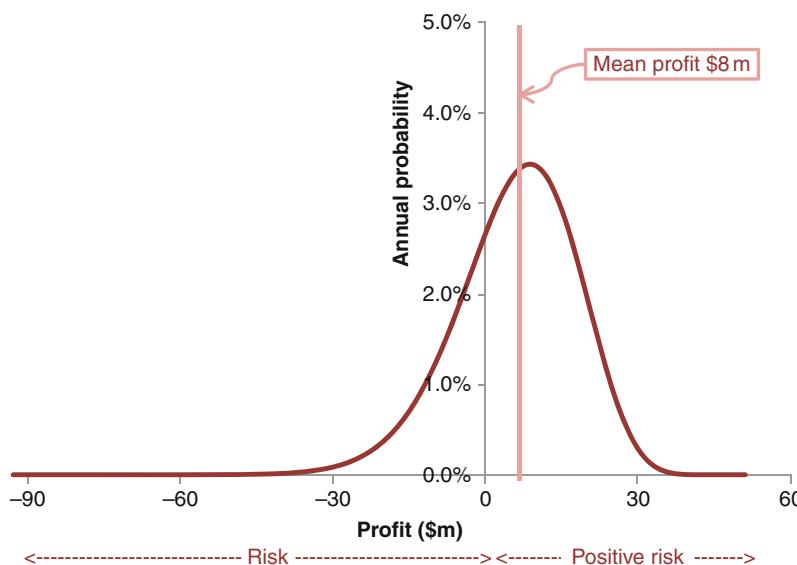

Fig. 17.1  
Positive risk

As well as the risks and benefits to an individual or corporation in relation to their actions, the uneven distribution of risk and reward often impels us to consider the wider consequences of our actions. This is particularly true of modern technological developments, many of which are *dual use* with benefit in one area or to one party having associated harm to another area or party. In such cases we have to consider the balance of consequences, and often these do not reduce to a utilitarian or financial measure from which a decision can be made. To give an example (POST 2009):

- ▶ Advances in DNA synthesis have enabled cheap and rapid synthesis of some viral genomes. There is concern that further advances and improved methods for delivering infectious agents may bring bioweapons production within the capabilities of terrorist groups.

Companies might unwittingly aid terrorists by providing DNA segments that could be joined to create the full genome of an infectious agent. In 2006, a *Guardian* reporter successfully ordered a small DNA segment of the smallpox genome for delivery to his home address.

The point here is that it is not just the *risk* that needs to be measured, it is the overall *risk-reward* or *cost-benefit* position, and this in turn will often come down to a judgment.

## Judgment

---

As Peter Bernstein said in the introduction to his book on risk (Bernstein 1996):

- ▶ The story that I have to tell is marked all the way through by a persistent tension between those who assert that the best decisions are based on quantification and numbers, determined by the patterns of the past, and those who base their decisions on more subjective degrees of belief about the uncertain future. This is a controversy that has never been resolved.

Given the complexity of the world and the inadequacy of many of our models to tackle risk, it is perhaps no coincidence that many of the risk assessments in business are qualitative, taking forms such as *Heat Maps* and *Risk Registers* in which risk is subjectively rated and mitigations identified. Some authors (e.g., Hubbard 2009) decry qualitative measures arguing that their predictive track record is poor. Indeed, we agree that many qualitative risk assessments can be lazy shorthands and that adoption of *Bayesian* subjective probability and recognition of secondary probability can sharpen risk assessment in many cases. However, there can still be factors that are outside the domain of the initial risk model for which judgment is needed. As an example, consider an insurance company which has, as its primary stated business exposure, loss due to a Florida hurricane. When asked off the record, though, the CEO might have loss of an underwriting team or withdrawal of a capital provider as her primary risks. The human factor is rarely far away from real-life risk yet rarely explicated in the risk model, albeit there is now a label for such risks – “operational risk.” Gerald Ratner, for example, famously put his company out of business with an injudicious comment about its products.

If judgment is an overlaying factor that emphasizes some risks beyond their strictly quantitative values – “risks outside the box” one might say – for chance and harm, what sort of measure is it? We propose that it is a categoric measure (such as the color-coding in *Heat Maps*) and represents the level of *importance* needed in decision-making.

## The Structure of Risk Decisions

We can now see five elements combining together in articulations of risk and decisions about risk – chance, harm, time, reward, and judgment. The schematic below illustrates these components and how they can project down to particular views of risk decision problems (Fig. 17.2):

The “projections” suppress or fix some of the dimensions, either because a dimension is irrelevant to the decision, or in order to make the problem tractable. For example, in evaluating projects, we often look at the chance of achieving an outcome – delivery on schedule – not necessarily the downside or upside consequences. Similarly, risk analysis tends to fix the time dimension and disregard the benefit dimension, while cost–benefit analyses fix the chance ranges (e.g., a “risk appetite”) and evaluate upside versus downside. In some cases, harm and reward might be on the same “dimension,” but generally they are quite different variables such as mortality and financial consequence. For instance, in a “dual use” technology, the harm might be mortality in the third world whereas the reward might be financial benefit to Wall Street investors.

The dimensions of risk decisions

## Recent Illustrations of Risk

### Volcanic Ash

The eruption of the Icelandic volcano Eyjafjallajökull in the spring of 2010 caused major disruption to travel and business. It came as a surprise to many, yet it had well-attested precedents. In 1783 Europe was plunged into a sulfuric acid smog resulting in mass death, summer heat, and winter freeze (Alfred 2010) from the Icelandic volcano Laki. It was also well known that volcanic clouds could cause problems after a passenger jet flew through the plume of Mount Galunggung in Indonesia on 24th June 1982. So although the threat was well known it was ignored (Cooke 2010):

- ▶ [OU's Dr Dave] Rothery has in his files a letter from British Airways dating from July 1989, turning down his request for funding for research into volcanic ash plume detection, on the grounds that it was "unlikely to be cost-effective".

"We've been saying there's a volcanic threat from Iceland for years and we need an ash monitoring system", says Rothery. "If we'd had a really good system in place, we'd have lost a couple of days flying and no more, I think. But the investment wasn't made".

In the absence of monitoring facilities, he says, data about the volcanic ash was based on computer modelling. "But you are only as good as your model. You need test flights, you need lidars – lasers looking upward from the ground, which give you a way of measuring the height and concentration and the particle size. And you can do the same from space not just with lasers but with infrared. There are all sorts of things you can do".

The same "head-in-the-sand" attitude applies to the thorny issue of how dangerous the ash actually is, and whether the six-day flight ban was justified he says. "There had been decades to work out what it was safe for an aircraft to fly through, and the airline industry hadn't done it. So the existing rule in place was: if you can detect any volcanic ash at all, you must not fly through it. That was just an arbitrary limit based on how good your detectors are".

Unsurprisingly, perhaps when it did happen, we were unprepared with untested computer models, no measurements of the effect of ash on air engines, and no acceptable threshold for flights to be suspended. As a result, we could not then avoid a precautionary overreaction with an economic loss estimated (Oxford Economics 2010) at \$5 billion and inconvenience to thousands of passengers whose flights were cancelled or delayed (The Economist 2010):

- ▶ No one denies that volcanic ash can cause jet engines to fail in flight. An engine's heat melts the fine-ground rock, which proceeds to encrust the cooler parts of the mechanism, stopping it from working. Lower concentrations can damage engines without having an immediate effect on how well they work. But where the boundaries between danger, potential damage and safety lie, and how they vary with the type and number of ash particles, was not taken into account in the decisions to close airspace. Things were made worse by the fact that the computer models of the ash cloud's dispersion gave only a very broad sense of where the ash might be.

By the early hours of April 15th, Britain's air-traffic controllers feared the worst. They had hoped the wind would carry the ash from Eyjafjallajökull south-east of the country, but the wind had changed. Guided by computer models used by volcanic-ash watchers at the Met Office, the air-traffic agency said it was withdrawing service. British airspace was closed.

Over the weekend both airlines and research agencies made test flights. Air France-KLM, British Airways, Lufthansa and others carried out over 40 flights. Subsequent engine inspection apparently revealed no unacceptable damage. On April 21st the CAA established a new rule, deeming regions thought to have less than 2,000 µg of dust/m<sup>3</sup> safe for flight. That threshold, the CAA says, was provided on the basis of data from equipment-manufacturers; Rolls-Royce, the leading European maker of jet engines for airliners, has made no comment on this. The new safety level is about 100 times higher than the background level of dust at ground level. It is also considerably higher than anything seen by research aircraft over Britain since the eruption started; those flights have encountered no patches of sky with an ash density of more than 400 µg/m<sup>3</sup>, 20 times the background level.

This example illustrates not only the importance of having measures and setting thresholds as we identified in the previous section, but that these are actually implemented.

## Hurricanes

---

Landfalling hurricanes are among the most damaging and costly events on earth. For the 2010 season which has just started, the conditions resemble those of 2005, the most active year on record which included hurricanes Katrina and Rita. The year 2009, by contrast, was benevolent like 2006, the quietest year on record. So what do we think is the risk of US hurricanes in 2010?

Is this a well-formed question? Checking our criteria, we have the *time* element (2010) so what are our measures of *harm* and *chance*? For *harm*, do we mean some physical proxy for harm potential like a certain windspeed at the eye wall or a storm surge in excess of a certain height? Or a harm that causes many deaths? Or one that causes a large economic loss? Or one that causes large loss to the insurance industry? What measure should we use? For the purpose of this discussion, let us measure harm by the insured loss due to property damage, as that is the basis for the index maintained by the Property Claims Services (PCS).

What, then, does *chance* mean? We could say we have a chance of having a certain magnitude of hurricane and this is associated to a given magnitude of insured loss. Or should that be the chance of a given level of loss or more? As we have discussed already, the answer is really a curve, with loss plotted against chance of exceeding a certain loss value. This curve is called the *EP* or *exceedance probability curve*.

How can we estimate the chance of a “severe” hurricane and what does “severe” mean, anyhow? Does it mean \$100,000 of insured damage or \$100 billion of insured damage? PCS assign catastrophe codes for events giving rise to \$25 m or more of insured property damage. An insurer could get losses from lots of different hurricanes depending on where they land, how much damage they cause, and how much risk they insure (the retained loss, the insured limits, and the share of the loss the insurer is taking). The way insurers have got round this variability is to estimate the *EP curve* using a computer model which simulates a wide range of events that damage the insured properties. The simulation could be on an *occurrence* (any single event in the year) or *aggregate* (total expected for all hurricanes in a year) basis.

We are still not done, though, because there’s a lot of uncertainty about the damage caused and, as already mentioned, *secondary uncertainty* (see AIR 2003 and RMS 2001) is applied to provide a revised *EP curve*.

There is a further complication as there are several models available and they can give quite different results for the same data and assumptions. The complication can be overcome by extending *secondary uncertainty* to give each model's results a different weight depending on their applicability to the risk. Choosing how to weight the various models is still a problem, though, and in many cases is a balanced judgment rather than necessarily being supported by objective evidence. For instance, one might have no particular view and so wish to sample from each model equally.

Yet we are still not finished. It is quite possible that we believe there is a systemic risk: for example, that the model used was miscalibrated or that this year is a La Nina year or that global warming has increased the frequency and intensity of storms (many scientists argue this, though many say we do not know, and some even argue the opposite). What do we do here? Well this is our *ROB* level of judgment outside the model. In some cases it is now possible to rerun the models with options such as *Near-Term Events Sets* which allow for a view on global warming. Ultimately, however, each person has to judge how to use the model results.

## Terrorism Insurance

---

Here we have a contrast between a “sophisticated” model as marketed by a leading provider of catastrophe modeling software and a simple pricing methodology adopted by some insurers (Shipley 2009). The sophisticated model uses game theory to analyze terrorist networks by modeling a wide range of factors (RMS 2010):

- ▶ The model quantifies the impact of all terrorist attack permutations on 3,400 high-risk potential target locations. Targeting patterns and prioritization emulates terrorist objectives and uses game theory to incorporate the effects of security and counter-terrorism measures. Appropriate attack modes can be selected to model the coverages and exclusions in place.

At the very least, such a model needs to set probabilities of attacks, probabilities of different choices of weapons, probabilities of different categories of targets, and estimates of the loss impact, which are highly dependent of course on the choice of weaponry and the selection of target (Woo 2004). None of these probabilities can be any better than an educated guess, as there is no serious numerical information to support them. In combination, these guesses produce something that has the appearance of a sophisticated mathematical model but a vast range of potentially credible outcomes.

An alternative approach is far simpler and makes no claim of statistical rigor. All it does is look at the aggregate insured values in various areas of the USA, and assume that terrorists will wish to make an impact so that major urban centers with concentrations of valuable assets are more at risk than suburban or rural settings. It then takes a guess at the maximum size of loss – can a conventional attack do more damage than a 9/11 given that there is and was no other similar concentration of property value anywhere in the world? Answer: unlikely – and the maximum number of such losses that the US government could tolerate over, say a 3-year period. All the insurer then has to do is charge a rate applied to insured values that will generate enough premiums to pay the selected amount of loss plus a profit margin.

This model is not very sophisticated, but it has no spurious accuracy and no false comfort!

## The Banking Crisis

---

The start of the new century saw a delusion that debt had been mastered by new financial derivatives which spread the risk objectively at a fair price as described, for example, in (Tett 2009) and (Lanchester 2010). Far from spreading the risk, though, these instruments concentrated and spiraled debt. Crucial to this spiraling of debt, other than the usual litany of greed and collusion, was a set of computerized models which appeared to vaporize the risk of default on mortgages and loans. Many commentators at the time (such as John Mauldin in his *Outside the Box* e-letters) pointed out that this was a massive folly but, as with bubbles of the past, the road back to reality required a massive crash. One of the primary causes of the crisis was mispricing of mortgage default (credit) risk using computer-based mathematical tools of convenience, such as Gaussian copulas (Salmon 2009), which incorrectly estimated the chance of a borrower defaulting and the correlation between defaulters. Our analysis in the previous section would identify this as a “risk of risk models” or *Model Risk* and, indeed, the Turner Report in 2009 identified several major weaknesses in regulation and behavior, most notably on the use of models (Turner 2009, p. 22):

- ▶ The very complexity of the mathematics used to measure and manage risk, moreover, made it increasingly difficult for top management and boards to assess and exercise judgement over the risks being taken. Mathematical sophistication ended up not containing risk, but providing false assurance that other *prima facie* indicators of increasing risk (e.g., rapid credit extension and balance sheet growth) could be safely ignored.

Modeling problems were, it says (Turner 2009, p. 44):

- ▶ Short observation periods
- Non-normal distributions
- Systemic versus idiosyncratic risk (Correlated behavior)
- Non-independence of future events (The past is not a guide to the future)

Since the collapse of Lehman’s and the crisis that followed, the scales have fallen from the eyes of those blinded by the credit bubble. Model risk has emerged as a crucial hole in the Basel II framework which defined risk management.

Yet it seems that not all the lessons have been learnt as Turner rounds off his report (Turner 2009, p. 45) with:

- ▶ But it would also suggest that no system of regulation could ever guard against all risks/uncertainties, and that there may be extreme circumstances in which the backup of risk socialization (e.g., of the sort of government intervention now being put in place) is the optimal and the only defence against system failure.

This seemingly sensible statement has a subtext of moral hazard that could be the Achilles heel of bank regulation. Do not worry, it implies, take the profits but, if it goes wrong, argue it is an “extreme circumstance” and let the government socialize the losses.

## What Have We Learned So Far?

---

The four illustrations used highlight the potential inadequacies of the measurement of risk. The volcanic ash fiasco highlights the need for a quantitative measure and threshold; the

hurricane example shows how a risk problem, even when articulated, has to deal with model risk and judgment; the terrorism insurance case shows how simple alternative models can help us understand risk in a practical way, and the banking crisis shows how extant risk measures failed to pick up massive systemic risk.

Clearly the current methods of risk assessment and management are seriously flawed. What can be done?

## The Measurement of Risk

---

The general considerations of risk and analysis of recent disasters indicate the changes which might make the definition and use of risk measurements more effective. This is not just a set of additional *processes*, but also a way of recognizing the *values* that society, companies, and individuals place on risk, whether retaining, assuming, or ceding the risk. Thus, while the process change might be to set an explicit threshold for unacceptable risk using practically achievable metrics, it is our values which determine the measures we choose (e.g., mortality or financial loss) and their levels of acceptability (e.g., 10 deaths per incident or no more than \$1 billion). We shall see that the recognition of values becomes even more important at the decision-making part of risk management, where judgments are made in contexts outside the domain of the risk problem.

For instance, the top risk identified by a quantitative risk analysis of an insurance business might be a severe hurricane hitting Miami this year, yet the risk uppermost in the mind of the CEO might be withdrawal of support of the company's capital provider due to investigation of a white collar crime. Here's a risk which is outside the risk management process due to its confidentiality and high level of uncertainty yet will necessarily govern the CEO's immediate actions in the business.

As another example, consider two projects in a program, one of which is of minor financial value and another which incurs large penalties if it fails to deliver. The former project is deemed to be status RED and the latter status GREEN. What is the status of the program? Is it GREEN? What if the first project is the €10,000 decoration of the conference room for the US President's visit to the EU to discuss waste management in 1 week's time whereas the second project is the delivery of a €10 m report on waste management report to the EU Council of Ministers in 3 month's time? Maybe RED would more adequately reflect the political importance of the first project.

Many books and articles and procedure manuals exist covering the theory and practice of risk management. Many include the central ideas of definition of risk as a combination of harm and probability, the use of models, and the choice of a measure (and maybe also a threshold). So we take these for granted to avoid repetition and instead address five areas of extension to current approaches:

1. Unknown unknown risk
2. Model risk
3. Multiple measures and thresholds

4. Risk and reward
5. ROB (there's always more Risk Outside the Box . . .)

We will describe each issue, then propose actions to address it.

## Unknown Unknown Risk

---

How can we possibly know what we do not know?

Some claim that the infrequent severe events that surprise us (beneficially as well as harmfully, but usually harmfully!) are *Unknown Unknowns* or *Black Swans*, and fatalistically argue that we cannot be expected to anticipate the un-anticipatable and should instead accept that some things are beyond our abilities to foresee. The logic seems unassailable – after all, we cannot know what we do not know, can we? Yet on closer inspection, these events usually are not such surprises after all, and we are anyhow adept at making allowances for the vagaries of events in our everyday lives. We may have forgotten that we do it and how it is done. First of all, the majority of surprise events were not unknown at all, it is just that we chose to ignore them – they were gray rather than black swans or “Unknown Knowns” in the sense that we knew about them but chose to disregard this knowledge. For example, was “9/11” a Black Swan? Hardly, as the possibility of an aircraft crashing into the World Trade Center was a known scenario and the possibility of both Towers going down had been considered by insurers (at least in the company for which I worked which insured the Port of New York Authority) albeit rejected as implausible. What was not considered was a deliberate attack that destroyed both buildings. Second, we can make allowances for *Unknown Unknowns* by looking at our track record of failure as practiced, for instance, in the insurance of difficult risks – it is an extra allowance in the premium for what we do not know about yet; a “margin of error.” Third, although the elements of unpredicted risk lurk unidentified in the present, generally they emerge as the risk landscape changes over time. The longer the period of time involved, the higher the risk of unforeseen events tripping us up.

Building on these observations, here are three suggestions on how we might identify *Unknown Unknowns*:

1. *Scenario tests.* By definition, these are a form of *known unknowns* so what scenario tests really do is consider responses to a challenging range of (generally adverse) possible futures in which (Wack 1985) “Decision scenarios describe different worlds, not just different outcomes in the same world.” Scenario planning is widely used in business, and quantitative examples in finance include *Lloyd’s Realistic Disaster Scenarios* in the insurance industry and *Stress Tests* and *Reverse Stress Tests* in both banking and insurance. The idea of a *Reverse Stress Test* is to ask what scenarios could breach capital limits, as opposed to a *Stress Test* which asks what the consequences of a particular scenario might be. (At the time of writing this chapter, though, banking regulators have not asked for scenarios of sovereign debt default, indicating they have some way to go in understanding the current world!)
2. *Past Experience.* One way to assess unforeseen outcomes is to check how well we have foreseen them in the past. If our track record is good, and the environment within which we are operating is not changing much, we might be justified in a low allowance for *Unknown Unknown* risk, but if the track record is poor it invites us to think through a greater range of options and models.

3. *Timescale.* Arguably, time is the greatest single enemy of risk management as the world changes and redefines the space of outcomes. The most obvious way to cater for this is through frequent reviews of risk, commensurate with the changes in the environment creating the risk. For instance, in the insurance business, quarterly risk reviews are carried out and especial care taken over multiyear policies. In a project, monthly or weekly progress reviews are often sufficient, but at critical stages it can be necessary to review project progress daily (in what is sometimes termed *daily prayers*) as there is so much risk to manage.

What might we do with better intelligence on *Unknown Unknowns*? We could take mitigative action – for example, reducing exposure or increasing prices for multiyear insurance policies if we are insurers. We could use the information to inform our choice of models and/or allowance for model risk. We might adjust our thresholds for acceptability of risk. Certainly, we could expect the assessment of *Unknown Unknowns* to color our view of risk appetite. Above all, though, it might inform our judgment of action relating to risk.

## Model Risk

---

Many authors have highlighted model risk as a primary contributory factor to the banking crisis – for example, the Turner Report (Turner 2009), reinsurance business executives (Montross 2010), and authors of handbooks (Gregoriou et al. 2010). In many cases, the choice of model and the variability consequent on that choice of model is the single biggest “risk of risks.” Overdependence on computerized models is a principal cause of erroneous decision-making especially where the call for simplicity causes a misstatement of the problem as, for instance, was seen so tragically in the overfishing of the Grand Banks (Pilkey and Pilkey-Jones 2006).

Despite this, regulators still shy clear of requesting explicit capital to reflect model risk. This may be to do with the psychology of requiring simplicity where it may not actually exist, or that the regulators feel able to factor in these uncertainties when setting the final regulatory capital number. A home has been found for “model risk” which has not been fed back into the quantitative risk assessment, and that is part of “operational risk.” Although there is variation of the definition of operational risk, it is generally (e.g., Basel 2010) held to cover “The risk of loss resulting from inadequate or failed internal processes, people and systems or from external events.” This includes the inadequacies of models. Whether in practice the model risk is adequately assessed and quantified, though, is quite another matter as in some cases the model risk at a “One in 200 Year” level would be substantial and there is little interest in management taking on additional capital requirement. Model risk is the Achilles heel of the regulators.

The problem seems clear, so what can be done? How can we ever have time to develop, examine and compare all the many models we can conceive for a given problem? As with *unknown unknowns* we seem to be caught in the trap of never being able to “know what we do not know.” Actually, we do already have alternative models. We even have methods of combining our degrees of confidence in such models. What we have not done is to incorporate such methods into risk assessments.

Here is a non-exhaustive list of checks that might be used to assess Model Risk:

1. *Model adequacy.* Is this model fit for purpose? There are various ways in which this might be tested. For instance: a careful evaluation of assumptions; a test for a particular scenario so that the consequences can be tracked through in detail rather than relying on the black box or

hoping the law of large numbers will somehow cancel out any systemic errors; comparison to other models; benchmarking against comparable risks. Such tests might be operated in concert. For instance, in probabilistic loss modeling in insurance, Model A might give a result quite different to Model B. One way to find out what is going on and which model to choose is to take some scenarios and compare them by individual component losses. We can then get a further view by taking the proportion of the estimated industry loss according to premium market share, and finally comparing (by class of business) the proportion of total insured value lost in each case against market benchmarks. These comparisons not only provide reasonableness tests but also flush out systemic errors. As we saw with the example of Terrorism Risk, for very complex problems it may be that computerized scenario-based models involve too many uncalibrated assumptions to be trustworthy, whereas a non-stochastic model can give a practical view of the risk based on simpler assumptions.

2. *Multi-model blending.* Supposing we have looked at the models and have decided that Model A and Model B are equally valid in our opinion, even though they give quite different results. If they are both scenario-based models it is possible to construct an effective selection of scenarios and associated losses by sampling from each set in equal measure. We would then end up with a new composite set of losses and thence a new composite risk curve reflecting our chosen blend. This blending can if required be made more sophisticated by allowing different blend mixes according to the type of scenario (for example, if we had greater confidence in Model A for large losses and Model B for smaller losses). The net result is nonetheless a composite event set.
3. *Recognition of model risk within a model.* This applies the idea of *Level 2 Risk* introduced by Kaplan and Garrick (Kaplan and Garrick 1981), which corresponds to the probability of probability models discussed above in the section  [Chance](#). It can also be applied in probabilistic scenario computations through the concept of *secondary uncertainty*. What this says is “Given that the event has occurred, what is the distribution of losses?” rather than “What is the mean loss for that event?” [*Primary uncertainty* in this terminology is the probability of the hypothetical scenario event.]

## Measures and Thresholds

Given a problem involving risk, we have seen that there are many challenges in deciding on measures of risk and thresholds of acceptable risk. While the general nature of the problem can be expressed in terms of risk curves of probability against harm, the metrics that are used to assess the risk can vary. Here are some examples of measures and thresholds:

- *Pollutants:* The concentration of the pollutant in air (or water), with maximum thresholds set according to their harmfulness. An example would include the various types of volcanic ash as they affect aircraft.
- *Mortality:* Although mortality is hardly acceptable to those directly associated with it, nonetheless levels of acceptability can be set in bands, as has been done by the Danish Government and the UK Health and Safety Executive (see Bedford and Cooke 2001, Chap. 18). Bands of fatalities (on a logarithmic scale) are plotted versus probability, in so-called *fC curves* (*fC* standing for frequency versus Consequence). The “acceptable” and “unacceptable” are then demarcated by regions of low frequency/low consequence and

high frequency/high consequence, respectively, with the middle region defined as “reduction desired.”

- *Value at Risk (VaR)*: As described above, VaR has vehement critics, with Nassim Taleb terming it “charlatanism” (Taleb 2006), and David Einhorn comparing it to “an airbag that works all the time, except when you have a car accident.” (Einhorn 2008). Their skepticism does not seem to imply that a probabilistic loss exceedance measure should not be used, but rather that the underlying models and the extreme value of the risk threshold is untestable. It could be reasonably responded that these are not in themselves flaws in VaR but rather in its application. Indeed, that is the view of this chapter subject to treating VaR as but *one measure* of risk, albeit a particularly valuable one when assessing downside consequences.
- *Credit risk*: In banking’s Basel II, regulatory capital requirement for credit risk offers a “standardized” measurement based on Ratings Agency ratings of the Counterparty. This incurs the further risk that the Rating Agencies get it wrong, as of course they did in the recent banking crisis.
- *The Learned Hand Formula* used in legal (tort) cases: This is especially interesting as it sets its own threshold to determine liability in an accident. It is an algebraic formula ( $B = PL$ ), according to which liability turns on the relation between investment in precaution ( $B$ ) and the product of the probability ( $P$ ) and magnitude ( $L$ ) of harm resulting from the accident. If  $PL$  exceeds  $B$ , then the defendant should be liable. If  $B$  equals or exceeds  $PL$ , then the defendant should not be held liable. (Grossman et al. 2006) explains how insurance markets collect and disseminate information about the expected values of all three variables in the Hand formula: the probability of accidents, the level of harm, and the burden of precaution.

## Risk and Reward

Decisions are rarely made only with regard to downside risk. In almost all cases, there are considerations of offsetting benefits or rewards. To take a current example, financial market regulators are requiring banks and insurers to hold levels of capital according to prescribed rules and processes as set out in the international Basel II accord for banks and, in the EU, Solvency II for insurance. But companies do not primarily want capital to protect against risk; they want it in order to generate a return for their investors. The risk part is an unavoidable necessity.

The diagrams below illustrate the typical probabilistic structure of profit and loss for two classes of business in an insurance company. The diagrams on the left show the probability (density) functions for profit and loss in a year for each class of business; the diagrams on the right show that the chance of losing \$30 m in either class is *the same*, and is 0.5% or once in 200 years, which is the Solvency II regulatory requirement for capital to support an insurance operation. Note that the two classes of business also have the *same mean profit* (☞ Fig. 17.3).

Although it is tricky to see, note the “fatter” tail of loss for Class of Business (CoB) 2. Other ways used to focus in on the purely risk perspective of these classes of business are shown in ☞ Fig. 17.4.

The *EP curve* view shows the *Exceedance Probability Curve* and, as you can see, the two classes of business cross over at the \$30 m loss and 0.5% probability level. What this means is that they have the *same chance* of 0.5% (1 in 200 years) of exceeding \$30 m loss in one year. The \$30 m is termed the *Value at Risk* or *VaR* for the 0.5% annual probability.

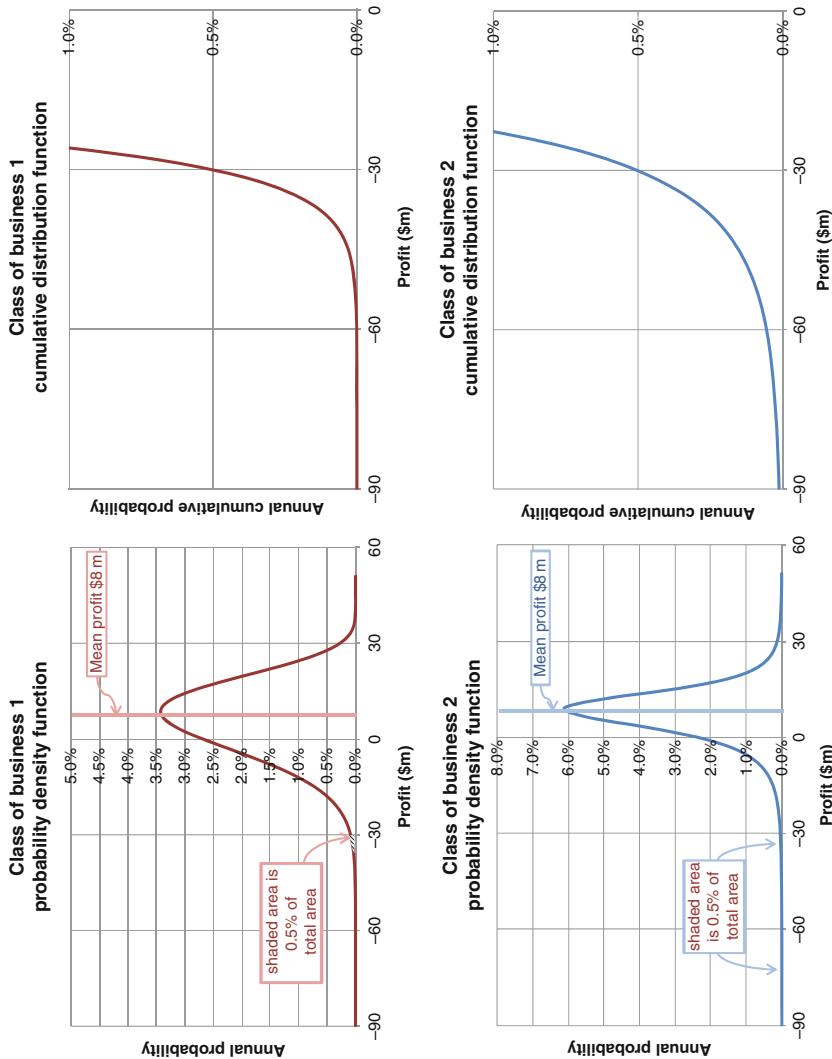

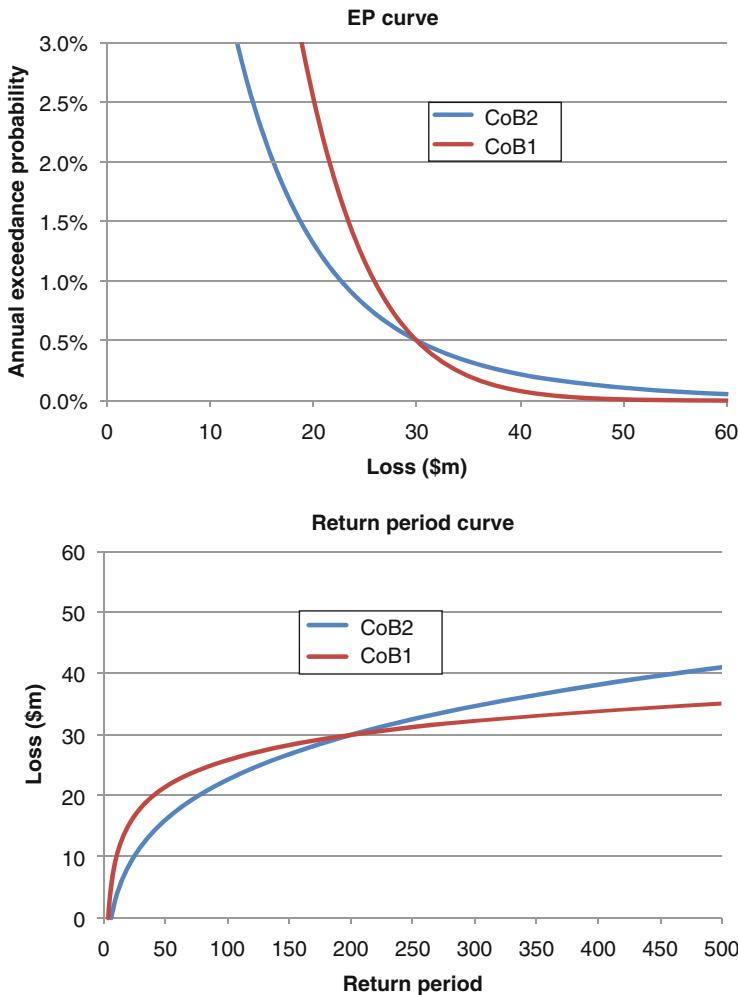

Fig. 17.3  
Two classes of business with the same 99.5% capital requirement and mean profit

**Fig. 17.4**  
Representation as exceedance probability (EP) curve and return period curve

CoB (Class of Business) 2 has a “fatter” tail (i.e., a larger chance of severe losses) than CoB 1 so it has a higher expected loss were it to breach the \$30 m VaR. This feature is often represented in a measure called the *Tail Value at Risk* or *TVaR* (also termed *Expected Shortfall*) which is the mean of losses *given that* the VaR loss point has been breached (for a given VaR probability).

In the *Return Period* view, the annual probability of exceedance is reciprocated to be expressed in terms of years (the *Return Period*) for a loss of that magnitude or more. Return Periods are often used in catastrophe insurance but are *not* intrinsic characteristics of individual catastrophes, being instead defined for a given insurance portfolio. What is then of interest is whether an insurance company’s Return Period for a given catastrophe is comparable to that of the entire industry. If it is not, then that insurance company is taking on risks with a profile different to that of the industry as a whole.

The Solvency II regulation sets capital based on the 200 year (99.5%) VaR point, but many insurance companies are practically assessing their risk at a lower Return Period of, say, 25 years using TVaR. This is because the lower Return Period represents risks they are likely to encounter in their business operation and TVaR allows for the extremity of the tail. Actuaries also like TVaR as a risk measure, as it satisfies the mathematical criterion of subadditivity (that the risk of the combined Portfolios A and B is less than or equal to the risk of A plus the risk of B) which VaR does not.

## ROB

---

Even having made the allowances described in the preceding sections, the world remains a risky place. There is always more Risk Outside the Box or *ROB*. Here's an example.

Suppose that Simple Insurance Ltd. has completed its Business Plan for the next year. The plan has taken into account stress test scenarios, reverse stress tests, multiple models, two different measures of risk and threshold, and optimized its portfolio based on an agreed risk appetite. All the risk boxes are ticked, the capital's in place, everything's fine. Or is it? The capital provider is rumored to be in trouble with subprime mortgages in Brazil. The commercial property underwriter is a maverick trader. The government is rumored to be putting a tax on all UK-originated business. Regulators are investigating questionable profit commissions. And so on and so forth. The environment in which we operate is so complex that we cannot necessarily represent all the risks we face in our models and measures.

*Risks Outside the Box* resemble *unknown unknowns* in that they look outside the extant model even though they are "known" by definition. We could spend our lives just worrying about all the many things that could go wrong, and even if we state them as assumptions (e.g., there will be no major change to regulation in the next year) there is still a risk that we might be mistaken. What can we do to identify *ROBs* and factor them into our plan?

In our Simple Insurance Ltd. example, the CEO, when asked his/her top risk, might answer "The Commercial Property Underwriter." Allowances for rogue underwriting might already exist in the measures of operational risk and some allowance might exist in the risk of failure of corporate governance. Yet how many companies are going to make significant allowance for a particular rogue trader as this is such a contentious and possibly legally difficult accusation? These types of risk slip through the quantitative models. The CEO can do plenty about this risk, though, as he/she might keep a close eye on the Commercial Property Underwriter's trading and develop contingency plans. The same applies to so many of the risks that affect us in life – we work at mitigating measures to bring them under control.

The most obvious action is to attempt to articulate the *ROB* (*See Risks Outside the Box*) back within the risk assessment process by incorporating it into the model, or making an allowance for model error, or maybe just overlaying a judgment category (e.g., flagging the risk as judged with RED importance). As the primary issue here is what decisions can be made based upon the risk assessment, *ROB* is primarily a matter for management.

## Applications

---

This section looks at two illustrations of the extensions to risk assessment introduced in the last section: the use of RAG (Red, Amber, Green) status setting, and the Solvency II regulations proposed for the insurance industry in the EU from December 2012.

## RAG

For those unaware of the term, *RAG Statuses* are categorizations of the state of something according to one of three values – Red (representing bad), Amber (representing neither bad nor good), and Green (representing good). That *something* might, for example, be a project, or a risk or a proposed action. In practice, more than three colors can be used, such as Purple for seriously bad, and Blue for future project tasks.

The gist of our analysis of RAGs is that we will think of them as *judgments* over and above an explicit quantitative rating of risk. The numbers may imply one RAG but there is the option to override it with judgment. This does not support the view that anything goes, rather that the difference between the analytic RAG status and the chosen RAG status is manifest and capable of rational justification.

RAGs are generally defined by ad hoc rules or set subjectively. In many applications they have an implicit meaning such as “chance of success” or “risk of failure” or “confidence in a beneficial outcome.” What we will do in this section is to flush out some of these meanings in a way that allows us to use RAGs in an analytical manner and, in particular, to explain *how to combine RAG Statuses*. Without a reliable method for combining RAG statuses, inconsistency can arise in the RAG statuses for phases of a project or risks within a class of risks. Note, though, that we always accept a RAG so constructed can be overridden to represent the *Judgment (ROB)* factor.

A popular application of RAGs is to project management. The idea here is that each project (or phase of a project or task within a phase of a project) receives a RAG status that represents the level of need for management attention. A project that is over budget and/or over time and/or failing to provide what it said it would is likely to be rated RED. A project on-time, on-budget, and delivering to scoped requirements is likely to be rated GREEN. Those in-between would be rated AMBER.

Applying our dimensions of risk, we might identify *Harm* as failure to deliver (perhaps with a financial consequence in contractual costs), *Reward* as meeting Requirements, and *Judgment* as the wider picture of whether the project has *Risks Outside the Box*, such as a reputational consequence even if the scope is small and the tangible costs and benefits are low.

In practice, many of the risk dimensions are fixed by the circumstances of a given project and the most important aspect of project management comes down to meeting deadlines, which involves the dimensions of *Chance* and *Time*. All sorts of factors can contribute to problems in meeting deadlines, such as lack of required resources (people, equipment), or failure of resources, or lack of money if over budget, or changes in requirements as problems turn out to more complicated than the original plan envisaged.

Taking a simple example, suppose we have two projects in a program of work, and that they are independent (albeit geared to a common objective). Modeling the chance of completion of a project by a Gamma function corresponding to a Poisson process, we can then use RAGs to represent ranges of the chance of completion in time.  *Figure 17.5* below shows how such bands could be set, how the probabilities of the individual projects change as the deadline is moved, and how the probability of the overall program changes on the basis that we are interested in measuring the probability of *both* projects being complete in time using the same banding.

You can see that we can have various combinations of component Project RAGs and an overall Program RAG that is more severe. The same probabilistic structure has been extended to networked Gantt charts akin to Bayesian Nets. The outcomes can then be computed by Monte Carlo simulation (e.g., Bedford and Cooke 2001, Chap. 15).

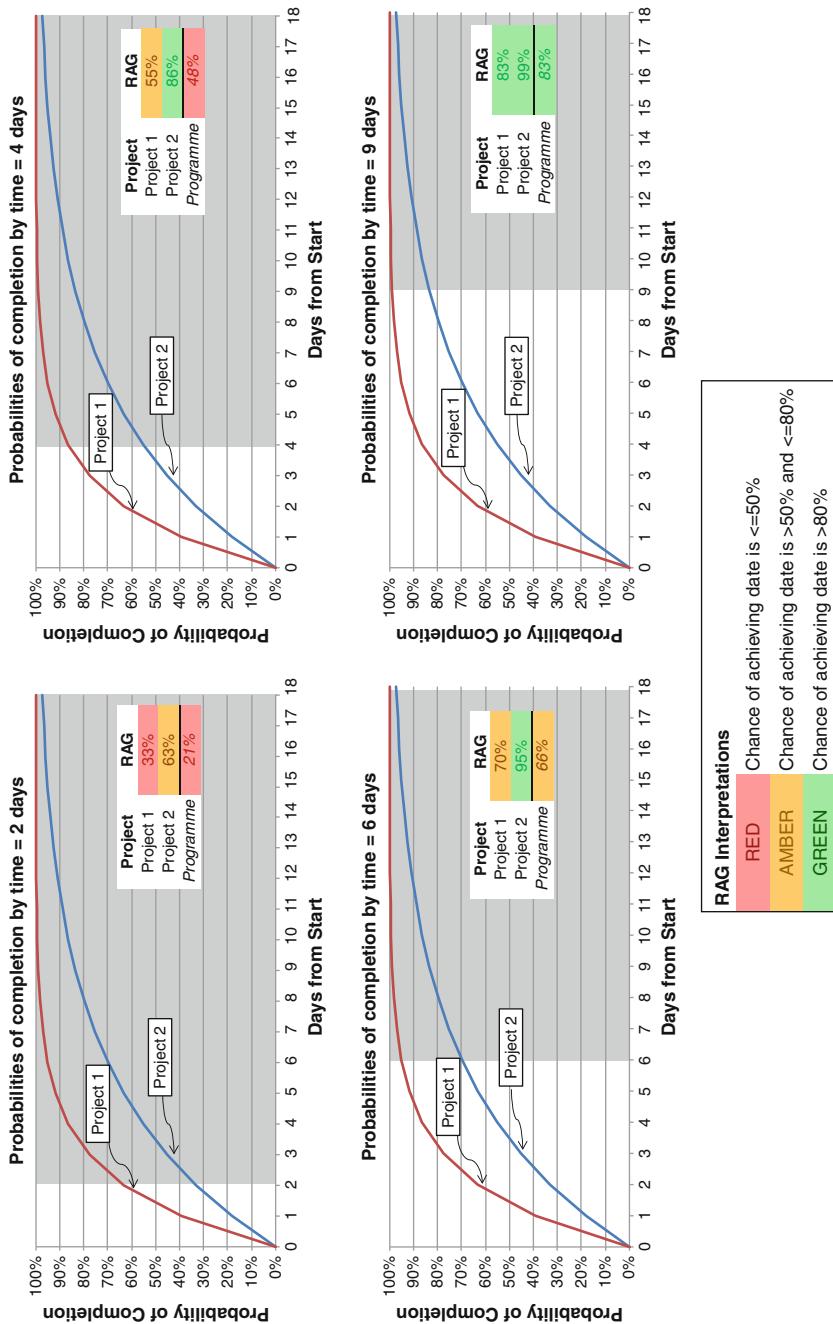

Fig. 17.5  
Project probabilities

The probabilistic method described is not the only way used to combine projects as a combination rule might simply be something like: "Program is RED if any project is RED or more than one Project is AMBER, Program is GREEN if all Projects are GREEN, else Program is AMBER." The rule can be set up as a simple calculation but does not have a ready interpretation in terms of underlying probabilities.

The conclusion is that RAG statuses are subordinate to the calculation of an underlying measure. Given rules for combination of the underlying measures, the combined default RAG status can be set, but there may well be reasons to override the computed RAG such as ROB factors.

Another simple RAG method is to take normalized weighted averages. Here, an RAG represents a banding of measures of our confidence in a certain sense, and the Projects may be "weighted" by their importance. The calculation then takes the sum of the weights times the mean point of the RAG band. For example:

RAG Status bands: GREEN = less than or equal to 1

AMBER = greater than or equal to 1 and less than 2

RED = greater than or equal to 2 and less than 3.

Project A has a weight of 2 and Project B a weight of 10.

If Project A is GREEN and Project B is AMBER, then the Program has RAG status:  
 $(0.5*2 + 1.5*10)/(10 + 2) = 16/12 = 1.33 = \text{AMBER}$

This linear weighting does not allow for the two dimensions of risk measurement – the play-off of chance and harm, or the judgment that associated the outcome distribution of chance and harm to RAGs.

To extend project management assessments to take account of the potential downside, we can introduce a measure of harm, to give what might be termed an *Impact Grid* assignment of RAG to the banded values of chance and harm, as shown in Fig. 17.6:

These assignments of RAG colors to the cells can be set up independently for each Project and for the Program, though there would generally be some level of consistency in what is

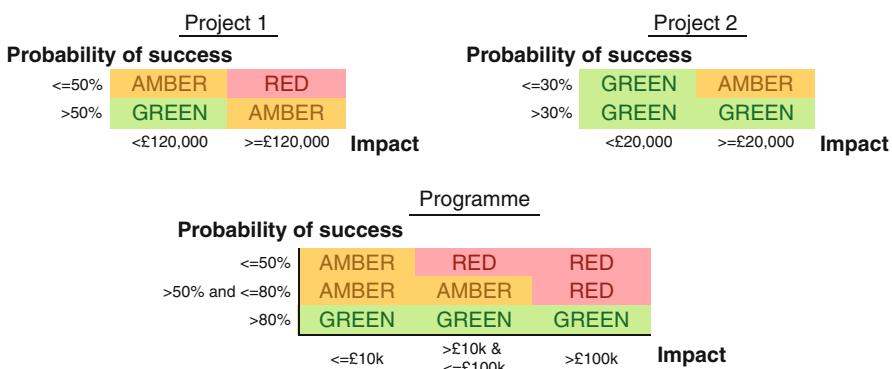

Fig. 17.6

Project risk impact matrices

considered important. However, if Project 2 above had major political implications then it might be set to RED unless the confidence of success were greater than 90%!

The method described works for binary outcome measures like project or task completion. However, the chance versus harm *curves* we have been considering in the theory of risk do not generally simplify to single points representing the risk. The principle still works, though, provided we can assign RAG colors to the chance/harm curves.

➊ *Figure 17.7* shows how this can work. There is an assignment from the risk probability curve using, say, the mean loss and associated chance, to the RAG status based on some quadrant chart of RAGs, against which each Risk can be rated, and then the Overall Risk can be rated in the same way from its composite risk probability curve.

## Solvency II

Solvency II (see, for example, Solvency II 2010) is the EU's regulatory requirement, due to be implemented in December 31, 2012, for the management of risk in the insurance industry notably, but not exclusively, to ensure the capital sufficiency of each insurer. There are many regulator and adviser web sites (e.g., <http://www.lloyds.com/The-Market/Operating-at-Lloyds/Solvency-II>) and books (e.g., Cruz 2009) on the subject, so this section will not recap the whole subject. Instead, we will look at one particular facet, the measurement of risk.

Solvency II adopts that simple and rational measure of risk, VaR, which we came across before, and sets the level of capital required to be 99.5% in a year or allowing a default once in 200 years. This is cautious, for sure; how can it not be sensible? How can it not be in everyone's interest to measure risk in the same way?

As seen in our earlier discussion, however, a VaR measure at low probabilities can be subject to high levels of uncertainty and overdependence on models. The Turner Report and many commentators highlighted model risk from VaR as a major weakness contributing to the banking crisis.

Another critical worry is that risk decisions are not made solely in the light of a once in 200 potential for loss. Otherwise no one would be in business. Instead, business is governed by risk and reward and deciding what to do is a judgment sometimes referred to as *risk appetite*. We are all familiar with this in our daily lives, and it is not that different in business. In Solvency II, however, the measure of risk is not variable, it is fixed. What we then have are two measures of risk which are likely to conflict – the regulatory risk and associated capital to protect society against failure of the company to only 1 year in 200, and the economic risk and associated capital by which a company decides to measure its performance.

➋ *Figure 17.8* shows how this works for the example Classes of Business we looked at earlier, constrained by their VaR for 99.5% being the same (\$30 m) and their mean profit being the same (\$8 m) ignoring cost of capital, and for which the interest charge of the capital is 20% pa (say). For instance, CoB1 might be a less risky line of business such as household fire, and CoB2 might be a riskier line such as US Property Catastrophe.

What we see clearly in the Risk–Reward plot is that if the insurer had a “risk appetite” corresponding to a 25 year return period (and many would have such a horizon) then Property Catastrophe would deliver them a better performance than household fire, but if they chose to be ultra-cautious and adopted a 500-year return period, then they would favor household over catastrophe.

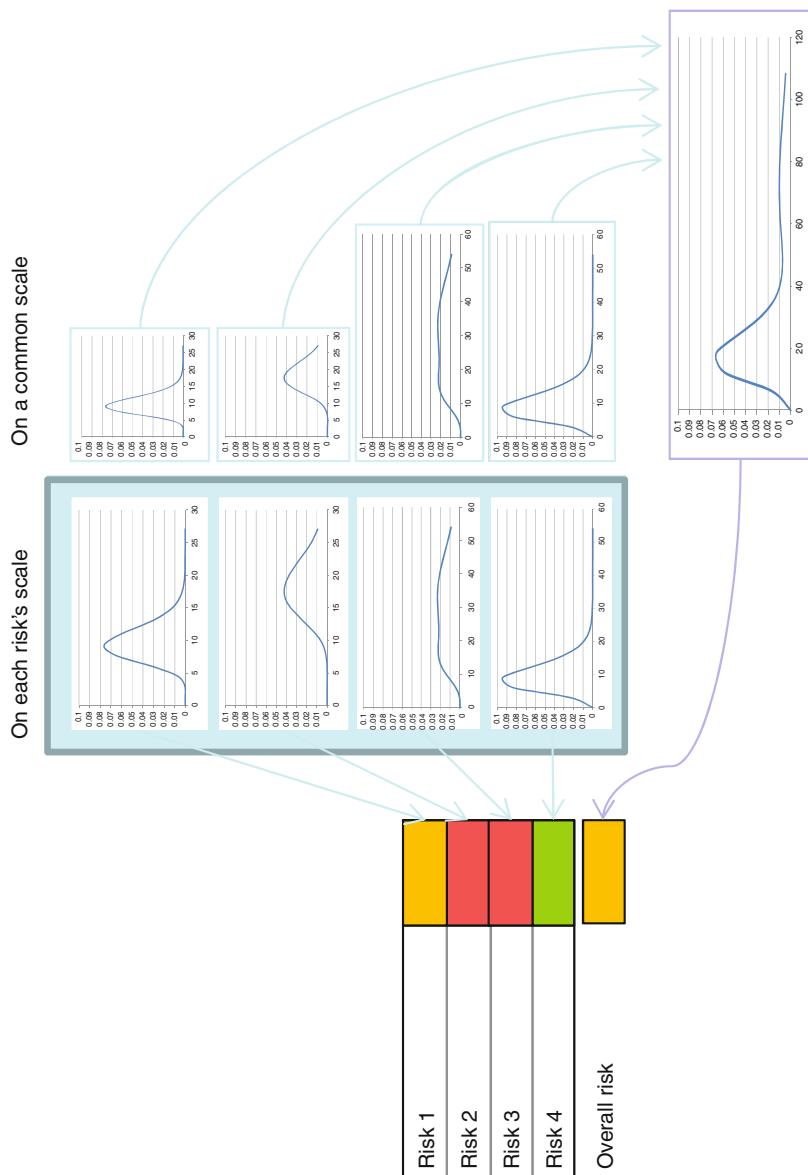

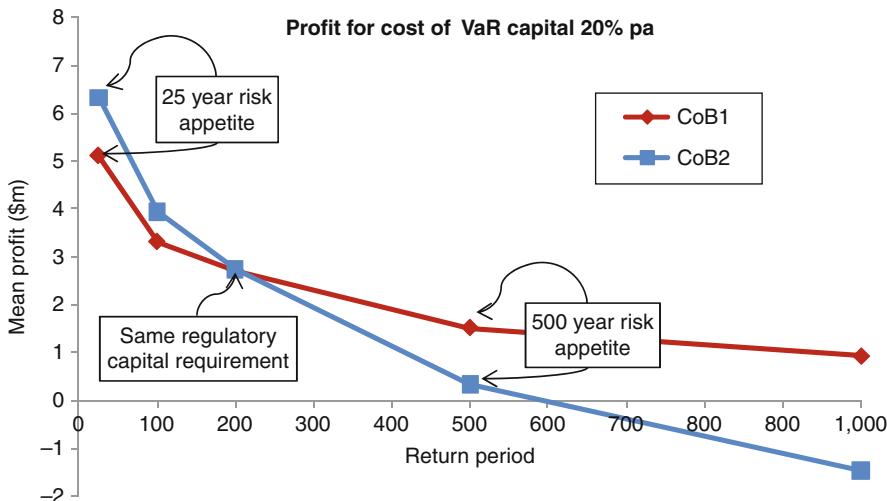

Fig. 17.7  
Combining risk RAGs in general

**Fig. 17.8**  
Risk-reward

The regulatory VaR risk measure is a constraint on the problem and not the risk measure most insurers will be using to manage their business performance.

## Summary

This chapter has set out arguments that risk is a multidimensional concept that cannot in general be reduced to simple measures such as “VaR” used in finance. Risk is proposed to have five dimensions – Time, Harm, Chance, Reward, and Judgment:

- A *Time* frame is a prerequisite of risk assessment sometimes overlooked or treated as implicit when it is of fundamental importance in the ability to anticipate or predict risk.
- *Harm* is downside and can be measured variously – such as mortality, morbidity, or a form of financial loss.
- *Chance* is frequency or probability depending on your point of view. The chapter adopts a “Bayesian” view in that practical risk assessments rest on models of reality so that probability is subjectively contextualized within that model.
- *Reward* is the counterbalance to harm that informs decision-making, sometimes made more complicated when one party’s harm is another’s reward.
- *Judgment*, also termed “Risks Outside the Box” (ROB), allows qualitative assessments that are not covered by the other dimensions and typically represent incompleteness or inadequacy of the model(s) chosen for the other four factors.

Reward and Judgment form part of decision-making about risk rather than risk in itself.

Illustrations of risk assessment, such as project management and Solvency II, are shown to exhibit these five dimensions, with the fifth – Judgment – perhaps the most important of all as it can express concern about the adequacy of any model or models representing the reality of the circumstances under consideration.

This highlights a primary concern in risk assessment, model risk – that is, the risk that we have the wrong model – and finding ways to express this form of uncertainty both qualitatively and, where possible, quantitatively.

## Further Research

---

That as a society we are still very poor at dealing with risk and its importance means this is a hugely popular area, with new developments all the time. Of relevance to the ideas proposed in this chapter are:

1. Developing an evidential factual basis for the many risks that are not readily quantifiable at present due to lack of historical evidence. For example, facts about the volcanic dust and its potential for damage to aircraft engines would have avoided the blind reactions when Eyjafjallajökull erupted. Similarly, in finance, databases on actual operational risks would improve everyone's attempts at quantitative estimates for these traditionally qualitative risks.
2. Shared computer modeling and database capabilities, where models of risk could be run over anonymized databases to compare to benchmarks and to test adequacy of capital and decisions about the business that relate to different risk appetites.
3. Methods for quantifying *model risk* could be developed throughout the insurance and banking industries, as well as in the scientific analysis of complex systems, such as climate change models.
4. Quantitative methods could be developed for combinations of RAG Statuses and use in project and risk management.

## Acknowledgments

---

The “Risk” section was adapted from “What is Risk?” (unpublished) by Rafaela Hillerband and Peter Taylor developed for the Risk Seminar Series at the James Martin School in Hilary Term 2008. I would also like to thank Rafaela for her editorial comments on the manuscript.

My thanks to David Shipley for the Terrorism Risk illustration, to Milan Vukelic and Andrew Baddeley for discussions on the use of reverse stress tests in insurance, to Professor Aurora Plomer for introducing me to Denis Noble’s “Music of Life” and the “Hand Formula,” and Chris Taylor, Milan Vukelic, David Shipley, Henry Ashton, Ben Matharu, and John Thirlwell for kindly commenting on drafts of the paper. Most of all, though, to Ian Nicol for his careful reading, questioning, and suggestions of re-expression for which the reader can be most grateful!

**Abstract:** This paper explores the pros and cons of classical theories of rational decision-making and so-called generalized theories of decision-making. It argues that even if they teach us a great deal about rationality and sound decision-making, and are very useful tools, theories of this kind have serious limitations. In particular they breakdown in the presence of epistemic risk and where there is value uncertainty. It is argued that in these situations we need to take a Socratic approach to risk analysis and risk management.

## Introduction

---

Rational decision-making is the easiest thing in the world. Just follow this simple rule:

(MEU) Choose the alternative with maximal expected utility.

Rational decisions are determined by a combination of our beliefs and desires – our beliefs determining the probabilities of the outcomes, our desires determining the utilities of the possible outcomes.

The classical view assumes that the rational decision maker can choose between a set of alternatives. The alternatives lead to different outcomes depending on the state of affairs each alternative brings into being. An ideal decision situation can therefore be described in terms of a simple decision matrix as shown in [Table 18.1](#).

If  $P(\cdot)$  is the probability function defined over states, the states being uncertain and outside the decision maker's control, and if  $u(\cdot)$  is the utility function defined over outcomes, representing the decision maker's preferences, the expected utility of alternative  $a_i$  is  $P(s_1)u(o_{i1}) + P(s_2)u(o_{i2}) + \dots + P(s_m)u(o_{im})$ . This is the value to maximize.

In this paper the classical theories of rational decision will be outlined and some of their shortcomings will be discussed. It will be argued that these theories ask too much of us – e.g., that we have perfect information and knowledge, that there is no epistemic uncertainty whatsoever, and that we have determinate preferences. Taking a couple of well-known problems, or paradoxes, as a point of departure, alternatives to the classical theories will be explored. Generalized theories, in their efforts to model epistemic uncertainty, give up one or more of the classical axioms. Examples will show that this leads to various types of more or less serious problem. Examining some contemporary risk debates (e.g., nanotechnology, stem cell research, synthetic biology), we clearly see that the evaluation of epistemic uncertainty is as problematic as assessment of the disutility of potential negative outcomes. The epistemic uncertainty creates epistemic risks. However, if our formal theories of rational decision-making cannot guide us, how do we then make decisions? A Socratic approach to decision-making and risk analysis is advocated.

**Table 18.1**  
A decision matrix

Alternatives	States			
	$s_1$	$s_2$		$s_m$
$a_1$	$o_{11}$	$o_{12}$		$o_{1m}$
$a_2$	$o_{21}$	$o_{22}$		$o_{2m}$
...	...	...		...
$a_n$	$o_{n1}$	$o_{n2}$		$o_{nm}$

## Rational Decision-Making

Several theories can be called classical theories of rational decision-making; all ask us to maximize expected utility in one way or another. The best known is probably L. J. Savage's theory, presented in *The Foundations of Statistics* (1954); the first complete theory is probably F. P. Ramsey's, presented in the paper "Truth and probability" (1929). Other examples of classical theory are Debreu (1959), Anscombe and Aumann (1963), and, more controversially, Jeffrey (1965). All outlined and discussed in Fishburn (1981). Here I want to briefly contour Ramsey's theory, sketching his aims and intentions and assessing what he achieves.

Ramsey showed that, under ideal conditions, people's beliefs and desires can be measured with a betting method, and that, given some intuitive principles of rational behavior, a measure of our "degrees of belief" will satisfy the laws of probability: that is, he gave us the modern theory of subjective probability. He was the first to state the Dutch book theorem, and he laid the foundations of modern utility theory and decision theory. In addition, he had a proof of the value of collecting evidence years before it became known through the independent work of Savage and I. J. Good (1967) (see also Sahlin's preamble to Ramsey 1990); he took higher order probabilities seriously; and, in a derivation of the "rule of succession," he introduced the notion of "exchangeability" (under a different name, see M. C. Galavotti's (1991) edition of Ramsey's notes). Ramsey's decision/probability theory is just about as complete as any such theory could be (see Sahlin 1990).

The aim of "Truth and Probability" is to analyze the connection between the subjective degree of belief we have in a proposition and the (subjective) probability it can be assigned, and to find a behavioral way of measuring degrees of belief. Ramsey shows: first, that we can measure the degree of belief a subject has in a given proposition; and, second, that if the subject is rational, his or her degrees of belief will have a measure satisfying the axioms of probability theory – a "subjective" or "personal" probability. In other words, Ramsey shows that, given his method of measuring the strength of "partial beliefs," the degrees of belief displayed by an ideally rational decision maker will be ruled by the laws of probability.

So how does Ramsey propose to measure people's beliefs and desires with a traditional betting method? We can measure a subject's belief simply by proposing a bet. We must "see what are the lowest odds which he will accept" (Ramsey 1926/1990, p. 68. All page references to the 1990, Mellor edition, *Philosophical Papers*, of Ramsey's works). The strategy is to offer the decision maker a bet on the truth value of the proposition  $p$  believed. Ramsey took this method to be "fundamentally sound," but argued that it suffers from "being insufficiently general, and from being necessarily inexact . . . partly because of the diminishing marginal utility of money, partly because the person may have a special eagerness or reluctance to bet. . ." (p. 68).

A bet is of the form:  $x$  if  $p$  is true,  $y$  if  $p$  is not true, where  $x > y$ . The "traditional method" tells us that the decision maker's degree of belief in  $p$  is  $(f - y)/(x - y)$ , where  $f$  is the greatest amount the decision maker is willing to pay for the bet. Notice that the smallest amount of money the decision maker would be prepared to pay for the bet coincides with the smallest amount for which the decision maker would sell it. If the bet is in money and the marginal utility for money is decreasing, it is obvious that using monetary outcomes will fail to give correct measures for (say) bets involving substantial sums of money. As Ramsey says the betting method, though "sound," is neither completely "general" nor very "exact."

Ramsey equates a degree of belief of  $\frac{1}{2}$  in an ethically neutral proposition  $p$  with indifference to two options:  $a$  if  $p$  is true,  $b$  if  $p$  is not true; and  $b$  if  $p$  is true,  $a$  if  $p$  is not true ( $a, b, c, \dots$ ,

denoting outcomes). “This comes roughly to defining belief of degree  $\frac{1}{2}$  as such a degree of belief as leads to indifference between betting one way and betting the other for the same stakes”(p. 74). An ethically neutral proposition of degree  $\frac{1}{2}$  comes close to something like a platonic idea of a fair coin.

This gives Ramsey a way of measuring value differences. Thus the notion that the value difference between  $a$  and  $b$  is equal to the difference between  $c$  and  $d$  simply means that if  $p_{\frac{1}{2}}$  is an ethically neutral proposition believed to degree  $\frac{1}{2}$ , the options ( $a$  if  $p_{\frac{1}{2}}$  is true, and  $d$  if  $p_{\frac{1}{2}}$  is not true) and ( $b$  if  $p_{\frac{1}{2}}$  is true, and  $c$  if  $p_{\frac{1}{2}}$  is not true) are equally preferable.

Ramsey proves a representation theorem saying that a subject’s preferences can be represented by a utility function determined up to a positive linear transformation. It is the binary preferences that are represented, and the very goal of the theorem is to isolate the conditions under which such preferences can be seen as maximizing expected utility. The representation guarantees the existence of a probability function and an unconditional utility function such that the expected utility defined from this probability and utility represents the decision maker’s preferences. To prove this theorem eight axioms are introduced. The axioms, following Suppes (1956), can be divided into three groups: behavioral, ontological, and structural.

A behavioral axiom is a rule that a rational person is supposed to satisfy when making a decision. One of Ramsey’s axioms states that the subject’s value differences are transitive: If the difference in value between  $a$  and  $b$  is equal to the difference between  $c$  and  $d$ , and the difference between  $c$  and  $d$  is equal to that between  $e$  and  $f$ , then the difference between  $a$  and  $b$  is equal to that between  $e$  and  $f$ . This is a typical behavioral axiom.

The ontological and structural axioms tell us what there is and give us the mathematical muscles necessary to prove the representation theorem. Ramsey’s first axiom, for example, states that “[t]here is an ethically neutral proposition  $p$  believed to degree  $\frac{1}{2}$ ” (Ramsey 1926/1990, p. 74). As it turns out, this ontological axiom is far more important than one might have expected. Ramsey’s two final axioms are structural: one is an axiom of continuity, the other an Archimedean axiom.

Ramsey’s utility theory is closely related to the theory developed by von Neumann and Morgenstern in *Theory of Games and Economic Behavior* (1944/1953) about two decades later. von Neumann and Morgenstern, however, use objective or stated probabilities, prizes, and lotteries to derive the utilities. Ramsey avoids these assumptions. As a result he need not postulate that subjects understand the information contained in a stated probability, nor need he assume that the information is well calibrated (i.e., that the subjective probabilities mirror the stated objective probabilities). In a betting method with value differences a number of problems are addressed. The worry that the traditional method, involving monetary outcomes, is insufficiently general and necessarily inexact no longer arises, and concerns about the diminishing marginal utility of money and risk-aversion (risk-proneness) fall away.

It is then possible to define the degree of belief in  $p$  “by the odds at which the subject would bet on  $p$ , the bet being conducted in terms of differences of value as defined” (Ramsey 1926/1990, p. 76). If the subject is indifferent between  $a$  with certainty, and  $b$  if  $p$  is true ( $p$  not necessarily being an ethically neutral proposition, although  $p$ ’s truth cannot change the relative values of the outcomes) and  $c$  if  $p$  is not true, the subject’s degree of belief in the proposition is defined as the difference in value between  $a$  and  $c$  divided by the difference in value between  $b$  and  $c$ .

This can be expressed formally as follows:

$$P(p) = (u(a) - u(c)) / (u(b) - u(c)),$$

where “ $P(.)$ ” denotes the subject’s degree of belief function and “ $u(..)$ ” denotes the subject’s utility function. Ramsey also shows how the degree of belief in a proposition, given the truth of another proposition, can be defined along the same lines, using a slightly more complicated pair of bets.

Ramsey then proves that the obtained measure of degree of belief is a probability measure – it obeys the axioms of probability theory. The probability of any proposition is greater than or equal to 0; the probability of a proposition plus the probability of its negation equals 1; and, if two propositions are incompatible, the probability of the disjunction equals the sum of the probability of the disjuncts. Furthermore, Ramsey proves the Dutch book theorem: “[h]aving degrees of belief obeying the laws of probability implies a further measure of consistency, namely such a consistency between the odds acceptable on different propositions as shall prevent a book being made against you” (Ramsey 1926/1990, p. 79). Having degrees of belief obeying the axioms of probability, having a coherent set of beliefs, is simply a logically necessary and sufficient condition of avoiding a Dutch book. It should be noted that a subject can have more or less any degree of belief whatsoever in a proposition provided the set of beliefs to which it belongs is coherent (consistent). It is essentially this feature of Ramsey’s theory that makes the theory subjectivist.

As mentioned above, Ramsey’s decision/probability theory is as close to being complete as any such theory can be. That is to say, it is complete in the sense that it deals with, and provides answers to, the fundamental questions we have – for example, the question answered above in the prolegomenon: How do we make a rational decision?

In the present context it is the rationality rules that are of particular interest. Basically there are two of them: ordering assumptions and independence assumptions (see Seidenfeld 1988).

Transitivity, which is an ordering assumption, is one kind of a rationality rule. Rational Man’s preferences are assumed to be transitive. This is something we, too, want our preferences to be, since if they are not, we risk becoming money pumps.

The independence axioms of decision theory and game theory – e.g., Savage’s Sure-Thing Principle – are another classical type of rationality axiom. Savage’s principle tells us that if an alternative  $A$  is judged to be as good as another  $B$  in all possible states and better than  $B$  in at least one, then a rational decision maker will prefer  $A$  to  $B$ . Savage (1954/1972) illustrates the principle with the following case:

- ▶ A businessman contemplates buying a certain piece of property. He considers the outcome of the next presidential election relevant to the attractiveness of the purchase. So, to clarify the matter for himself, he asks whether he would buy if he knew that the Republican candidate were going to win, and decides that he would do so. Similarly, he considers whether he would buy if he knew that the Democratic candidate was going to win, and again finds that he would do so. Seeing that he would buy in either event, he decides that he should buy, even though he does not know which event obtains, or will obtain, . . . [E]xcept possibly for the assumption of simple ordering, I know of no other extralogical principle governing decisions that finds such ready acceptance (p. 21).

Similarly, moving to game theory, and assuming stated probabilities, the so-called strong independence axiom tells us that for all outcomes  $A$ ,  $B$ ,  $C$ , and probability  $p > 0$ ,  $A$  is better than  $B$  if and only if a prospect  $A$  with probability  $p$  and  $C$  with probability  $1 - p$  is better than a prospect  $B$  with probability  $p$  and  $C$  with probability  $1 - p$ .

Savage formulated the Sure-Thing Principle in 1954 in *The Foundations of Statistics*. By his own account, his view of probability derives mainly from the work of de Finetti (1937, 1974) and is inspired by Ramsey's theory. Savage's theory is in many respects similar to Ramsey's, but instead of giving us a narrative of an ideal he presents a normative theory: that is, Savage's theory tells us how we *ought* to choose. Ramsey's theory, by contrast, is descriptive. If we assume, however, that the decisions of the ideal decision maker, Rational Man, are the best that can be made, and that we human beings want to and maybe should follow in his, her, or its footsteps, a normative interpretation of Ramsey is not far away.

The Sure-Thing Principle and the ordering axioms are accepted by many (perhaps most) normative decision theorists (see Fishburn 1981 for a review of normative theories). Though they sometimes appear counterintuitive (we will discuss a few paradigm cases of this below), they are considered cornerstones of rationality that we ought to follow.

But be aware that even if the classical theories have much in common, especially in their view of rationality, they are not identical. Thus the ontological and structural axioms are different. Ramsey is working with propositions and words (outcomes or consequences), Savage with events and consequences. Savage defines acts as a function from states to consequences, which, when set against Ramsey's theory, is an innovation. And also small differences can matter.

Schervish et al. (1990) have shown that classical theories such as those developed by Savage, von Neumann and Morgenstern, Anscombe and Aumann, and de Finetti all have a problem with state-dependent utilities. Theories using (horse) lotteries and prizes to derive probabilities cannot guarantee the existence of unique probabilities. The problem is that the utility of a prize is the utility of that prize given that a particular state of nature obtains. And even "constant" prizes might have different values in different states of nature – with the implication that the subject's preferences can be represented by far too many utility functions. As a consequence there is no unique subjective probability distribution over states of nature. Ramsey saw that his method of using preferences among bets to quantify value differences required the states defining the bets to be value-neutral. For that, he proposed "ethically neutral propositions." In Ramsey's theory the outcomes have state-dependent utilities, which can be measured through bets involving an ethically neutral proposition. The question, however, is whether the concept of an ethically neutral proposition (Axiom 1: "There is an ethically neutral proposition believed to degree  $\frac{1}{2}$ ") can be understood and pressed into service without our making use of lotteries. If not, Ramsey faces the same problems as did the descendants of his theory; but if it can be done, Ramsey's theory has a clear advantage over the other classical theories.

## The Paradoxes of Ellsberg and Allais

---

In a classic paper Daniel Ellsberg (1961) asks us to consider a decision problem. Imagine an urn containing 30 red balls and 60 that are either black or yellow, in unknown proportions. A ball is to be drawn at random from the urn. You are asked to make two choices. The first choice is between alternatives  $e_1$  and  $e_2$ . If you choose  $e_1$  you will receive \$100 if a red ball is drawn and nothing if a black or a yellow ball is drawn. If you choose  $e_2$  you will receive \$100 if a black ball is drawn, nothing if a red or yellow ball is drawn. The second choice is between alternatives  $e_3$  and  $e_4$ . If you choose  $e_3$  you will receive \$100 if red ball is drawn, \$100 if a yellow ball is drawn, and nothing if a black ball is drawn. If you choose  $e_4$  you will receive \$100 if a black ball is drawn, \$100 if a yellow ball is drawn, and nothing if a red ball is drawn.

The problem can be represented by a decision matrix as shown in [Table 18.2](#).

Studies have shown that a vast majority of subjects prefer  $e_1$  to  $e_2$ , and  $e_4$  to  $e_3$  (see Kahneman and Tversky 1979; Sahlin 1991). This pair of preferences violates the Sure-Thing Principle. Note that  $e_1$  is the same alternative as  $e_3$ , except for the sure-thing: \$100 if yellow. And  $e_2$  is identical to  $e_4$ , except for the sure-thing: \$100 if yellow.

It can also be argued that preferring  $e_1$  to  $e_2$  (or for that matter  $e_4$  to  $e_3$ ) is, in isolation, irrational. Ramsey might, and Savage definitely would, argue that the two alternatives have the same expected value, i.e., \$33. The uncertainty when it comes to the proportion of black and yellow balls is of no significance. The exact proportion is unknown and it is thus reasonable to assume that all possible proportions have the same probability (applying a principle of indifference). The proportion of black and yellow balls is a random variable, with respect to a known probability, and the *expected* proportion of balls is 30-30-30. This is, to use Savage's phrase, the "composite probability" that ought to be used in rational decision – which implies, in this case, that  $e_1$  is as good as  $e_2$ .

It is important to note that Ellsberg's paradox teaches us two things. First, the reliability or unreliability, and the determinacy or indeterminacy, of probabilities influences our actions. Second, violating the independence assumption expressed in the Sure-Thing Principle sometimes seems perfectly rational – does it not? There must be theories that prescribe and describe the Ellsberg types of choice. Or, is the only option for those of us who choose  $e_1$  and  $e_4$  to confess irrationality and resolve to work hard to become a better person, i.e., adapt our decisions to the norm?

Maurice Allais (1953) attacks the classical theory of rational decision-making with a nice example known, in popular parlance, as Allais's paradox.

You have two choices. The first choice is between alternatives  $a_1$  and  $a_2$ , the second between  $a_3$  and  $a_4$ . If you choose  $a_1$  you get nothing (\$0) with probability 0.01, a nice round sum of \$2,500,000 with probability 0.10, or \$500,000 with probability 0.89. If you choose  $a_2$  you get \$500,000 with certainty.

The alternatives  $a_3$  and  $a_4$  have the following outcomes. If you choose  $a_3$  you get nothing with probability 0.90 and \$2,500,000 with probability 0.10. If you choose  $a_4$  you get \$500,000 with probability 0.11 or nothing with probability 0.89.

The paradox can be represented by a decision matrix as shown in [Table 18.3](#).

Most people prefer  $a_2$  to  $a_1$ , but  $a_3$  to  $a_4$ . As in Ellsberg's paradox it is the sure-thing, in this case the \$500,000 with probability 0.89, that causes the problem. Bar the sure-thing,  $a_1$  would have given the same outcomes as  $a_3$  and  $a_2$  would have given the same outcomes as  $a_4$ . If  $a_3$  is, so to speak, better than  $a_4$  without the sure-thing, why is it not so with the sure-thing?

This type of "irrational" choice is dubbed "the certainty effect," by Kahneman and Tversky (1979). It appears to be the best known violation of expected utility theory. In controlled

**Table 18.2**  
**Ellsberg's paradox**

	Red	Black	Yellow
$e_1$	\$100	Nothing	Nothing
$e_2$	Nothing	\$100	Nothing
$e_3$	\$100	Nothing	\$100
$e_4$	Nothing	\$100	\$100

■ **Table 18.3**  
**Allais's paradox**

	0.01	0.10	0.89
$a_1$	\$0	\$2,500,000	\$500,000
$a_2$	\$500,000	\$500,000	\$500,000
$a_3$	\$0	\$2,500,000	\$0
$a_4$	\$500,000	\$500,000	\$0

empirical studies Kahneman and Tversky have investigated the following version of Allais's paradox. Their subjects were asked to choose between:

$A_1$ :	2,500	With probability 0.33
	2,400	With probability 0.66
	0	With probability 0.01

and

$A_2$ :	2,400	With certainty
---------	-------	----------------

And to choose between:

$A_3$ :	2,500	With probability 0.33
	0	With probability 0.67

and

$A_4$ :	2,400	With probability 0.34
	0	With probability 0.66

Their empirical finding was that 82% of the subjects preferred  $A_2$  to  $A_1$  and that 83% preferred  $A_3$  to  $A_4$ . Together these choices violate expected utility theory. That is, the pair of preferences implies a pair of incompatible utility inequalities:  $0.34u(2,400) > 0.33u(2,500)$ , by the first preference, but, at the same time, the reverse inequality holds by the second preference. In Allais's paradox, given the preference of  $a_2$  over  $a_1$ , we obtain  $0.11u(\$500,000) > 0.10u(\$2,500,000)$ , an inequality reversed by the preference of  $a_3$  over  $a_4$ . In both cases we have to assume that  $u(\text{nothing}) = 0$ , and that subjective probability assessments reflect stated probabilities.

Note that to secure a violation of the independence assumption expressed in the Sure-Thing Principle we must assume that we have the same utility function in both choice situations – that is, that one and the same utility function is in play when we choose between  $a_1$  and  $a_2$  (or  $A_1$  and  $A_2$ ) and when we choose between  $a_3$  and  $a_4$  (or  $A_3$  and  $A_4$ ). The violation lapses if we assume, or can show, that we are employing distinct utility functions in the two decision situations (Sahlin 1991). Introspection tells me that I, for one, do not have the same utility function in the two

choice situations. In the first situation I know that I can with certainty collect \$500,000 (or 2,400). I therefore evaluate the \$2,500,000 (or 2,500) outcome in the light of this possible prosperity, rather than in the light of my present wealth. The \$500,000 (or 2,400) changes my levels of aspiration and thus my utility assessments. In the second choice situation there is no choice which, with certainty, will give a small fortune in dollars. I, and you, have to evaluate the possible outcomes with respect to our present wealth. This simple observation makes the empirical findings on Allais's paradox less robust and therefore less interesting perhaps than similar results obtained in connection with the Ellsberg paradox (Sahlin (1988)).

Ellsberg's paradox and Allais's paradox have been very influential. Two relatively simple thought experiments have made decision theoreticians lose faith in the commandments of the classical theory. They have triggered numerous of empirical studies and influenced many descriptive theories (including Prospect Theory, see Kahneman and Tversky 1979), and they have made us question our rationality – we are irrational and only ideal decision makers are rational (see Bränmark and Sahlin 2010; Sahlin and Bränmark 2011). They have also inspired the development of new, generalized “normative” decision theories. And this is the topic of the following section.

## Generalizations, Improvements, and Failures

---

Ramsey's, Savage's, and other classical theories seek to represent a subject's preferences with a utility function determined up to an affine transformation, and a subject's state of belief by a unique probability measure, to any degree of precision. Ellsberg's paradox – and to some extent Allais's paradox – shows that this aim leads to assumptions that are far too strong. The assumptions made by the classical theories are also put in question by numerous of empirical findings (if normative theory should bother about the trifles of everyday life, see Sahlin 1988, 1991) and by philosophical arguments and questions. What is a decision maker? Does a decision maker have, in addition to full beliefs and degrees of belief, higher order beliefs? Should the normative theory be designed for an ideal, unrealistic agent or a more plethoric decision maker? What is our aim: large inapplicable norms, or far from faultless prescriptive theories, with known blemishes, the good supervisor (see Sahlin and Vareman 2008).

It is not too difficult to calculate the probability that a white ball will be drawn from an urn containing 99 white balls and 1 black ball. It is far more difficult to estimate, with reasonable precision, the probability that my friend in Canberra is at this very moment drinking tea. And it is almost impossible, in the light of what we know today, to say with the degree of precision required by the classical theories what the probability is that, if they are transplanted, iPS-cells (induced pluripotent stem cells) will behave the same way as ePS-cells (embryonic stem cells). There simply are too many things we know too little about, like undiscovered epigenetic factors (Sahlin et al. 2010).

It is well known that in choice situations degrees of indeterminacy or unreliability may influence decisions. We may, for example, think that the probability is the same (say 0.99) in all three of the examples above, but still, if we have a choice, we prefer to bet on a fair gamble if the outcome is determined by the drawing from the urn, but not if it is determined by what is going on in Australia or the advancements of stem cell research. We have a feeling that we know more about the urn than we do about our friends' habits and the very latest findings in bioscience. The stability of our knowledge influences our decision-making. In other words, there are situations in which there are important

differences of degree in our knowledge, or understanding, of the various factors underlying our decisions – a difference in ignorance that cannot be mirrored by a unique probability measure, or captured in the classical theories, or for that matter seeds of those theories (detectable in Jeffrey 1965 and Bolker 1967).

The probabilities given by Ramsey's theory (and similar theories like Savage's, Anscombe and Aumann's, and Jeffrey's) are the result of the decision maker's inability to express fully a strength of preference. Ramsey's theory does not take unreliability into account. He discusses higher order probabilities, but not as an integrated part of the 1926 theory (Sahlin 1993). The necessary clarity of perception of uncertainty (caused, in part, by the quantity and quality of information with which the decision maker is equipped) is simply not introduced.

It appears, then, that it is necessary to create theories that allow indeterminate, or unreliable, probabilities and utilities so that those theories can be applied to real-life decision problems. But, as it turns out, this improvement is not an uncomplicated matter. A comparison of two theories, two attempts to solve the problem, will reveal some of the difficulties with this type of generalized decision theory.

In a number of important works Isaac Levi (1980, 1986, 1988) has developed a decision theory permitting the decision maker indeterminate probabilities and imprecise preferences. Levi assumes that the decision maker  $X$ 's knowledge and information at time  $t$  about states of nature is contained in a convex set  $B_{X,t}$  of probability distributions.  $B_{X,t}$  is the set of *permissible* distributions. Levi's approach provides an impressively adequate and complete representation, allowing the quality and quantity of the decision maker's information to be more fully accounted for.

Levi also generalizes the classical theory by introducing a set of “permissible” utility functions (denoted  $G$ ). The classical theory assumes that there is but one utility function representing the decision maker's preferences (not counting affine transformations, which anyway are not countable). A set of utility functions tells us far more about the uncertainty and robustness of the decision maker's preferences than a single function does.

As long as the decision maker's beliefs and values can be represented by a unique probability distribution and a single utility function it is possible to maximize expected utility. But with sets of measures the situation is different. We cannot maximize over intervals or sets. Generalized decision theories therefore have to offer new decision rules. Levi suggests we use a three-step procedure, a lexicographically ordered set of carefully chosen rules, of the following sort.

First, a decision alternative is said to be *E-admissible* if and only if there is some probability distribution in the set  $B_{X,t}$  and some utility function in the set of utility functions  $G$  such that the expected utility of the action alternative relative to the two distributions is maximal among all the available decision alternatives. It is then stated that a decision alternative must be E-admissible in order to be choice-worthy.

An alternative is *P-admissible* if it is E-admissible and it is “best” with respect to E-admissible option preservation among all E-admissible options. This condition has to do with the possibility of deferring decision. “[T]he injunction to keep one's options open is a criterion of choice that is based not on appraisals of expected utility but on the ‘option-preserving’ features of options” (Levi 1980, pp. 156–163).

Finally, a P-admissible alternative is *security-optimal* if and only if the minimum utility value assigned to some possible outcome of the decision alternative is at least as great as the minimal utility value assigned to any other P-admissible alternative. And a decision alternative is S-admissible if it is E-admissible, P-admissible, and security-optimal (relative to some of the

decision maker's utility functions). It is the S-admissible alternatives that are admissible for final choice. If there is more than one admissible alternative, a dice, or similarly random device, has to be introduced.

After Ramsey's work, Levi's theory is an indisputable breakthrough. One of the theory's great innovations is the way it represents the decision maker's beliefs and desires. Another improvement is the carefully developed set of decision rules.

A theory with ambitions similar to Levi's is presented by Gärdenfors and Sahlin (Gärdenfors and Sahlin 1982, 1983; Sahlin 1983, 1985, 1993). The theory assumes that the decision maker's knowledge and beliefs concerning states of nature can be represented by a set  $P$  of probability distributions, which is the set of epistemically possible distributions. This set consists of those measures which do not contradict the knowledge the decision maker has.  $P$  is restricted by way of a second-order measure of reliability. A second-order probability measure,  $\rho$  defined over the set of "first-order" probability measures, allowing for a representation not only of the decision maker's first-order beliefs but also of his or her higher order beliefs. As a basis for action, a decision maker should use those and only those measures of  $P$  that are epistemically reliable, which implies that a subset  $P/\rho_0$  of  $P$  is to be used when making a decision, with  $\rho_0$  being a level of aspiration with respect to epistemic uncertainty. This restricted set can be compared with Levi's set  $B_{X,t}$ . Note, for example, that unlike Levi's set,  $P/\rho_0$  does not have to be convex.

Gärdenfors and Sahlin's theory is a two-step rule for making decisions. First, the expected utility of each choice alternative, and each probability distribution in  $P/\rho_0$ , is computed, and the minimal expected utility of each alternative is determined. (Gärdenfors and Sahlin do not introduce a set  $G$  of utility functions, although to do so would be straightforward.) Second, the choice alternative with the largest minimal expected utility is selected. So, instead of the classical goal of maximizing expected utility, it is suggested that we should *maximize the minimal expected utility* (MmEU).

Gärdenfors and Sahlin's theory "solves" the Ellsberg paradox straight out – or rather, the theory gives a recommendation that accords with Ellsberg's findings. In Ellsberg's example the set of epistemically possible distributions is  $(1/3, x, 2/3 - x)$ ,  $0 \leq x \leq 2/3$ . It is a reasonable assumption that  $P = P/\rho_0$ . The minimal expected utilities for the four alternatives,  $e_1$ ,  $e_2$ ,  $e_3$ , and  $e_4$ , can now be calculated. If  $1/3u(\$100) > u(\$0)$ , then MmEU tells us that  $e_1$  should be preferred  $e_2$ , and  $e_4$  preferred to  $e_3$ . Ellsberg's subjects – and the subjects in, for example, Goldsmith and Sahlin's (1983) experiments – remind us that decision makers' do not just perceive epistemic uncertainty, but are capable of consistently using this uncertainty when making decisions. The alternatives  $e_2$  and  $e_3$  involve greater "epistemic risk," or greater epistemic uncertainty, than  $e_1$  and  $e_4$ , and are consequently (in the present outcome matrix) avoided.

But this solution comes at a cost. Seidenfeld (1988) has constructed a simple but ingenious decision problem. Imagine that Seidenfeld has a stone in one of his pockets. Your task is to predict whether it is in his left or right pocket. If you say Left and the stone is in the left pocket he gives you \$100, and if you say left and it is in the right pocket he gives you \$10. If you say Right the outcomes are reversed; you get \$100 if the stone is in the right pocket and \$10 if it is in the left pocket. Your choices, Left and Right, therefore have the same minimal expected value of \$10. MmEU tells you to be indifferent between the two options.

Now construct a 50:50 gamble with outcomes Left or Right – that is, a 50:50 gamble with outcomes \$10 or \$100. It can be assumed that this gamble has an expected value of \$27.50 (with dollars reflecting utilities).

In a clever move, Seidenfeld now constructs two further gambles. Gamble 1 is this: if a fair coin lands on heads you can either choose Left or \$9 in cash, if it lands tails you can choose either Right or \$9. Gamble 1 has the same value as the 50:50 gamble between Left and Right, i.e., \$27.50. Gamble 2 is this: if a fair coin lands heads you can either choose Left or \$11, if it lands tails you have a choice between Right and \$11. Left and Right have the same expected value, \$10, so you will in both choice situations take the “sure-thing,” the 11 dollars. This means that Gamble 1 is worth \$27.50 and Gamble 2 is worth \$11. So far so good. But note, says Seidenfeld, if the coin lands on heads Gamble 1 gives \$10 but Gamble 2 one dollar more. And so it does if the coin lands on tails. So is not Gamble 2 the obvious choice?

What Seidenfeld’s example shows is that theories like Gärdenfors and Sahlin’s can make counterintuitive recommendations in consecutive choice situations. This is a problem that the theory shares with all normative, prescriptive, and descriptive theories (e.g., Prospect Theory) that sell the independence postulate to obtain explanatory power or rational resilience. Levi’s theory, with its lexicographically ordered set of decision rules, with E-admissibility as the cornerstone, avoids the trap.

But Levi’s theory is not without blemishes. For instance, it does not give us a direct solution to the Ellsberg paradox. Note that  $e_1$  and  $e_2$  are both E-admissible; they are both S-admissible, too. The same holds for  $e_3$  and  $e_4$ . In other words,  $e_1$  is as good a choice as  $e_2$ : both are admissible. And  $e_3$  is as good a choice as  $e_4$ : both are admissible. Levi (1986) explains how this (perhaps unwanted) consequence can be avoided.

The problem with Ellsberg-type choices is the unreliable probability distribution. We simply do not know the proportion of black and yellow balls. We do know, however, that the actual distribution is one of 61 possible permutations. Let  $h_i$  be the hypothesis that  $i$  balls are black. The probability of drawing a black ball given that  $h_i$  is true is  $i/90$ . For each alternative and each distribution the expected value conditional on  $h_i$  can be determined. The two original decision matrixes can now be redrawn. Each alternative,  $e_1$ ,  $e_2$ ,  $e_3$ , and  $e_4$ , now has 61 possible outcomes, not 3. The outcomes are expected values, not fixed monetary prizes.

Levi points out that this transformation of the original problem changes nothing when it comes to E-admissibility. All four alternatives are E-admissible. However, the security values are different.  $e_1$ ’s security level is  $100/3$ ,  $e_2$ ’s security level is 0, and for  $e_3$  and  $e_4$  the levels are  $100/3$  and  $200/3$ , respectively. In the pursuit of security-optimal choices,  $e_1$  should be preferred to  $e_2$ , and  $e_4$  to  $e_3$ . This is an artful transformation of the two original decision matrixes that neatly harmonizes the recommendations given by Levi’s theory with Ellsberg’s findings.

This can be seen as trickery. Levi’s theory states that an alternative is security-optimal if and only if the minimum utility value assigned to some possible *outcome* of the decision alternative is at least as great as the minimal utility value assigned to any other admissible alternative. What is meant by an outcome here? Is an expected value an outcome? Utilities defined over what? We know that it is far more difficult to find counterexamples to preference principles in a probability free world than it is when probabilities are allowed to, as it were, infect values. And if state-dependent utilities are a problem for the classical theory, with the type of outcomes it deals in, Levi’s move introduces new levels of dependence. Another thing one might ask is whether every one of the 61 possible distributions has the same probability. Is it more likely that there are 30 black and 30 yellow balls in the urn than it is that there are no black and 60 yellow balls? If so, does this show that Levi’s theory needs a measure of epistemic reliability,  $\rho$  – needs higher order probabilities? Perhaps not to solve the present problem, but with an ounce of creativity the degree of indeterminacy can be readily multiplied.

Plainly, it is not much of an argument to say that Levi's "solution" to Ellsberg's paradox feels somewhat counterintuitive. Our philosophical intuitions simply diverge. What is a problem, however, is that Levi's theory violates one of the fundamental ordering principles of rational choice, and it is this violation that affords him the explanatory power. Luce and Raiffa's Axiom 7, the *principle of independence of irrelevant alternatives*, says that if a decision alternative is suboptimal in a decision situation it should not be possible to make it optimal by adding new alternatives. Luce and Raiffa illustrate this with a charming example. "Doctor: Well, Nurse, that's the evidence. Since I must decide whether or not he is tubercular, I'll diagnose tubercular. Nurse: But, Doctor, you do not have to decide one way or the other, you can say you are undecided. Doctor: That's true, isn't it? In that case, mark him not tubercular" (Luce and Raiffa 1957, pp. 288–289). Levi's theory does not satisfy this condition, but the MmEU criterion does.

The following decision problem (Gärdenfors and Sahlin 1982; Sahlin 1985) demonstrates the problem. Imagine a decision matrix with two alternatives, two states and consequently four possible outcomes. If  $a_1$  is chosen and state 1 ( $s_1$ ) obtains the outcome is 0 (let us say, utilities) and if state 2 ( $s_2$ ) obtains the outcome is also 0.  $a_2$  gives 11 and -9, respectively. Assume that Levi's set  $B_{X,t}$  consists of all convex combinations of the two probability distributions  $P_1$  and  $P_2$ , defined by  $P_1(s_1) = 0.4$  and  $P_1(s_2) = 0.6$  and  $P_2(s_1) = 0.6$  and  $P_2(s_2) = 0.4$ . Both  $a_1$  and  $a_2$  are E-admissible, but  $a_1$  the only admissible alternative because of its better security level, it is security-optimal. However, if we add a new alternative,  $a_3$ , which gives -10 if  $s_1$  obtains and 12 if  $s_2$  obtains,  $a_2$  is all of a sudden rendered optimal by Levi's theory.

This simple three-by-two matrix shows another thing. Assume that in this situation Levi's  $B_{X,t}$  contains the same set of distributions as Gärdenfors and Sahlin's  $P/p_0$ . Levi's decision rules recommend  $a_2$ , but MmEU recommends  $a_1$ . Which of the two theories should the decision maker use as the basis of a decision? But the decision maker does not only have these two theories to choose between. Henry Kyburg (1983) has suggested a theory to be used in situations where the quality and quantity of information leads to unreliable probability estimates. His decision principle says that the decision maker ought to reject any choice  $c$  for which there is an alternative whose minimum expected utility exceeds the maximum expected utility of  $c$ . Kyburg's theory tells us that we have no reason to choose one of the alternatives instead of another. Just for fun, let us now invent and apply a "new," fourth generalized "theory" with renewed decision rules. It is not hugely plausible to do this, but why not replace MmEU with a maxi–max rule, MMEU? Such an amendment would deliver a theory that recommends  $a_3$ , an alternative recommended by none of the three theories so far considered.

In an emergency ward decisions are made constantly, under great pressure of time and in circumstances that are stressful in other ways, too. There is not always time for reflective decision-making: there is a risk that affects influence the hard choices too much. Sometimes the quality and quantity of information is such that the probabilities are unreliable. Also the values can be more or less indeterminate – sufficiently unreliable and indeterminate to make the classical theories inapplicable. In situations like this a decision support system could aid the doctor's decision-making. Assume that such a tool has been developed. The developers, knowing that there are competing generalized decision theories, have programmed the machine to use several theories and present their converging or diverging recommendations. A patient is in a critical condition. The doctor feeds the decision tool with the information available, presses "run," and waits for advice. Unfortunately the computer gives not one, but several recommendations. Theory 1 recommends that a complicated and dangerous operation

is performed immediately. Theory 2 recommends new tests and that the patient be put under observation. Theory 3 regrets that, in this type of situation, it cannot give one and only one recommendation, since there are too many equally good options. What shall the doctor do now? It seems that to settle on just one of the conflicting recommendations, he or she will have to know as much about the theories as those who developed them. That may be asking too much of a decision maker.

Savage was aiming at a complete normative theory. So was Ramsey – at least, if we should put our trust in Rational Man or *Homo economicus* (two ideals in one). Strait is the gate and narrow is the way, but not if we opt for one of the generalized theories. Which theory should we choose? Is there a way to tell which is preferable? If there were a definite answer to this question, would not that imply that we knew what the ideal generalized theory would look like? But obviously there is no such theory, since this type of theory always gives up one or other of the commandments of classical theory. At best we can use several theories and hope for converging recommendations. That is a good thing. Or we could investigate and try to say under what circumstances one theory performs better than another, but this too seems a hopeless task.

We have seen that the classical theories of rational decision-making are not useful if probabilities and values are unreliable. We have also seen that the attempts to develop more general decision theories, designed to deal with this type of higher order uncertainty, all have their own problems. Leaving the straight and narrow road traveled by the classical decision theories leads straight down to too warm a place for any decision theoretician. On the flanks of the choice between giving up ordering or giving up independence lie Scylla and Charybdis.

## Epistemic Risk

---

Keynes (1933) once wrote: “When he [Ramsey] did descend from his accustomed stony heights he still lived without effort in a rarer atmosphere than most economists care to breathe.” Ramsey’s theories are indeed crystal-clear, complicated masterpieces; they do not make for easy reading, and they involve theoretical assumptions dissociating them from the types of problem we – you and I, or society at large – have to discuss and solve. We have seen that the traditional theories of rational decision-making are perfect tools for action if there is no epistemic uncertainty or value uncertainty. But, examining some contemporary risk debates (e.g., GMOs, nanotechnology, stem cell research, electromagnetic fields), we find that the evaluation of epistemic uncertainty seems as problematic as the assessment of the disutility of potential negative outcomes. The epistemic uncertainty causes epistemic risks, making it hard to identify, assess, and manage the outcome risks, i.e., the different negative things that might or might not happen as the result of our decisions.

A good example is nano-safety. Nanotechnology offers tremendous technological breakthroughs, but its promises come with a risk. It is impossible to say what the risk of nanotechnology is. There is no such (single, overall) risk. What can be assessed is the risk of individual innovations, inventions, tools and methods. At the same time, this field of research moves almost at the speed of light. This means that the systematization described below could well have been overtaken, or entrenched for that matter, by results published since this article was sent to the editors. I will therefore say “we believe” instead of “we know.” And our beliefs are sometimes based on a single article – sometimes supported by collateral evidence.

There are many types of nanoparticle. Fullerenes are molecules composed of carbon. Buckyballs are spherical fullerenes and nanotubes are cylindrical in shape. We also have, for

example, nanobuds (the combination of tubes and buckyballs – tubes with a verruca) and nanowires.

Let us briefly look at some of the health effects we believe that fullerenes can have. But also indicate what type of knowledge we lack. (A good survey of our present toxicological knowledge can be found in Ostiguy et al. (2008). See also Hermerén 2007 and 2008.)

*Nanotubes.* There are studies indicating, for example, that nanotubes can pass through the cellular membrane and that they can accumulate in the cell and end up in the cell nucleus. Other studies indicate that nanotubes have an effect on the respiratory system and that they can cause mechanical blockage of the airway (studies on rats). We believe that nanotubes are toxic, and that their toxicity depends on, among other things, size. There is also a study indicating that single-stranded DNA interacts with the nanotube (Zheng et al. 2003). If so, does this have an effect on transcription or methylation processes?

However, we do not know if nanotubes have an effect on, for example, the nervous system, or the liver, or whether they have developmental implications.

The problem is that today the quality and quantity of the information we have and knowledge we believe we have is not very robust. There are considerable epistemic uncertainties.

*Buckyballs.* There are studies indicating that buckyballs, spherical carbon nanoparticles, can affect metabolism. Toxicity studies have shown kidney effects resulting in a decrease in body weight and dwarfed vital organs. And several studies indicate that this type of particle can have an undesired effect on the respiratory system.

However, so far we do not know if these particles have an effect on the gastrointestinal system, or on the reproductive system or reproductive outcomes. Nor do we know whether, and if so, under what precise circumstances, they are carcinogenic.

Another complication is that most studies have been done on so-called  $C_{60}$  balls/molecules (a truncated icosahedron with a diameter of 1.1 nm). This buckyball can be found in, for example, soot. However, there are also buckyballs with 70, 72, . . . 100 carbon atoms. Again, there are Boron buckyballs – for example,  $B_{80}$ . The studies on  $C_{60}$  do not give us a robust picture of the possible health effects of other balls.

The problem is that today the quality and quantity of the information we have is not very robust. There is considerable epistemic uncertainty.

*Nanowires.* There are metallic, semiconducting, and insulating nanowires. Nanowires are one-dimensional and have fascinating properties that we do not find in three-dimensional materials.

There is an expectation that we will be able to press these wires into all sorts of service, but much is still at an experimental stage. One idea is that they will become the nuts and bolts of the next generation of “computers.” By following the movements in the surroundings of nanowires, nanoscientists have shown that these wires can generate electricity (e.g., see Xu et al. 2010). It takes but a scrap of imagination to see that nanowires will, potentially, be used for deep brain stimulation – for example, in the battle against Parkinson’s disease – or used in the treatment of patients with various types of heart condition.

To date few studies have looked at the health effects of nanowires. The epistemic uncertainty is, if not complete, considerable. Eriksson Linsmeier et al. (2009) studied brain-tissue response to nanowire implantations (in rats). They found that nanowire implantation induced both an astrocyte reaction and a microglial response, but that both phenomena declined over time. The authors found “no significant difference in the neuronal fraction for the nanowire-implanted animals compared to controls at all time points” but that that some nanowires were

able to pass the blood-brain barrier and leave the brain. They concluded that nanowires have short- and long-term effects which “require precaution and further investigation.” Since the types of nanowire we construct in labs are not found in nature, it is questionable whether we, or the environment, are adapted to adjust to this type of particle. Abundant reasons make it obvious that we need to improve our epistemic state.

Once again, the problem is that today the quality and quantity of the information we have is not very robust. There is considerable epistemic uncertainty.

To sum up. At present it seems that we know with differing degrees of epistemic certainty that nanoparticles can pass through various protective barriers, spread throughout the body, and accumulate in organs (e.g., the lungs and brain) and cells. We also believe we know that factors such as specific surface, surface properties, and number of particles have an effect on such things as toxicity. A worry is the potential accumulation of nanoparticles. This may or may not result in new properties – over time larger particles with new properties build up, particles that may or may not be harmful. We simply do not know.

There are four paradigmatic types of decision. The complete picture is, of course, greatly more complicated than a simple four-by-four matrix.

In *Type 1* situations the decision maker has extensive knowledge and information, expressed in terms of precise probability estimates. He has also clear and distinct preferences and values.

*An example* of a Type 1 situation: In *The Foundations of Statistics* Savage (1954/1972) asks us to consider a situation in which your wife or husband has just broken five good eggs into a bowl. A sixth egg lies beside the bowl and you have to decide what to do with it. You can break it into the bowl, break it onto a plate for inspection, or throw it away without inspection. If you know your eggs you know the probability that the sixth egg is also good. There is no epistemic uncertainty. And clearly a six-egg omelet is better than a five-egg omelet and the chore of washing up a plate, which in turn is better than five destroyed eggs and no omelet at all.

In *Type 2* situations the quality and quantity of information is poor, and it is difficult to represent the underlying uncertainty in terms of probability. On the other hand, the decision problem is one in connection with which the decision maker still has clear and distinct preferences and values: he knows what he wants and desires.

*An example* of a Type 2 situation: Many of the most well-known, contemporary risk issues fall within this category: GMOs, stem cell research and therapies, nanotechnology, and synthetic biology. We all want the good things that the new technologies promise. But we do not want the risks, and given our present state of knowledge it is also hard to say with precision what, and how great, the risks are. The possible risks of nanotubes and buckyballs are but one example. There are others. A group of scientists, the JCVI team, has recently shown how a small bacterial genome can be synthesized, and how this synthetic genome can be put into a cell to create a cell controlled completely by the synthetic genome (Gibson et al. 2010). As they point out, instead of (just) reading the book of nature we can now write it. Little imagination is needed to see the good things this technology could, potentially, offer. One idea is that in the future we might be able to create energy-producing bacteria, thereby dealing with a number of environmental problems. Another is that we might put ourselves in a position to create far more efficient vaccines for numerous diseases. However, there are risks – are there not? – to both the environment and us as individuals. But what are the risks? How great are they? What does our present epistemic state look like?

In *Type 3* situations the quality and quantity of information is good – good enough to assess precise probabilities. However, the decision maker lacks harmonious, clear and distinct preferences and values. Perhaps his appetites are out of keeping with his valuations.

An example of a Type 3 situation: ICDs (Internal Cardiac Defibrillators) are implants monitoring the patient's heart rhythm. If life threatening arrhythmias are detected by the ICD device it gives the patient a stinker of an electric shock. Before the device is implanted the patient is informed about the risks and benefits. A problem is that the device can be triggered when the patient has no arrhythmia. The probabilities relevant to a decision are known with reasonable precision, but they are known at type, not token, level. This is a decision-situation where our preferences and utilities are blurred or all but indistinct. We lack experience. An experience we hope we never will have. A special problem is that we have to choose between a quick and painless death, on the one hand, and a long drawn-out and maybe not especially painless ending, on the other.

In *Type 4* situations both information and preferences are unfixed or unreliable.

An example of a Type 4 situation: Imagine a 3-year-old child with high-risk neuroblastoma (Castor and Sahlin 2008). She has been treated according to the standard protocols used by pediatricians: she has been given hematopoietic stem cell transplantation, for example – a treatment not without complications and considerable suffering. But not all children respond to stem cell treatment, and let us assume this is a case of recurring neuroblastoma. What are the odds that a hematopoietic stem cell transplantation that failed to succeed the first time will work at the third or fourth attempt? With the number of refractory instances, the relevant probabilities become harder and harder, if not impossible, to estimate; and as our epistemic state deteriorates, our desires and values become more and more unstable.

Type 1 situations are readily detected in the paradigmatic cases with which classical theories of rational choice and decision-making deal. But the traditional theories are ill equipped to handle the three other types of situation. We have seen that in situations of Types 2, 3 and 4 the traditional theories are no guides to action. Here we need theories that help us to represent unreliable or indeterminate beliefs and imprecise values. We must introduce more complex, but also more complete, decision procedures. “Maximize expected utility,” the mantra of the classical theories, is, for simple mathematical reasons, no longer an available option. This means that we must use one or more of the generalized theories as a basis for action. Ideally these will deliver the same recommendation.

Which of the four situation-types best describes nanoscience and the risks of nanotechnology? The answer is: all four. We have to address the individual risk problems one by one, not together in an undifferentiated lump. Furthermore, as our knowledge improves we have to

		Epistemic uncertainty	
		Low	High
Value uncertainty	Low	Type 1	Type 2
	High	Type 3	Type 4

Fig. 18.1  
Types of decision

revalue the risks. What to begin with was a Type 4 situation can, with the arrival of new knowledge and information, turn into a Type 3 situation and end up as a Type 1 problem.

Examples involving nuclear power plants, BSE, GMOs, electro-magnetic fields, and nanotechnology have taught us that various kinds of factor create epistemic uncertainty. Good risk analysis requires careful inspection of our present epistemic state. It is simply not enough to identify and evaluate outcome risks, i.e., the negative consequences of our actions. An estimation and evaluation of current levels of ignorance is crucial. We must know what type of knowledge we have and the value situation we are in (Type 1, 2, 3 or 4).

If we cannot use the traditional methods for rational decision-making and risk analysis, what shall we do? The generalized theories discussed above are good tools and help a lot, but as we have seen they are less than perfect. What we should do, I think, is promote a Socratic approach to risk analysis. What does this mean?

In Plato's *Apology* Socrates declares: "Probably neither of us knows anything really worth knowing: but whereas this man imagines he knows, without really knowing, I, knowing nothing, do not even suppose I know. On this one point, at any rate, I appear to be a little wiser than he, because I do not even think I know things about which I know nothing" (Blakeney 1929, pp. 67–68).

Socrates tells us that it is important that we monitor the epistemic uncertainties we have. This means that we should not let statistics and traditional methods of decision analysis force us to pretend that we are in Type 1 situations when in fact we are glued in the opposite corner dealing with Type 4 decisions. Instead we shall give an as-frank-as-possible picture of the epistemic situation – trying our best to say what is known, describing the stability of our knowledge, and honestly conceding what we do not know. This, I believe, is the only way to avoid the prospect of the new technologies becoming stigmatized, and loss of public trust. The bottom line is that we have a moral obligation to give an honest, complete description of our epistemic state.

But how is this goal to be achieved? We must identify factors that produce epistemic uncertainty. A complete list of factors is impossible to give, but here are some important and well-known factors producing epistemic uncertainty and value uncertainty (Sahlin 1992; Sahlin and Persson 1994; Sahlin et al. 2010; Vareman et al. 2011).

*The unreliable research process.* Research is a mechanism which, off-and-on, gives us incorrect or indeterminate results. Sometimes the machinery works flawlessly, sometimes chance has an unfavorable effect on the results, and sometimes the investigation does not work at all. To accept the results without asking whether or no they are the result of a working mechanism is to wink at all forms of epistemic uncertainty. A Socratic approach to risk analysis demands of us that we carefully scrutinize the strength of the different pieces of evidence we have, that we assess their evidentiary value and find out if they corroborate, or conflict with, each other.

*The fact of irrationality.* Contemporary psychologists have taught us a great deal about the way we perceive risks, and about the way affects and emotions influence our behavior. Their research has shown that, as decision makers, as risk-assessors, and as risk-controllers, we are shortsighted, one-eyed, and prone to serious errors of refraction. We generate too few, and too narrow, hypotheses. We gather information, or evidence, in favor of our guesses that is too narrow, readily available, and skewed in favor of preferred beliefs. Once we have a pet hypothesis, we look for confirmatory material, neglecting countervailing evidence. We are simply not rational – not in the way our theories of rationality (logic, probability and decision-making) assume, at any rate. This is an alarming fact, considering the serious risk-assessment and risk-management tasks that lie ahead of us.

The fact of irrationality then pushes us in the direction of epistemic uncertainty. It sends us into Type 2 and Type 4 situations. This must be avoided, and it can only be avoided if we take a Socratic approach to what we are doing.

*The choice and lack of theories.* Physics is the science of prediction. But sometimes even physicists run into problems. The n-body problem is still elusive. Many differential equations are too hard to solve, and if we seek to replace them with one we can solve we might end up with a rather bad approximation or model. Redhead (1980) gives a simple, powerful and illuminating example. Suppose our theory tells us that  $(1 - x)dy/dx = \cos \lambda x + y$ . And assume we study the theory using an approximation, in terms of a power series of  $x$ , and a model in which  $\cos \lambda x$  is set to 1. As Redhead points out, both the approximation and the model will mislead us, for in different ways they introduce epistemic uncertainty. That theories are permeated by epistemic uncertainty is shown by, for example, the vacuum catastrophe. The calculations undertaken by Quantum field theory missed the target by an order of 107 (see Bax 2004). Some of the phenomena the nanoscientist can observe are also hard work for the theoretician. This, of course, is a problem. We want to be able to say what will happen in advance, not be surprised by experiments which in turn are hard to underpin with sound theoretical explanations. And prediction becomes even more of a challenge when we merge physics and biology. Can we predict anything here, or do we have to search for knowledge by carefully designed experiment? The science is one of small steps.

Traditionally, toxic risks are understood in terms of dose-response ratios. However, nanoparticles do not behave like the chemicals with which we are more familiar. For them, dose, understood in terms of concentration and mass, is no longer an applicable model (Ostiguy et al. 2008). Factors like specific surface, dimension, number of particles, and surface properties are often far more important, and it must not be forgotten that the properties of the nanoparticles can change or become totally different when the particle size decreases or increases, or when particles lump or interact. For similar reasons it seems that in the case of nanoparticles the step from in vitro to in vivo might be bigger than usual. We need new models. And, adding to the epistemic uncertainty, we do not know much about species differences. Today's deficiency in models, theories and data simply yields a considerable amount of epistemic uncertainty – an uncertainty that we should take into account when making decisions, but one that should also arouse our curiosity and inspire new research.

*Unrealizable research.* We might get caught in situations where, for moral or practical reasons, it is difficult to carry out controlled experimental studies. As a result we might have to rely on indirect evidence rather than solid, direct empirical evidence.

The best way to discover the effects of toxic substances on humans is to conduct experiments on humans, not animals. But that is often impossible, because the tests would be unethical, so we end up relying on animal experimentation. Our moral commitments, then, create uncertainty. They produce epistemic risk. But that is a fact that we have to accept.

There are also practical problems. In testing toxic substances, one works with three dose groups: a control group (zero dose) and two groups of animals exposed to higher or lower doses of the substance. In a 28-day dose toxicity test, 5 animals of each sex and dose group are used, i.e., 30 animals in total. To obtain significant results with groups of that size, the experiment must be carried out at high dose levels well above those we are normally exposed to. In the light of this type of experiment, it is difficult to say what increase in risk can be expected at the normal dose level. In addition to statistical limitations and the limitations of the experimental design, there is the problem of extrapolation. The hamster, for example, is 10,000

times less sensitive to some toxins than the guinea pig, and man is neither a hamster nor a guinea pig.

To return to nanowires, the complex properties these have will raise new questions about the type of knowledge we can obtain. They also favor a Socratic approach to risk analysis – i.e., the idea that we should avoid thinking we know things about which we know nothing (and maybe never can know robustly).

*Time, a problem.* Time causes a particular problem when it comes to risk assessment and risk management. What will the environmental effects of nanoparticles be in the long run? How do the particles affect human beings over the longer term? Assume that it is the accumulation of particles that is the biggest risk. Assume that the effect of the particles first becomes visible after several decays. In the case of nanoscience and nanotechnology it is today (but not necessarily tomorrow), and for obvious reasons, it is difficult, if not impossible, to say with any precision what will happen in the long run. It is also, for as obvious reasons, difficult to study this type of problem or phenomenon. The further possibility that the traditional dose-response model is not applicable might add to the difficulties here.

Why is it significant to know what we do not know – especially when it comes to risk-assessment and risk management? Why is this the best way to do risk analysis?

First, we cannot be rational if we do not take our complete state of knowledge into account.

Second, the Precautionary Principle says that “when an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause and effect relationships are not fully established scientifically.” There are several problems with a principle of this kind (Peterson 2006, 2007). It can, for example, come in conflict with some of the basic principles (axioms) of rational decision-making, and if it is not applied with care it is also capable of paralyzing research. A Socratic approach allows for rational decision-making when the epistemic uncertainty is considerable – e.g., using the tools and techniques of the generalized theories of rational decision-making (presented and discussed above) (see Vareman 2011).

Third, psychological studies have taught us that if its attendant uncertainties and risks are not handled with care an entire research area can become stigmatized. The public feel they can no longer trust the scientists, and trust is essential when it comes to risk-communication (Slovic 1997). I contend that a Socratic approach builds trust and blocks stigmatization.

Fourth, knowing what you do not know is the spark of creativity. If we have indications that a particular particle is harmful, but we do not really know if it is, why should that fact or feature of our present epistemic state make us gloomy? It should make us curious, inspire us to look for the underlying mechanisms, encourage us to seek out new knowledge. More than once a lack of knowledge and connected efforts to avoid epistemic uncertainty have been rewarded with a Nobel Prize.

## Further Research

---

Two suggestions for further research conclude this paper.

Saari (1994) has shown how voting theory can be explained with the tools of classical geometry. He shows that with a sufficiently powerful mathematical framework competing ideas and methods can be understood and unified, controversies can be resolved, and famous theorems become predictable spin-offs. Is it possible to do something similar for classical and generalized theories of rational decision-making? Can we provide a geometry or topology of

decision-making? We want to develop a higher-level theory that can be used to evaluate existing theories and in understanding decision rules – a theory that tells us, for example, when and under what circumstances a generalized theory works, but also when it does not work, and then why.

Risk analysis has focused too much on outcomes, on accidents, catastrophes, mishaps, and harm. The examples presented above show that epistemic factors are as important, sometimes far more important. It is therefore essential that epistemic uncertainty and epistemic risk be researched. To make good decisions we need to understand how epistemic uncertainty is produced and in what way it influences our decision-making and risk-taking. The problem of epistemic risk needs to be addressed both by the theoreticians and those doing empirical research.

## Acknowledgments

The author wishes to thank Naomi Halas, Johannes Persson, Christelle Prinz, Bengt E Y Svensson, and Niklas Vareman for valuable comments and suggestions. A special thanks to Pascal Engel and Kevin Mulligan for inspiration and time for reflection.

**Abstract:** Rational choice theory (RCT) is beset with paradoxes. Why, then, bother with a theory that raises numerous counterexamples, contradictions, and a seemingly endless stream of mutually conflicting remedies? In contrast to this impression, I argue in this chapter that RCT paradoxes play much more productive roles. Eight paradoxes are described in detail, some of their proposed solutions are sketched out, and they are classified according to the kind of paradox they pose. At their example I argue that RCT paradoxes, rather than providing evidence for straightforward rejections of the theory, play important roles in education and in normative research.

## Introduction

---

Rational choice theory (RCT) is beset with paradoxes. Why, then, bother with a theory that raises numerous counterexamples, contradictions and a seemingly endless stream of mutually conflicting remedies? That, at least, may be the impression of a novice student of RCT. In contrast, I argue in this chapter, RCT paradoxes play a much more productive role. Rather than suggesting straightforward rejections of the theory, or repellents to any newcomer, paradoxes play important roles in education and in normative research.

RCT has a clear normative function: it offers tools for judging how people *ought* to form their preferences – and by extension, how they ought to choose. A major problem is that there is no hard basis against which to test normative theoretical claims – one cannot seek to falsify such a theory with controlled experiments. Instead, researchers have to rely on normative intuitions about assumptions and conclusions, and use theory to check whether these intuitions can be held consistently. This is where RCT paradoxes play a crucial role: they elicit normative intuitions that pitch RCT assumptions and conclusions against each other. If a paradox leads to a revision of the theory, it serves a research purpose. If it leads to a better understanding of the assumptions and their conclusions, it serves an educational purpose. Thus, many RCT paradoxes have proved, and continue, to be productive.

The chapter continues with a brief overview of RCT in the first section, recalling the normative claims it really makes. The second section discusses how its normative validity can be examined, and the roles paradoxes play in that. The third section offers a classification of different kinds of paradoxes. Eight selected paradoxes are surveyed in the fourth section, sub-sectioned into paradoxes of preference, belief, expected utility, and strategic interaction. Each one is explained, some of its proposed solutions are sketched out, and it is classified according to the scheme proposed in the fifth section. Section ➔ [Further Research](#) concludes the chapter.

## Rational Choice Theory

---

RCT is the dominant theoretical approach in microeconomics (although economists rarely use the term “rational choice theory”). It is also widely used in other social-science disciplines, in particular political science. In this context, the term rational choice theory is often associated with the notion of economic “imperialism,” implying that its use extends economics methodology into their fields.

Explicit theories of rational economic choice were first developed in the late nineteenth century, and commonly linked the choice of an object to the increase in happiness an additional increment of this object would bring. Early neoclassical economists (e.g., William Stanley Jevons) held that agents make consumption choices so as to maximize their own happiness. In contrast, twentieth-century economists disassociated RCT and the notion of happiness: they presented rationality merely as maintaining a consistent ranking of alternatives. Such a ranking is commonly interpreted as agents' desires or values.

Having no foundation in an ultimate end, the notion of rationality is reduced to the consistent ranking of choice alternatives, the consistent derivation of this ranking from evaluations of possible outcomes, and a consistency of beliefs employed in this derivation. Thus, "rationality" explicated in RCT is considerably narrower and possibly sometimes at odds with colloquial or philosophical notions. In philosophical contexts it often includes judgments about ends, the prudent weighting of long-term versus short-term results, and insights into purportedly fundamental moral principles. Nothing of this sort is invoked in RCT, which simply claims that a rational person chooses actions in a manner consistent with his or her beliefs and evaluations. Accordingly, a person considered "rational" in this sense may believe that the moon is made of green cheese, may desire to waste his or her life, or may intend to bring widespread destruction.

At the core of RCT is a formal framework that (1) makes the notion of preference consistency precise and (2) offers formal proof that "maximizing one's utility" is identical to "choosing according to a consistent preference ranking." A brief sketch of this framework follows. (The framework presented here is based on von Neumann and Morgenstern 1947. Alternative formal frameworks are to be found in Savage 1954 and Jeffrey 1990.)

Let  $A = \{X_1, \dots, X_n\}$  be a set of alternatives. Alternatives are either pure prospects or lotteries. A pure prospect is a future event or state of the world that occurs with certainty. For example, when purchasing a sandwich from a well-known international restaurant chain I may expect certain taste experiences with near certainty. Lotteries, also called prospects under risk, are probability distributions over events or states. For example, when consuming "pick-your-own" mushrooms an agent faces the lottery  $(X_1, p; X_2, 1-p)$ , where  $X_1$  denotes the compound outcome (which has probability  $p$ ) of falling ill due to poisoning and  $X_2$  (with probability  $1-p$ ) the compound outcome of not doing so. More generally, a lottery  $X$  consists of a set of prospects  $X_1, \dots, X_n$  and assigned probabilities  $p_1, \dots, p_n$ , such that  $X = (X_1, p_1; \dots; X_n, p_n)$ . Obviously, the prospects  $X_1, \dots, X_n$  can be lotteries in themselves.

RCT takes preferences over actions to be evaluations of lotteries over action outcomes. Its main contribution is to specify the relationship between preferences over actions, and preferences as well as beliefs over the compound outcomes of the respective lottery. It does so by proving *representation theorems*. Such theorems show that, under certain conditions, all of an agent's preferences can be represented by a numerical function, the so-called utility function. Furthermore, the utility numbers of an action (i.e., lottery)  $X = (X_1, p_1; \dots; X_n, p_n)$  and its compound outcomes  $X_1, \dots, X_n$  are related to each other through the following principle:

$$u(X) = \sum_i p_i \times u(X_i) \quad (1)$$

In other words, the utility of a lottery is equal to the sum of the utilities of its compound outcomes, weighted by the probability with which each outcome comes about. This is an important result that significantly constrains the kind of preferences an agent can have. Of course, because the representation result is a formal proof, all the constraining information must already

be present in the theorem's assumptions. I will sketch the main features of these assumptions here. (For a detailed discussion, see the references in footnote 2. For more in-depth overviews, see textbooks such as Luce and Raiffa (1957), Mas-Colell et al. (1995, Chaps. 1 and 6) and Resnik (1987). Hargreaves Heap et al. (1992, pp. 3–26) give an introductory treatment.)

RCT assumes that, at any time, there is a fixed set of alternatives  $A = \{X_1, \dots, X_n\}$  for any agent. With respect to the agent's evaluation of these prospects, it assumes that agents can always say that they prefer one prospect to another or are indifferent between them. More specifically, it assumes that the agent has a preference ordering  $\succeq$  over  $A$ , which satisfies the following conditions. First, the ordering is assumed to be *complete*, that is,

$$\text{either } X_i \succeq X_j \text{ or } X_j \succeq X_i \text{ for all } X_i, X_j \in A. \quad (2)$$

Second, the ordering is assumed to be *transitive*, that is,

$$\text{if } X_i \succeq X_j \text{ and } X_j \succeq X_k, \text{ then also } X_i \succeq X_k \text{ for all } X_i, X_j, X_k \in A. \quad (3)$$

Completeness and transitivity together ensure that the agent has a so-called weak ordering over all prospects.

The second domain in which RCT makes consistency assumptions concerns beliefs. In particular, it assumes that each rational agent has a *coherent set of probabilistic beliefs*. Coherence here means that beliefs can be represented as probability distributions that satisfy certain properties. In particular, it is assumed that there is a probability function  $p$  over all elements of  $A$ , and that this function satisfies the following assumptions: first, for any  $X$ ,  $0 \leq p(X) \leq 1$ ; second, if  $X$  is certain, then  $p(X) = 1$ ; third, if two alternatives  $X$  and  $Y$  are mutually exclusive, then  $p(X \text{ or } Y) = p(X) + p(Y)$ ; finally, for any two alternatives  $X$  and  $Y$ ,  $p(X \text{ and } Y) = p(X) \times P(Y|X)$  – in other words the probability of the alternative “ $X$  and  $Y$ ” is identical to the probability of  $X$  multiplied by the probability of  $Y$  given that  $X$  is true.

The third domain in which rational choice theory makes consistency assumptions concerns preferences over lotteries. In particular, it assumes the *independence condition*. If a prospect  $X$  is preferred to a prospect  $Y$ , then a prospect that has  $X$  as one compound outcome with a probability  $p$  is preferred to a prospect that has  $Y$  as one compound with a probability  $p$  and is identical otherwise: that is, for all  $X, Y, Z$ : if  $X \succeq Y$  then  $(X, p; Z, 1-p) \succeq (Y, p; Z, 1-p)$ .

These assumptions (together with a few others that are not relevant here) imply that preferences over lottery prospects  $X = (X_1, p_1; \dots; X_m, p_m)$  are represented by a utility function such that for all  $X, Y$ :

$$X \succeq Y \Leftrightarrow \sum_i [p_i \times u(X_i)] \geq \sum_i [p_i \times u(Y_i)]. \quad (4)$$

This formal result has been given different interpretations. My focus in the following is on the *normative* interpretation of RCT.

## Normative Validity and the Role of Paradox in RCT

RCT is often interpreted as a theory of how people *ought* to form their preferences – and by extension, how they ought to choose (for a history of this approach, see Guala 2000). Although the normative content of the theory is limited to the norms of a consistent ranking of choice

alternatives, I showed in the previous section that this notion of consistency depends on a number of substantial axioms. This raises the question of the *normative validity* of these axioms: why ought people to choose in accordance with them?

Various attempts have been made to defend the normative validity of RCT and its axioms. The most prominent justifications are pragmatic: they seek to show that agents who fail to retain RCT-consistency will incur certain losses. Two well-known examples are the *money pump* and the *Dutch book* arguments (for more on this and other normative justifications, see Hansson and Grüne-Yanoff 2009).

Interpreted literally, neither the money pump nor the Dutch book is very convincing. An agent could simply refuse to accept money-pumping trades or Dutch-booking bets. Thus, rationality does not literally require one to be willing to wager in accordance with RCT. Defenders of pragmatic justifications may argue that money pumps or Dutch books reveal possible vulnerability from RCT-violations: a RCT violator might have an incentive to accept a money pump trade or a Dutch book bet, while a RCT-abider does not. However, even such a hypothetical interpretation is problematic. For example, one could deny that the situations considered are normatively relevant to actual preferences. Consequently, it could be argued that norms of preference consistency are primitive in the sense that they are not derived from anything, and in particular not from pragmatic considerations.

Instead, some argue that normative judgments arise directly through human intuition, guided by reflection. These judgments are grounded in characteristic human responses of an emotional or motivating kind. (Such a view does not presuppose a non-cognitivist account of normative judgment. At least on the epistemological level, even cognitivist theories of normativity are likely to appeal to something like natural human responses – no doubt refined by education and reason – to explain how we identify moral facts and evaluate moral claims.) While considerations such as the money pump or the Dutch book may elicit such intuitions, it would be misguided to assume that pragmatic considerations form their basis. Rather, normative intuitions themselves are basic, and form the basis of normative validity judgments of RCT, in this view.

So much the worse for the normative validity of RCT axioms, one might be tempted to reply. To be sure, our emotional or motivating responses to questions of preference consistency often differ and are contradictory. Hence, it seems to follow that any proposed set of axioms is nothing more than the expression of a subjective intuition, fuelled at best by positional or rhetorical power.

Defenders of a stronger validity claim may respond in at least two ways to this challenge. First, they may point out that normative intuitions are not merely claimed to be valid individually, but rather that RCT makes a claim about the normative validity of the whole set of assumptions *and all the results deduced from it*. For example, the maximization of expected utility is a consequence of standard RCT axioms, not an axiom itself. If one has doubts about the normative validity of this conclusion, one has to trace it back to these axioms, re-check their validity, and weight one's doubts in the conclusion against one's confidence in them. This view of normativity thus rests on the idea of a reflective equilibrium: we “test” various parts of our system of normative intuitions against the other intuitions we have made, looking for ways in which some of them support others, seeking coherence among the widest set, and revising and refining them at all levels when challenges to some arise from others (for more on the method of reflective equilibrium, see Daniels 2008).

Second, the defender may point out that normative intuitions are widely accepted only if they withstand being tested in a communally shared effort of “normative falsification” (Guala 2000). Savage described this effort as follows:

- ▶ In general, a person who has tentatively accepted a normative theory must conscientiously study situations in which the theory seems to lead him astray; he must decide for each by reflection – deduction will typically be of little relevance – whether to retain his initial impression of the situation or to accept the implications of the theory for it (Savage 1954, p. 102).

Theorists have to engage in thought experiments in order to elicit these normative intuitions – or “initial impressions,” as Savage calls them. Thereby they investigate their normative intuitions in as wide a scope of hypothetical situations as possible, either challenging or confirming particular normative judgments. At the end of this process they only use the intuitions that hold up against normative falsification to challenge the theory:

- ▶ If, after thorough deliberation, anyone maintains a pair of distinct preferences that are in conflict with the sure-thing principle, he must abandon, or modify, the principle; for that kind of discrepancy seems intolerable in a normative theory (Savage 1954, p. 102).

Normative falsification and reflective equilibrium thus go hand in hand: the former generates “corroborated” normative intuitions, and the latter weighs the importance of these intuitions against conflicting intuitions in the theory under scrutiny.

How, then, does one go about normative falsification? How are “situations” constructed in which one obtains “initial impressions” that conflict with the theory? This is where RCT paradoxes come into play. These paradoxes are exemplar narratives of situations that have posed problems for RCT, many of which have been discussed amongst experts for decades. Sometimes agreed-upon solutions exist, and the paradox is used only for pedagogical purposes – to increase understanding of the theory or to illustrate the process of thought experimentation. At other times, competing solutions are offered, some of which may threaten the current theory. In that case, RCT paradoxes constitute the laboratory equipment of ongoing decision-theoretical research.

## The Notion of Paradox

---

Philosophers have distinguished between two accounts of paradoxes. The *argumentative model*, proposed by Quine (1966) and Sainsbury (1988), defines a paradox as an argument that appears to lead from a seemingly true statement or group of statements to an apparent or real contradiction, or to a conclusion that defies intuition. To resolve a paradox, on this account, is to show either (1) that the conclusion, despite appearances, is true, that the argument is fallacious, or that some of the premises are false, or (2) to explain away the deceptive appearances. The *non-argumentative model*, proposed by Lycan (2010), defines a paradox as an inconsistent set of propositions, each of which is very plausible. To resolve a paradox under this account is to decide on some principled grounds which of the propositions to abandon.

Consequently, the argumentative model allows distinguishing different kinds of paradoxes. Quine divides them into three groups. A *veridical paradox* produces a conclusion that is valid, although it appears absurd. (Quine thought of paradoxes pertaining to the truth of deductive

statements. In contrast, the validity of decision-theoretic assumptions and conclusions concerns normative validity, which may or may not be reducible to truth. I will therefore use “validity” where Quine spoke of “truth.”) For example, the paradox of Frederic’s birthday in *The Pirates of Penzance* establishes the surprising fact that a 21-year-old would have had only five birthdays had he been born in a leap year on February 29.

A *falsidical paradox* establishes a result that is actually invalid due to a fallacy in the demonstration. DeMorgan’s invalid mathematical proof that  $1 = 2$  is a classic example, relying on a hidden division by zero.

Quine’s distinction here is not fine enough for the current purposes. A falsidical paradox in his terminology, so it seems, can be the result of two very different processes. A genuine falsidical paradox, I suggest, identifies the root of the invalidity of the conclusion in the invalidity of one or more of the assumptions. In contrast, what I call an *apparent paradox* establishes the root of the invalidity of the conclusion in the unsoundness of the argument.

A paradox that is in neither class may be an *antinomy*, which reaches a self-contradictory result by properly applying accepted ways of reasoning. Antinomies resist resolutions: the appearances cannot be explained away, nor can the conclusion be shown to be valid, some premises shown to be invalid, or the argument shown to be unsound. Antinomies, Quine says, “bring on the crisis in thought” (1966, p. 5). They show the need for drastic revision in our customary way of looking at things.

The non-argumentative account rejects Quine’s classification, pointing out his assumption of an intrinsic direction in the relationship between “assumptions” and “conclusions.” This, so Lycan argues, may give the wrong impression that certain kinds of paradoxes are to be solved in particular ways. Conversely, he points out that two theorists may disagree on whether a paradox is veridical or not: “one theorist may find the argument veridical while the other finds the ‘conclusion’s’ denial more plausible than one of the ‘premises’” (Lycan 2010, p. 3). In what follows, I will make use of Quine’s classification. Nevertheless, I stress – in agreement with Lycan – that it is only to be understood as an indicator of how the majority of theorists have sought resolution, not as a claim about the intrinsic nature of the paradox itself.

## The Paradoxes

---

Below I survey a selection of paradoxes that are currently relevant to RCT. By relevant here I mean that they challenge one or more of the RCT axioms that are currently in wide use. For more comprehensive literature on paradoxes, also in RCT, see Richmond and Sowden (1985), Diekmann and Mitter (1986), Sainsbury (1988), and Koons (1992).

The survey is structured according to the aspect of RCT under challenge. As it turns out, it is not always clear which axiom is being challenged. I therefore divide the subsections into paradoxes of preferences, belief, expected utility maximization, and strategic choice.

### Preferences

---

Of the many paradoxes challenging assumptions about preferences I will survey two: the Sorites Paradox applied to preference transitivity and Allais’ paradox.

Sorites paradoxes are arguments that arise from the indeterminacy surrounding the limits of application of the predicates involved (for a general overview, see Hyde 2008). The Sorites scheme has been applied to RCT in order to cast doubt on the rationality of the transitivity of preference. Quinn's (1990) version goes as follows:

A person (call him *the self-torturer*) is strapped to a conveniently portable machine, which administers a continuous electric current. The device has 1,001 settings: 0 (off) and 1 … 1,000, of increasing current. The increments in current are so tiny that he cannot feel them. The self-torturer has time to experiment with the device so that he knows what each of the settings feels like. Then, at any time, he has two options: to stay put or to advance the dial one setting. However, he may advance only one step each week, and he may never retreat. At each advance he gets \$10,000.

Since the self-torturer cannot feel any difference in comfort between adjacent settings, he appears to have a clear and repeatable reason to increase the current each week. The trouble is that there are noticeable differences in comfort between settings that are sufficiently far apart. Eventually, he will reach settings that will be so painful that he would gladly relinquish his monetary rewards and return to zero.

The paradox lies in the conclusion that the self-torturer's preferences are intransitive. All things considered, he prefers 1–0, 2–1, 3–2, and so on, but certainly not 1,000–1. Furthermore, there seems to be nothing irrational about these preferences.

- The self-torturer's intransitive preferences seem perfectly natural and appropriate given his circumstances (Quinn 1990, p. 80).

If this were correct, the normative validity of the transitivity axiom would be in doubt. Defenders of transitivity argue that there is a mistake either in the conception of the decision situation or in the process of evaluation that leads to the intransitive preferences. Both Arntzenius and McCarthy (1997) and Voorhoeve and Binmore (2006) follow the first option in rejecting the implicit assumption that there is a “least-noticeable difference”: a magnitude of physical change so small that human beings always fail to detect a difference between situations in which a change smaller than this magnitude has or has not occurred.

Instead, they argue that it is rational for the self-torturer to take differences in long-run frequencies of pain reports into account. In other words, when repeatedly experimenting with the machine he may well experience different amounts of pain at the same notch. He will represent this information about how a notch feels by means of a distribution over different levels of pain: two notches “feel the same” only if they have the same distribution. Then it is implausible that all adjacent notches feel the same when the self-torturer runs through them in ascending order, and the intransitivity disappears.

Thus, Quinn's paradox has been treated as an apparent paradox: an implicit, illegitimate assumption of the derivation – of a “least-noticeable difference” – is exposed, and the dependency of the deductive conclusion on this assumption is shown.

*Allais' Paradox* (Allais 1953) sets up two specific choices between lotteries in order to challenge the sure-thing principle (an axiom in Savage's decision theory, related to the axiom of independence). This choice experiment is described in ► [Table 19.1](#). In this experiment, agents first choose between lotteries *A* and *B* and then between lotteries *C* and *D*.

RCT prescribes that agents choose *C* if they have chosen *A* (and vice versa), and that they choose *D* if they have chosen *B* (and vice versa). To see this, simply re-partition the prizes of the two problems as follows: Instead of “2,400 with certainty” in *B*, partition the outcome such that it reads “2,400 with probability 0.66” and “2,400 with probability 0.34.” Instead of “0 with

**Table 19.1**

Allais' two pairs of choices

Choice problem 1 – choose between:					
A:	\$2,500	With probability 0.33	B:	\$2,400	With certainty
	\$2,400	With probability 0.66			
	\$0	With probability 0.01			
Choice problem 2 – choose between:					
C:	\$2,500	With probability 0.33	D:	\$2,400	With probability 0.34
	\$0	With probability 0.67		\$0	With probability 0.66

**Table 19.2**

The re-described choice pairs

Choice problem 1* – choose between:					
A:	\$2,500	With probability 0.33	B*:	\$2,400	With probability 0.34
	\$2,400	With probability 0.66		\$2,400	With probability 0.66
	\$0	With probability 0.01			
Choice problem 2* – choose between:					
C*:	\$2,500	With probability 0.33	D:	\$2,400	With probability 0.34
	\$0	With probability 0.66		\$0	With probability 0.66
	\$0	With probability 0.01			

probability 0.67" in C, partition the outcome such that it reads "0 with probability 0.66" and "0 with probability 0.01." Of course, these are just redescriptions that do not change the nature of the choice problem. They are shown in [Table 19.2](#).

Through this redescription, we now have an outcome "2,400 with probability 0.66" in both A and B\*, and an outcome "0 with probability 0.66" in both C\* and D. According to the RCT independence condition, these identical outcomes can be disregarded in the deliberation, but once they are disregarded it becomes clear that option A is identical to option C\* and option B\* is identical to option D. Hence, anyone choosing A should also choose C and anyone choosing B should also choose D.

This result has been found both empirically and normatively challenging for RCT. (In sharp contrast to the RCT result, in an experiment involving 72 people, 82% of the sample chose B and 83% chose C (Kahneman and Tversky 1979).) On the normative level, many people seem to have intuitions contradicting the above conclusions:

- When the two situations were first presented, I immediately expressed preference for Gamble 1 [A] as opposed to Gamble 2 [B] and for Gamble 4 [D] as opposed to Gamble 3 [C], and I still feel an intuitive attraction to these preferences (Savage 1954, p. 103).

This empirical and normative challenge has given rise to a number of alternatives, including prospect theory (Kahneman and Tversky 1979), weighted utility (Chew 1983) and

rank-dependent expected utility (Quiggin 1982). However, the normative validity of these theories is often controversial. Many decision theorists have rather followed Savage, who despite his initial intuitions decided that the sure-thing axiom was, after all, correct. He arrived at this by redescribing Allais' choice situation in yet another form, observing a change of preference from  $C$  to  $D$  in this case, and concluded that "in revising my preferences between Gambles 3 [C] and 4 [D] I have corrected an error" (Savage 1954, p. 103). Decision theorists following Savage have thus treated Allais' paradox as a veridical paradox: the initial impression that the conclusion is absurd is explained away, and the theoretical conclusion is confirmed to be correct.

## Belief

---

I discuss only one paradox of belief here, namely the *Monty Hall problem*. It is posed as follows:

- ▶ Suppose you're on a game show, and you're given the choice of three doors: Behind one door is a car; behind the others, goats. You pick a door, say No. 1, and the host, who knows what's behind the doors, opens another door, say No. 3, which has a goat. He then says to you, "Do you want to pick door No. 2?" Is it to your advantage to switch your choice? (vos Savant 1990).

After picking a door at random, it may seem that it is rational to believe that the remaining door holds the car with probability  $\frac{1}{2}$ . After all, either the chosen door or the other one conceals the prize – so should both doors rather be assigned an equal probability of holding the car?

They should not. At first, before the contestant picks a door, it is rational for him or her to believe that the car is behind any of them with probability  $\frac{1}{3}$ , knowing that the host will be able to open a door not holding the prize since at least one of the other doors must conceal a goat. Therefore, when the host opens a door the contestant does not learn anything relevant to his or her belief in having chosen the winning door – it remains at  $\frac{1}{3}$ . Now the offered swap is equivalent to the opportunity of opening both other doors – and he or she should rationally believe that this offers a  $\frac{2}{3}$  probability of winning the car. Hence, it is advantageous to swap.

The Monty Hall problem clearly falls into the class of veridical paradoxes: the argument is correct and does not rely on implicit illegitimate assumptions, and the conclusion, despite appearances, is valid. Furthermore (unlike in most other paradoxes discussed here), the result can be experimentally confirmed: the frequency of the prize being behind the other door is observed indeed to converge to  $\frac{2}{3}$  (hence there is even a pragmatic confirmation of the normative intuition). The striking thing about this paradox is that the presentation of the correct answer initially created a huge outcry, not least from academically trained mathematicians and logicians (see <http://www.marilynvossavant.com/articles/gameshow.html> for a selection). The correct solution appeared to be false, but this appearance was explained away with the help of standard probability theory.

## Expected Utility

---

I will now discuss three paradoxes that challenge some fundamental assumptions about the rationality of expected utility maximization: the Ellsberg paradox, Newcomb's problem and the Envelope paradox.

The *Ellsberg paradox* (Ellsberg 1961) goes as follows. An urn contains 30 red balls and 60 other balls that are either black or yellow. You do not know how many black or yellow balls there are, but you do know that the total number of black balls plus the total number of yellow balls equals 60. The balls are well mixed so that each individual one is as likely to be drawn as any other. You are now given a choice between two gambles (☞ [Table 19.3](#)).

You are also given the choice between these two gambles with regard to a different draw from the same urn (☞ [Table 19.4](#)).

Standard (Bayesian) decision theory postulates that when choosing between these gambles, people assume a probability that the non-red balls are yellow versus black, and then compute the expected utility of the two gambles. This leads to the following line of reasoning. The prizes are exactly the same. Hence, according to expected utility theory, a rational agent (weakly) prefers *A* to *B* if and only if he or she believes that drawing a red ball is at least as likely as drawing a black ball. Similarly, a rational agent (weakly) prefers *C* to *D* if and only if he or she believes that drawing a red or yellow ball is at least as likely as drawing a black or yellow ball.

Now, if drawing a red ball is at least as likely as drawing a black ball, then drawing a red or yellow ball is also at least as likely as drawing a black or yellow ball. Thus, supposing that a rational agent (weakly) prefers *A* to *B*, it follows that he or she will also (weakly) prefer *C* to *D*, whereas supposing instead a weak preference for *D* over *C*, it follows that he or she will also weakly prefer *B* to *A*. When surveyed, however, most people (strictly) prefer Gamble *A* to Gamble *B* and Gamble *D* to Gamble *C*. Furthermore, they often insist on this choice, even if the theory is explained to them. Therefore, the normative validity of some assumptions of RCT seems in question.

Ellsberg's paradox poses an interesting challenge to RCT. On the one hand, some scholars have insisted that the standard solution is correct, making it a veridical paradox whose paradoxical impression is explained away. Fox and Tversky (1995), for example, offer an empirical explanation of why people may be biased in their decision-making through an impression of comparative ignorance. Such bias, of course, has no normative validity: it only explains why people have wrong intuitions about what should be chosen. On the other hand, others have argued that this ambiguity aversion is part of a rational decision, in a similar way as a risk aversion is (Schmeidler 1989). Such a position would suggest that the Ellsberg paradox is falsidical, brought about by assuming away the (normatively relevant) impact of ambiguity aversion.

■ **Table 19.3**  
Ellsberg's first pair of choices

Gamble A	Gamble B
You receive \$100 if you draw a red ball	You receive \$100 if you draw a black ball

■ **Table 19.4**  
Ellsberg's second pair of choices

Gamble C	Gamble D
You receive \$100 if you draw a red or yellow ball	You receive \$100 if you draw a black or yellow ball

*Newcomb's Problem* (Nozick 1969) involves an agent's choosing either an opaque box or the opaque and a transparent box. The transparent box contains one thousand dollars ( $\$T$ ) that the agent plainly sees. The opaque box contains either nothing ( $\$0$ ) or one million dollars ( $\$M$ ), depending on a prediction already made concerning the agent's choice. If the prediction was that the agent would take both boxes, then the opaque box will be empty, and if it was that the agent would take just the opaque box then the opaque box would contain a million dollars. The prediction is reliable. The agent knows all these features of the decision problem.

Table 19.5 displays the agent's choices and their outcomes. A row represents an option, a column a state of the world, and a cell an option outcome in a state of the world.

Standard RCT posits that a rational agent should choose the option that maximizes expected utility. This approach recommends taking only one box, for the following reasons. First, the prediction is reliable. In other words, if the agent chooses only one box, then the probability that "take one box" was predicted is high. Similarly, if the agent chooses two boxes, then the probability that "take two boxes" was predicted is high. Hence the probability of outcome  $\$M$  given that the agent chose only one box will be high, and the probability of outcome  $\$M + \$T$  given that the agent chose two boxes will be low – sufficiently low in most plausible cases for the expected utility of "taking one box" to be higher than that of "taking two boxes." Hence one-boxing is the rational choice according to the principle of expected-utility maximization.

Yet this recommendation violates two deeply entrenched intuitions. First, it violates the principle of dominance, according to which an agent prefers one action to another if he or she prefers every outcome of the first action to the corresponding outcomes of the second. The normative validity of dominance is widely agreed upon. Yet, two-boxing clearly dominates one-boxing in this sense. Consequently, RCT violates dominance.

Second, it violates the intuition that actions should be chosen on the basis of their causal effects rather than their probabilistic correlations to benefits or drawbacks. Because the prediction is made before the agent chooses, the choice has no causal impact on it, and the probabilistic correlation should not matter.

This analysis has motivated a reformulation of decision theory on causal rather than evidential grounds. In various accounts, causal decision theorists seek to represent causal influence with their probability functions rather than with mere probabilistic correlation (see e.g., Gibbard and Harper 1981; Skyrms 1980; Joyce 1999). They clearly see Newcomb's problem as a falsidical paradox based on the misspecification of a decision maker's relevant beliefs.

Some authors opposing the causal approach hold that it yields the wrong choice in Newcomb's problem, in other words two-boxing rather than one-boxing. Horgan (1985)

Table 19.5  
Newcomb's problem

	Prediction of one-boxing	Prediction of two-boxing
Take one box	$\$M$	$\$0$
Take two boxes	$\$M + \$T$	$\$T$

and Horwich (1987), for example, argue that one-boxers fare better than two-boxers, and that one-boxing is therefore the rational choice of action. They both see Newcomb's problem as a veridical paradox, and propose explaining away the conflicting intuition about dominance and causal influence with reference to pragmatic success. Causal decision theorists, in turn, reject the relevance of these pragmatic considerations for the validity of the above intuitions. They insist that Newcomb's problem is an unusual case, which rewards irrationality: one-boxing is irrational even if one-boxers prosper.

The *two-envelope paradox* goes as follows. You are asked to make a choice between two envelopes. You know that one of them contains twice the amount of money as the other, but you do not know which one. You arbitrarily choose one envelope – call it Envelope A – but do not open it. Call the amount of money in that envelope  $X$ . Since your choice was arbitrary, there is a 50–50 chance that the other envelope (Envelope B) will contain more money, and a 50–50 chance that it will contain less. Would you now wish to switch envelopes?

Calculating the apparent expected value of switching proceeds as follows. Switching to  $B$  will give you a 50% chance of doubling your money and a 50% chance of halving it. Thus it seems that the expected value of switching to  $B$  is  $E(Y-X) = 0.5*1/2X + 0.5*2X - X = 0.25X$ . Hence, switching to  $B$  will give you a 25% higher expected return than sticking with  $A$ . This seems absurd. First, many people have an intuition that one should be indifferent between  $A$  and  $B$  as long as the envelope remains unopened. Second, once you have switched to  $B$  in line with the above argument, a symmetrical calculation could persuade you to switch back to  $A$ . Therein lies the paradox.

It is now widely agreed that the expected gain from switching,  $E(Y-X)$ , is mathematically undefined because the value of the infinite sum of all probability-weighted values of  $Y-X$  depends on the order of summation (Meacham and Weisberg 2003). However, the conclusions from this observation differ widely. Clark and Shackel (2000) argue that there is a “correct” order of summation, which results in a zero infinite sum, and that this result justifies indifference before opening the envelope. In contrast, Meacham and Weisberg (2003) express reservations about selecting the “correct” order of summation: because the expected gain from switching is undefined, standard decision theory does not rank switching against keeping.

Dietrich and List (2005) go along a different route and offer an axiomatic justification for indifference before opening without appeal to infinite expectations. They supplement standard decision theory with an additional axiom, the “indifference principle,” according to which if two lotteries have identical distributions, a rational agent is indifferent between them. From this they are able to deduce a justification for indifference before opening. All three of these responses, although formulated against each other, consider the two-envelope paradox falsidical: Clark and Shackel and Dietrich and List introduce additional assumptions, which yield the intuitive conclusion, whereas Mechaem and Weisberg insist that the argument is fallacious, and no conclusion is warranted from the given assumptions.

## Strategic Interaction

Game theory is closely related to RCT. Although it requires certain assumptions beyond those of the standard RCT axioms, its models give additional significance to those standard RCT axioms that also play a role in game theory. For this reason, I include two game-theoretic paradoxes here: the Prisoners' dilemma and the paradox of common knowledge.

The One-Shot *Prisoners' Dilemma* has attracted much attention because standard game-theoretic solution concepts unanimously advise each player to choose a strategy that will result in a Pareto-dominated outcome. It goes as follows.

Two gangsters who have been arrested for robbery are placed in separate cells. Both care much more about their personal freedom than about the welfare of their accomplice. A prosecutor offers each the following deal: choose to confess or remain silent. If one prisoner confesses and the accomplice remains silent all charges against the former are dropped (resulting in a utility of 3 in [Table 19.6](#) – the first number in each cell is the utility of this outcome for the player who chooses between rows, and the second number, the utility for the player who chooses between columns). If the accomplice confesses and the first prisoner remains silent however, the latter will do time (utility 0 in [Table 19.6](#)). If both confess, each will get reduced sentences (utility 1), and if both remain silent the prosecutor has to settle for token sentences for firearms possession (utility 2) (for extensive discussion and a literature review, see Kuhn 2009).

The choice situation is solved by appeal to a simple dominance argument. For each player, if the other player stays silent it is better to confess than to stay silent. If the other player confesses, it is also better to confess than to stay silent. Hence, no matter what the other player does, it is always better to confess.

This result is often described as paradoxical in the following sense. The outcome obtained when both confess, although it is rational for each to do so, is worse for each than the outcome they would have obtained had both remained silent. Both would prefer to reach the outcome "stay silent, stay silent," but their individually rational actions led them to the inferior result "confess, confess." (To add some more urgency to this example, consider the structurally similar problem of the "tragedy of the commons," according to which multiple individuals acting independently and rationally will ultimately deplete a shared limited resource even when it is clear that it is not in anyone's long-term interest for this to happen (Hardin 1968).) How can such an inferior outcome be the result of rational decisions?

Some authors argue that the Prisoners' Dilemma indeed exposes a limitation of RCT rationality. Gauthier (1986), for example, suggests that, instead of always confessing, it would be rational for players to commit to playing cooperatively when faced with other cooperators who are equally committed to not exploiting one another's good will. This argument crucially depends on player confidence in that most players are clearly identifiable as being committed to cooperating or not. Whether such a belief can be rationally justified is questionable, and with it the whole solution to the dilemma.

The majority of authors see no conceptual problem in the Prisoners' Dilemma. The assumptions say nothing about the necessary selfishness of the players (charity organizations may also find themselves in such situations!), and no other illegitimate assumptions are

[\*\*Table 19.6\*\*](#)

**The Prisoners' dilemma**

	Stay silent	Confess
Stay silent	2,2	0,3
Confess	3,0	1,1

evident. The argument itself is valid, and the conclusion is not contradicted by normative intuitions. The only problem is terminological: some people chafe against the idea that the conclusion is supposed to be the result of rational decision-making. However, they simply subscribe to a different concept of rationality that RCT does not support. Hence the Prisoners' Dilemma is a veridical paradox, whose paradoxical nature relies on terminological ambiguity.

*Backward induction* is the process of reasoning backward in time, from the end of a problem, to determine a sequence of optimal actions. It proceeds by first considering the latest time a decision can be made and choosing what to do in any situation at that time. One can then use this information to determine what to do at the second-to-last time for the decision. This process continues backward until one has determined the best action for every possible situation at any point in time.

Let us take a concrete example, the “centipede game.” This game progresses from left to right in Fig. 19.1. Player 1 (female) starts at the extreme left node, choosing to end the game by playing *down*, or to continue (giving player 2, male, the choice) by playing *right*. The payoffs are such that at each node it is best for the player whose move it is to stop the game if and only if he or she expects it to end at the next stage if he or she continues (if the other player stops the game or if it is terminated). The two zigzags stand for the continuation of the payoffs along those lines. Now backward induction advises resolving the game by starting at the last node *z*, asking what player 2 would have done had he ended up there. A comparison of player 2's payoffs for the two choices implies that he should have rationally chosen *down*. Given common knowledge of rationality, the payoffs that result from this choice of *down* can be substituted for node *z*. Let us now move backwards to player 1's decision node. What would she have done had she ended up at node *y*? Given player 2's choice of *down*, she would have chosen *down*, too. This line of argument then continues all the way back to the first node. Backward induction thus recommends player 1 to play *down* at the first node.

What, then, should player 2 do if he actually found himself at node *x*? Backward induction tells him to play “*down*,” but backward induction also tells him that if player 1 were rational he would not be facing the choice at node *x* in the first place. This is not a problem in that Backward induction predicts that player 2 will never find himself at *x* unless both players are irrational.

Yet what does this imply for the Backward-induction reasoning process itself? Backward induction requires the players to *counterfactually* consider out-of-equilibrium play. For example, player 1, according to Backward induction, should choose *down* at node 1, because she knows that player 2 would have chosen *down* at node 2, which in turn she knows because she would have chosen *down* at node 3, and so on, because ultimately she knows that player 2 would have chosen *down* at *z*. She knows this because she knows that player 2 is rational,

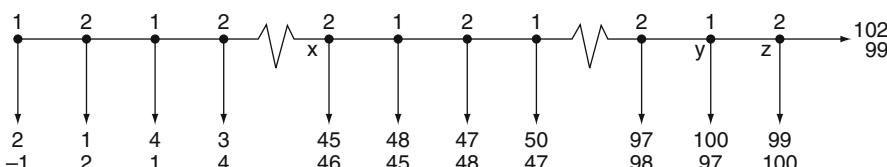

Fig. 19.1  
The centipede game

and that player 2 knows that she is rational, and so on. In the language of game theory, because rationality is *common knowledge* amongst the players, backward induction applies (for more on common knowledge, including a formal treatment of this paradox, see Vanderschraaf and Sillari 2009).

Given common knowledge of rationality, each player can affirm the counterfactual “A rational player finding himself or herself at any node in the centipede would choose *down*.” Yet we also concluded that if a player *finds* himself or herself at any node with an index number larger than two then both player and opponent know that they *are* not rational. What if that conclusion also made true the counterfactual “if a player *found* himself or herself at any node with an index larger than two then both player and opponent *would* know that they are not rational”? If it did, Backward induction would break down: it requires (1) common knowledge and (2) counterfactual consideration of how players would choose if they found themselves at nodes with indices larger than two. However, (2) implies that both player and opponent would know that they are not rational, contradicting (1). Herein lies the paradox (Pettit and Sugden 1989; Bicchieri 1989).

This is an intensely discussed problem in game theory and philosophy. There is space here only to sketch two possible solutions. According to the first, common knowledge of rationality implies backward induction in games of perfect information (Aumann 1995). This position is correct in that it denies the connection between the indicative and the counterfactual conditional. Players have common knowledge of rationality, and they are not going to lose it regardless of the counterfactual considerations they engage in. Only if common knowledge were not immune to evidence, and would be revised in the light of the opponents’ moves, might this sufficient condition for backward induction run into the *conceptual problem* sketched above. However, common knowledge, by definition, is not revisable, and thus the argument has to assume a *common belief* in rationality instead. If one looks more closely at the versions of the above argument (e.g., Pettit and Sugden 1989) it becomes clear that they employ the notion of common belief rather than common knowledge. Hence, the backward-induction paradox is only apparent: the argument that led to the seemingly contradictory conclusion is unsound.

The second potential solution obtains when one shows, as Bicchieri (1993, Chap. 4) does, that limited knowledge (and *not* common knowledge) of rationality and of the structure of the game suffice for backward induction. All that is needed is that a player at each information set knows what the next player to move knows. This condition does not get entangled in internal inconsistency, and backward induction is justifiable without conceptual problems. In that case, the backward-induction paradox is falsidical.

## Further Research

I have surveyed eight paradoxes of RCT. There is considerable divergence among them, under a rather rough classificatory scheme, even in this small selection. First, there are the veridical paradoxes, like the Prisoner’s dilemma, the paradoxical nature of which rests merely on terminological ambiguity. Ways of explaining away the paradoxical appearance of other veridical paradoxes such as the Monty Hall problem are obvious, but are baffling to the novice. They can still serve an educational purpose, however, in that studying them clarifies the meaning of the assumptions and the derivation of the conclusion.

Second, there are (relatively) clear cases of falsidical paradoxes, such as the two-envelope paradox. Here, there is a clear research result: RCT needs revision.

Third, there are some clear cases of apparent paradoxes, such as the self-torturer, in which the whole bluster is caused by a fallaciously set up argument.

Finally, there are cases on which researchers cannot agree. These include Newcomb's problem, Allais' and Ellsberg's paradox, which vacillates between veridical and falsidical assessment, and the Backward-induction paradox, which vacillates between falsidical and apparent assessment. In all these cases the verdict is still open as to whether they necessitate RCT revision or not. Hence their continuing examination is part of active research in this area.

**Abstract:** A person who adopts a risky option undertakes a risk. However the option turns out, the person experiences a risk. A typical person is averse to that risk, and so, if the option's adoption is rational, the option has attributes that compensate for the risk it involves. A multi-attribute assessment of a risky option examines the option's attributes, scores the option with respect to them, and checks whether its overall score justifies the option despite the risk it involves.

The multi-attribute approach to risk is an elaboration of Bayesian decision theory. It assumes utility maximization as a standard of rationality and offers a method of assessing an option's utility. Given uncertainty about an option's outcome, it assumes that the option's utility equals the option's expected utility. To an expected-utility analysis of an option's utility using the probabilities and utilities of the option's possible outcomes, it adds an analysis of every possible outcome's utility. It breaks down a possible outcome's utility into the possible outcome's utility with respect to various attributes.

Some versions of the multi-attribute approach to risk treat risk as an attribute, and other versions fold an evaluation of an option's risk into its evaluation with respect to other attributes. This chapter presents the multi-attribute approach to risk, its most prominent versions, objections to the approach, and ways of addressing the objections.

Although descriptive accounts of people's decisions may use a multi-attribute analysis of an option's utility, this chapter examines only evaluative forms of multi-attribute analyses of utility. The evaluative forms use multiple attributes to evaluate the options in a decision problem. The literature also calls these forms of analysis normative or prescriptive.

In a decision problem, the multi-attribute approach to risk provides a transparent evaluation of options and a transparent evaluation of a decision among the options. The approach's transparency makes it a valuable tool for decisions that require a public justification, such as decisions that trustees make for their clients, in particular, decisions that government regulatory agencies make on behalf of the public. To display the usefulness of the multi-attribute approach to risk, this chapter reviews its application to decisions that a trustee makes for a client.

## Introduction

---

Each spring, graduating seniors bent on academic careers receive offers of admission into graduate programs. A student with several offers evaluates each with respect to features such as the quality of the program, the amount of financial support, and the geographic location of the program. The best program may offer the least financial support and have the worst location. Is it sensible to pick the second best program if it offers the best financial support and has the best location? Decisions require trade-offs between goals such as entering a top program, being fully funded, and living in an attractive area. The multi-attribute approach to risk is a method of making trade-offs, including trade-offs between risk and other factors.

An agent in a decision problem has a set of options and resolves the problem by selecting an option. The multi-attribute approach to decisions, in its canonical form, evaluates each option with respect to multiple attributes and uses these evaluations to reach an overall evaluation of the option. Then it uses options' overall evaluations to reach a decision. When some options in a decision problem involve risks, the multi-attribute approach may use risk as an attribute. A very risky option may receive a low mark with respect to that attribute. Its overall evaluation is low unless better marks with respect to other attributes compensate for its low mark.

concerning risk. The multi-attribute approach to decision problems with risky options constitutes the multi-attribute approach to risk. Some government agencies take this approach to regulatory decisions, which often involve trade-offs between safety and other social values. This chapter explains the multi-attribute approach to risk, illustrates its value for decisions that trustees make for clients, and explores ways of improving the approach to risk.

The chapter adopts a broadly Bayesian method of making decisions. It assumes that an agent assigns utilities to options and, if rational, adopts an option of maximum utility among options. Moreover, when an option's outcome is uncertain, it assumes that the agent assigns a probability and utility to each of the option's possible outcomes. If the agent is rational, the utility she assigns to an option is a probability-weighted average of the utilities she assigns to its possible outcomes. See in this handbook, [Chap. 15, A Rational Approach to Risk? Bayesian Decision Theory](#).

Bayesian decision principles govern ideal agents, who have no cognitive limits and know all logical and mathematical truths. To simplify exposition of the multi-attribute approach to risk, this chapter focuses on rational ideal agents. For such agents, an option's utility equals its expected utility. Because for the agents the chapter treats, this equality holds, the chapter generally does not distinguish an option's utility and its expected utility. It also assumes, as is common in Bayesian decision theory, that an option's expected utility has the same value with respect to every partition of the option's possible outcomes.

Although in their standard forms Bayesian decision theory and the multi-attribute approach to risk treat an ideal agent in an ideal decision problem, they are useful guides for a real agent in a real decision problem. To show how to make precise their extensions to realistic cases, section [Further Research](#) briefly sketches ways of relaxing standard idealizations and formulating general decision principles that cover all cases.

## History

---

The multi-attribute approach to decisions about risk uses a traditional method of evaluating an option, namely, the method of considering the pros and cons of the option's realization, weighing the pros and cons, and finally adding the pros and cons to obtain the option's comprehensive evaluation. The multi-attribute approach uses an option's scores with respect to attributes as pros and cons, weights attributes according to importance, and adds an option's weighted scores with respect to attributes to obtain the option's comprehensive evaluation. The approach gains precision by being explicit about the set of attributes, their weights, and the method of combining an option's evaluation with respect to the attributes into an overall evaluation of the option.

## Multi-Attribute Utility Analysis

---

In a decision problem, such as selecting dinner from a menu, an agent has a set of options. The agent resolves the problem by adopting an option from the set. An option is an act that the agent fully controls. If an agent directly controls an option, then rationality approves of the option only if it compares well with other options that the agent also directly controls. Rationality requires an option at the top of an agent's preference ranking of options.

In the decision problems this section considers, comparisons of options depend on how the options score with respect to a set of attributes. The main components of a multi-attribute evaluation of an option are: (1) a set of attributes with respect to which the option is evaluated and (2) a method of combining evaluations with respect to attributes to obtain an option's overall evaluation. Options' overall evaluations yield a ranking of the options, and the ranking identifies rational options. They are the options at the top of the ranking.

Numbers called utilities represent options' evaluations. An assignment of a utility to an option indicates how it compares with other options. This chapter takes utility as strength of desire held all things considered and takes utility as attaching to a proposition because desire attaches to a proposition. A rational ideal agent's degrees of desire comply with the principles of utility theory. Rationality gives them the usual structure of utilities.

According to another common interpretation of utilities, they are assignments of numbers to options and to outcomes of options that obey the expected utility principle and that represent preferences among options. Representation theorems identify conditions on preferences that suffice for preferences having such a representation and its being unique given a choice of scale for utilities. This interpretation makes the expected utility principle hold as a matter of definition. To make the expected utility principle an interesting normative requirement instead of a definitional truth, this chapter takes utilities as degrees of desire rather than as artifacts of a mathematical representation of preferences.

Given that rational degrees of desire satisfy the expected utility principle, the methods of proving the representation theorems show how to measure utilities on a utility scale. A rational ideal agent's preferences among options involving chance, because of the structure of these preferences, permit an outside evaluator to infer the agent's utility assignments to options and to their possible outcomes. In some cases, comparisons among options are so richly structured that, given the utility scale, only one utility representation satisfies the expected utility principle. In this case, it yields the agent's utility assignment. Although in special cases an agent's utility assignments are inferable from her preferences, in the cases this chapter treats, her utility assignments to possible outcomes generate her utility assignments to options and her preferences among options. Her utility assignments to an option's possible outcomes explain her utility assignment to the option, and her utility assignments to options explain her preferences among options.

A multi-attribute evaluation of an option generates the option's utility from its utilities with respect to a set of attributes. It assigns a utility to the option with respect to each attribute and then combines those restricted utilities to obtain the option's comprehensive utility. Because the procedure uses utilities to indicate comparisons of options, theorists call the procedure multi-attribute utility analysis and call its rationale multi-attribute utility theory. Keeney and Raiffa ([1976]1993) present a canonical version of multi-attribute utility analysis, with a thorough explanation of its steps and with many illustrations. Mullen and Roth (1991, Chaps. 3, 7); Kleindorfer et al. (1993, Sect. 4.2.3, Appendix C), and Ellis (2006) present valuable summaries of multi-attribute utility theory.

A utility scale used to represent an option's evaluation with respect to an attribute may be either ordinal or cardinal. If the utility scales for all attributes are cardinal scales, an aggregation of utilities with respect to attributes may be additive and may weight utilities with respect to attributes before adding them.

To illustrate the procedure of evaluation, consider an evaluation of travel by train and travel by plane. A multi-attribute evaluation of these modes of transportation may use the attributes of speed and comfort. A cardinal scale fits speed. The plane is three times as fast as the train, say.

The scale may use the utility of the train's speed as the unit for utility with respect to speed. Then on the scale for speed, taking the train has a utility of 1, and taking the plane has a utility of 3. An ordinal scale fits comfort. Although the train is more comfortable than the plane, it is typically not some number of times as comfortable. Suppose, however, that for an especially sensitive passenger, the train is twice as comfortable as the plane. Using the utility of comfort on the plane as the unit for the scale of utility with respect to comfort, the utility of taking the plane is 1, and the utility of taking the train is 2. In this special case, a cardinal scale fits both attributes.

Imagine that for the passenger, speed is four times as important as comfort. Using the weight of comfort as a unit for the scale for weights, the weight of comfort is 1 and the weight of speed is 4. This quantitative weighting of attributes is a stretch, but simplifies the illustration. Section  [Further Research](#) considers how to relax such simplifying assumptions.

 [Table 20.1](#) displays a multi-attribute assessment of the two modes of travel. It uses the weights of attributes to combine an option's utilities with respect to attributes into a comprehensive utility. Because taking the plane has the greater comprehensive utility, the decision principle to maximize utility recommends it.

A multi-attribute utility analysis often takes attributes of options to be types that various options realize in different ways. Variables represent attribute types that many options may instantiate. A value of the variable represents an option's instantiation of the attribute. For example, suppose that in a decision problem the options are jobs. An attribute of the options is income, and a variable represents income for a job. The various jobs available differ in income. A job's income supplies a realization of the attribute, that is, a value for the income variable. Deliberation may compare options according to their instantiations of an attribute type; for example, it may compare jobs according to the incomes the jobs provide.

Although taking attributes as types is common, attributes may be tokens, or instances of properties. A multi-attribute analysis may take a job's particular income as an attribute without treating its income as an instance of an attribute-type. Then the set of attributes for one option may differ from the set of attributes for another option. Although using the same set of attribute types for all options facilitates comparisons of options, an option's evaluation may use attributes that pertain to it exclusively. For each option, an evaluation may use a different set of attributes. The attributes for an option may be the option's particular features.

## Related Methods

---

The multi-attribute approach to risk may, for simplicity, compare options pair-wise without first generating an overall evaluation of each option. For example, one option may surpass all other options with respect to every attribute. In that case, the option is atop any ranking of options. Its comparison with other options need not evaluate each option with respect to all attributes and

 **Table 20.1**

**Multi-attribute assessment of modes of travel**

	Utility for speed	Utility for comfort	Weighted utility
Train	1	2	$4(1) + 1(2) = 6$
Plane	3	1	$4(3) + 1(1) = 13$

thereby generate an overall score for the option. Reaching a comparison of two options does not require assigning scores to each option. However, this chapter, for simplicity, considers only decision problems in which an option's evaluations with respect to attributes generate the option's overall evaluation, and the options' overall evaluations generate comparisons of options.

The main alternative to a multi-attribute evaluation of the options in a decision problem is a single-attribute evaluation of the options. A single-attribute evaluation uses utility as an attribute and assigns a utility to each option. Its evaluation of an option does not break down the option's utility into its utilities with respect to multiple attributes. Options' utilities generate comparisons of options. An option of maximal utility tops the ranking of options and constitutes a rational choice.

Although a single-attribute evaluation of options is simpler, a multi-attribute evaluation better justifies a decision. A single-attribute evaluation of an option does not offer an account of the option's utility, unless it derives the option's utility using an expected-utility analysis, and then does not offer an account of the utilities of the option's possible outcomes. A multi-attribute evaluation of an option shows how the option's utility, or a possible outcome's utility, arises from its utilities with respect to the option's or possible outcome's attributes and their weights in the option's or possible outcome's overall assessment.

This chapter, unlike some presentations of multi-attribute utility theory, distinguishes multi-attribute utility analysis from multidimensional utility analysis. Multi-attribute utility analysis divides an option's comprehensive utility into the utilities the option has with respect to a set of attributes. Its division uses the attributes as a dimension of analysis. The attributes form just one dimension of analysis, however. Other forms of utility analysis use other dimensions of analysis. For example, expected-utility analysis divides an option's utility into the utilities of chances for the option's possible outcomes. The possible outcomes form another dimension of utility analysis. Also, utilitarianism divides an option's utility into the utilities the option generates for the individuals it affects. The individuals form a dimension of utility analysis. A multidimensional analysis of an option's utility uses multiple dimensions of analysis, for example, attributes, possible outcomes, and people. Weirich (2001) offers an account of multidimensional utility analysis.

A multi-attribute analysis of an option's utility uses the dimension of attributes. It is appropriate when the option is sure to have a certain outcome, and the option will affect only its agent. Given uncertainty, a multi-attribute utility analysis evaluates each of an option's possible outcomes according to a set of attributes. Then it obtains the option's utility as a probability-weighted sum of the utilities of its possible outcomes. Because the last step constitutes a traditional expected-utility analysis, the process is also a multidimensional form of utility analysis. The literature counts as a multi-attribute utility analysis any analysis of an option's utility that uses the dimension of attributes, possibly along with other dimensions such as the dimension of possible outcomes.

This chapter generally treats multi-attribute utility analysis in its pure form, using only the dimension of attributes, and only occasionally treats its combination with expected-utility analysis. When it entertains an expected-utility analysis of an option's utility using probabilities of the option's possible outcomes, it adopts the standard Bayesian interpretation of probabilities, according to which probabilities are rational degrees of belief and attach to propositions as belief do. It uses propositions to represent possible outcomes. In some cases a rational ideal

agent's subjective probabilities may be inferred from the agent's preferences among gambles, but nonetheless the subjective probabilities are causes of the preferences in the cases this chapter treats.

## Current Research

---

The previous section introduced multi-attribute utility theory. This section reviews the theory's application to risk, a topic of current research. A major issue is whether to treat risk as an attribute or to assume that utility assignments with respect to other attributes handle risk.

### Government Regulation

---

An option's assessment with respect to attributes is the cornerstone of the multi-attribute approach to risk. As an application of the approach, consider government regulation to reduce risk. Regulatory goals provide attributes for assessing regulations. A government agency's decision to regulate a risky technology typically involves trade-offs between regulatory goals, such as safety and freedom. For example, the Food and Drug Administration's decision to halt genetic therapy for severe combined immunodeficiency, or "Bubble Boy" disease, because of cases in which the therapy caused leukemia, promotes safety but limits freedom by denying a treatment option. Because a regulation makes trade-offs among goals, its justification assesses the regulation with respect to each relevant goal and then combines the assessments. The regulation's assessments with respect to regulatory goals and the goals' relative weights yield the regulation's overall assessment. The regulation's comparisons with other options, according to overall assessments of options, settle whether, among options that an agency's mandate allows, the agency's regulation is optimal.

The set of attributes with respect to which the multi-attribute approach to risk assesses an option may use specific objectives in place of general goals and so may include several types of benefit and several types of risk. For example, a new ointment may create multiple benefits and multiple risks because it may soften skin and remove wrinkles but also in rare cases damage capillaries and weaken defenses against skin cancer. A multi-attribute evaluation of marketing the ointment may, as attributes, use soft skin, fewer wrinkles, risk of capillary damage, and risk of skin cancer. It may assess a regulatory agency's options with respect to each of these attributes and then combine the options' relative assessments into the options' overall assessments. The agency's decision to authorize marketing the new ointment then uses a multi-attribute assessment with respect to specific objectives rather than with respect to general regulatory goals.

The grain of the set of attributes is a matter of practicality. Although a general goal is risk reduction, an evaluation may achieve accuracy more easily by focusing on specific objectives concerning reduction of various types of risk. An apt choice of a set of attributes facilitates a multi-attribute assessment of options.

Some features of the set of attributes are critical for a reliable application of the multi-attribute approach. Keeney and Raiffa ([1976]1993, p. 51) offer this advice about selection of attributes: "It is important in any decision problem that the set of attributes be *complete*, so that

it covers all the important aspects of the problem; *operational*, so that it can be meaningfully used in the analysis; *decomposable*, so that aspects of the evaluation process can be simplified by breaking it down into parts; *nonredundant*, so that double counting of impacts can be avoided; and *minimal*, so that the problem dimension is kept as small as possible.” They acknowledge (p. 53) that for a specific decision problem a suitable set of attributes is not unique, and they suggest choosing a set of attributes that serves the purposes of an analysis of the decision problem and that facilitates assessments of probabilities and utilities of options’ possible outcomes. Selection of a set of attributes is partly a pragmatic matter.

Keeney and Raiffa’s second criterion for a set of attributes requires them to be operational. The term operational has different meanings in different disciplines. By operational attributes, Keeney and Raiffa mean attributes that can be measured. They do not mean attributes that have operational definitions in the philosophical sense. Hardly any interesting attributes have precise, accurate definitions that reduce the attributes to the results of observationally verifiable operations.

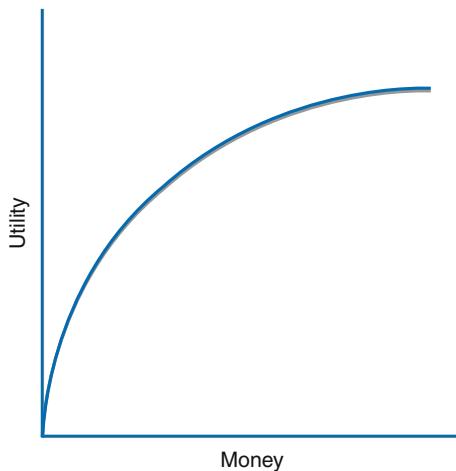

Peterson (2007, pp. 74–75) notes that some methods of aggregating attributes yield different rankings of options depending on which set of attributes they use. For instance, a ranking of treatments for a disease may change if in a population a possible side effect, cardiotoxicity, is divided into cardiotoxicity for each of two subpopulations. The side effect may emerge with significant frequency only in one of the subpopulations. Such a change in ranking, if the different sets of attributes meet all relevant criteria, makes the multi-attribute approach yield ambiguous directions. A thorough defense of multi-attribute assessments of options must show that all properly selected sets of attributes yield the same ranking of options.

The multi-attribute approach to regulation of risk has the following main steps. Given the emergence of a potentially beneficial but risky technology, it evaluates each regulatory option, including not imposing a regulation, with respect to a set of regulatory goals, and then combines those evaluations to obtain the option’s overall evaluation. It uses options’ overall evaluations to compare the options and to select one. It explicitly evaluates each option with respect to the goal of risk reduction, or it considers each option’s risk during its evaluation of the option with respect to other goals. See in this handbook, [Chap. 45, EU Risk Regulation and the Uncertainty Challenge](#).

## Risk as an Attribute

A risk is a chance that something bad will happen. Most people are averse to risk. They will forgo a benefit to decrease risk. For example, they will pay premiums to insure a house against damage from fire. If a fire occurs, having insurance reduces the net harm the fire causes the homeowner and so reduces risk by reducing the stakes. Another way to reduce risk is to lower the probability of harm. A homeowner may do this by installing a fire alarm and keeping a fire extinguisher handy. These measures lower the probability of serious fire damage and, by lowering that probability, reduce the risk of that harm.

Economists take the shape of a person’s utility curve for a commodity to represent a person’s aversion to risk. In a typical graph of a utility curve for money, the horizontal axis represents money, and the vertical axis represents utility. If a person is averse to risks concerning money, then the person’s utility curve for money is concave down, that is, it bends down, as [Fig. 20.1](#) shows.

**Fig. 20.1**  
**A concave utility curve for money**

If a person's utility curve for money is concave, then the more money she has, the less she wants an additional dollar. As a result, she will not buy a gamble at its fair monetary value. Take a gamble that yields a dollar gain or a dollar loss depending on whether a fair coin lands with heads up or with heads down. The gamble's fair monetary value is \$0. Given the concavity of the utility curve for money, a dollar lost has more value than a dollar gained. Therefore, the expected utility of the gamble is less than the utility of \$0. So the gamble's utility for the person is less than the utility of no monetary gain or loss. Hence, she refuses the gamble when it is offered for free.

Keeney and Raiffa ([1976]1993, pp. 148–158) and Gollier (2001) explain the view that aversion to risk amounts to having a concave utility curve for commodities. See also in this handbook, [Chap. 5, The Economics of Risk: A \(Partial\) Survey](#).

The multi-attribute approach to risk, as Keeney and Raiffa ([1976]1993) present it, does not treat risk as an attribute. It assumes that the shape of the utility curve for an option's possible outcomes registers aversion to risk, so that representing risk as an attribute and assigning utilities to risks is unnecessary. However, this section argues that the shape of the utility curve for an option's possible outcomes does not adequately represent aversion to risk. The section therefore departs from that representation of aversion to risk and advocates treating risk as an attribute in a multi-attribute assessment of a risky option.

Aversion to risk taken as the concavity of a utility curve for a commodity does not distinguish the aversion from the diminishing marginal utility of the commodity. It also makes aversion to risk relative to a commodity and so not an attitude that applies to risks involving multiple commodities. Finally, the account of aversion to risk neither describes risk nor explains aversion to risk. It is silent about the nature of risk and the origin of aversion to risk.

Treating risk as an attribute of an option conforms with the understanding of risk in ordinary life. Risk is a feature of some options, and aversion to that feature of options, risk aversion, prompts aversion to risky options. More specifically, an option is risky because of

a chance that it will produce a bad result. Aversion to risk is aversion to that chance, the risk of a bad result. It is more intense the greater the risk, and a risk is greater the greater the probability of a bad result and the worse the bad result. In a wager, risk depends on the stakes as well as the probability of losing the stakes. Bell and Raiffa (1988) call this ordinary type of aversion to risk “intrinsic risk aversion” and distinguish it from diminishing marginal utility.

This chapter, for theoretical simplicity, extends risk to include the chance that something good will happen. An agent may be averse to having a good result depend on chance. Aversion to risk in the broad sense includes such an aversion. It amounts to aversion to having things one cares about, both good and bad, depend on chance.

An option’s risk depends not only on the probabilities of the option’s possible outcomes but also on their utilities. A probability distribution of the utilities of possible outcomes displays the option’s risk, but some measures of risk try to represent the risk more succinctly. They claim that some parameters of the distribution capture the essence of the option’s risk. A rough measure of an option’s risk takes it to depend on the variance of the utilities of the option’s possible outcomes. Often, the larger the variance, the greater the risk. A gamble that yields a gain of \$10 or a loss of \$10 depending on the outcome of a fair coin toss is riskier than a gamble on the toss that yields a gain of \$1 or a loss of \$1. The variance of the utility of the possible outcomes is greater for the first gamble than for the second gamble, even though the probabilities of winning and of losing are the same for both gambles. The variance is a crude measure of risk, however, and theorists such as Keeney and Raiffa ([1976]1993, pp. 159–165) and Luce (1980) advance more subtle measures. See in this handbook, [Chap. 17, The Mismeasure of Risk](#).

Allais’s paradox presents a good reason for treating risk as an attribute rather than letting the shape of utility curves handle it. In one version of this paradox, a person prefers \$3,000 to a 4/5 chance of \$4,000 and prefers a 1/5 chance of \$4,000 to a 1/4 chance of \$3,000. These preferences are rational, but no utility function for money explains their rationality.  $U(\$3,000) > 4/5U(\$4,000)$  according to the first preference, and  $1/5U(\$4,000) > 1/4U(\$3,000)$  according to the second preference. No utility function for money yields these inequalities, however, because multiplying both sides of the second inequality by 4 yields the inequality  $4/5U(\$4,000) > U(\$3,000)$ , which is the opposite of the first inequality. The two inequalities are inconsistent. The shape of the utility curve for money therefore does not explain the two preferences. Rather, aversion to risk accounts for the first preference, and a judgment that two low probabilities are not significantly different accounts for the second preference. This explanation of the two preferences treats risk as an attribute of risky options.

Risk depends on probabilities, and because probabilities may be either physical or evidential, risks may be either physical or evidential. A physical probability depends on physical features of the world. The physical probability of drawing a red ball from an urn depends on the percentage of red balls in the urn. An evidential probability for a person depends on the person’s evidence. For a juror, the evidential probability that a defendant is guilty fluctuates as the prosecuting and defending attorneys present evidence for and against the defendant’s guilt. The defendant’s physical probability of guilt does not fluctuate during the trial; it is either 0% or 100% throughout the trial. At the start of a typical trial, the juror knows the evidential probability but not the physical probability of guilt. Evidential probabilities for a person are accessible to the person because they depend only on the evidence in the person’s possession. Evidential risks are also called epistemic risks. For more discussion of them, see this handbook, [Chap. 18, Unreliable Probabilities, Paradoxes, and Epistemic Risks](#).

The size of an option's evidential risk depends not only on the probabilities and utilities of the option's possible outcomes but also on the weight of the information yielding the possible outcomes' probabilities, that is, the extent of the evidence grounding the probability assignment to possible outcomes. The information's weight affects the probability assignment's robustness. The greater the weight, the more robust the probability assignment. A robust probability assignment, an assignment unlikely to change much as new information arrives, reduces risk. If two drugs have the same risk of a side effect but one has been more extensively tested, then that drug, because of the more extensive evidence grounding probabilities concerning its possible outcomes, carries less evidential risk. A risk-averse person prefers taking the more extensively tested drug because it carries less evidential risk.

## Risk-Return Assessment of Investments

---

A common application of the multi-attribute approach to risk is the risk-return method of assessing investments. The method evaluates an investment by evaluating the risk it involves, by evaluating the investment's expected return, and by combining the two evaluations to obtain an overall evaluation of the investment. The method treats risk as an attribute of an investment and treats aversion to risk as an aversion to that attribute; it does not take an investor's aversion to risk as the concavity of the investor's utility curve for money.

A financial planner may use a questionnaire to assess an investor's attitude toward risk and toward return, and may use financial data to obtain an investment's risk and expected return. Investing in bonds has less risk but a lower expected return than investing in stocks. Because of an investor's aversion to risk and willingness to reduce returns to reduce risk, a financial planner may recommend investing in bonds rather than in stocks. The reduction in risk compensates for the lower expected return.

To assess an investment's expected return and risk, a financial planner typically uses data about the investment type's past returns and their variation. Financial experts debate measures of risk and aversion to risk, and the method of combining aversion to an investment's risk with attraction to its expected return to obtain an overall evaluation of the investment. A common *mean-risk* formula begins with the investment type's mean return and subtracts from it a proportion of the standard deviation (the square root of the variance) for returns from the investment type. That is, from expected return it subtracts risk. Raiffa (1968, pp. 55–56) presents and criticizes this mean-risk formula. Despite flaws, the formula may be useful for rough appraisals of investments in a limited range of cases. It fits the mold for a multi-attribute analysis of an investment's utility if the mean return's utility replaces the mean return, the risk's utility replaces the risk's size, and the constant of proportionality weights the risk's utility so that the mean return's utility minus the proportion of the risk's utility equals the investment's utility.

Another method of evaluating investments uses the *coefficient of variation*:  $\sigma/\mu$ , where  $\sigma$  is the standard deviation for returns from the investment type, and  $\mu$  is the mean of returns from the investment type, or the investment's expected return. The smaller the coefficient of variation, the better the investment. This risk-return method of evaluation uses division rather than subtraction to combine assessments of an investment with respect to the two attributes, return and risk. It fits the multi-attribute mold if the utility of the mean return divided by the utility of the risk's size is inversely proportional to the investment's utility.

A refinement of the coefficient of variation is the *Sharpe ratio*:  $(R - R_f)/\sigma$ , where  $R$  is the investment type's expected return,  $R_f$  is the risk-free rate of return, and  $\sigma$  is the standard deviation for returns from the investment type. The factor  $R - R_f$  is expected return in excess of return obtainable without risk, or *excess expected return*. The Sharpe ratio, as the previous two formulas, uses standard deviation to measure risk. It uses division to combine assessments of an investment with respect to excess expected return and with respect to risk. The larger the ratio, the better the investment. The ratio yields a multi-attribute assessment of an investment if the utility of the expected excess return divided by the utility of the risk's size is proportional to the investment's utility.

The risk-return methods of assessing investments are useful even if they do not yield investments' utilities but only numbers that agree with a utility ranking of investments. This section uses risk-return evaluations of investments only to illustrate the multi-attribute approach to risk and so does not explore issues concerning limitations and refinements of this method of evaluating investments. Weirich (1987) reviews some of the issues. Textbooks on financial management, such as Brigham and Houston (2009, Chap. 8), also explore them.

## Multi-Attribute Utility Functions

---

A multi-attribute utility function obtains an option's utility from the utilities of the option's attributes. Its justification shows that the option's utility depends exclusively on the utilities of its attributes so that options that are equivalent in utilities of attributes have the same utility. Addition is commonly, but not exclusively, used for combining attributes' utilities to obtain an option's utility. A justification for using addition includes showing that attributes' utilities have equal weights from the perspective of the option's utility. If they do not have equal weights, then an option's utility may equal, instead of the sum of its attributes' utilities, a weighted sum of their utilities.

Whether an option's utility is a function of its attributes' utilities depends partly on the set of attributes. An option's utility may be a function of its attributes' utilities for some set of attributes but not for another set. This section assumes a set of attributes that meet the criteria that section  [Government Regulation](#) reviewed. Meeting those criteria enhances the prospects that an option's utility is a function of its attributes' utilities.

An aggregation function yielding an option's utility from its utilities with respect to attributes implies an ability to move from one option to another of the same utility by replacing an instance of an attribute of the first option with another instance of the same attribute, provided that the two instances of the attribute have the same utility. In fact, an option's utility is a function of its attributes' utilities if and only if interchange of equivalent parts of options yields equivalent options. The possibility of such interchanges assumes that multiple instances of an attribute with the same utility exist and that substituting in an option one instance of an attribute for another instance yields distinct options. Consequently, interchanges do not occur for the attribute of financial gain if the utility of money is strictly monotonically increasing. In that case, no two financial gains have the same utility. No interchanges of distinct gains with the same utilities are possible. Moreover, if all attributes have strictly monotonically increasing utility, then an option's utility is a function of its attributes' utilities. No two options with attributes having the same utilities have different utilities. If options differ, then they

have different instances of attributes, and those instances have different utilities. This section treats cases in which two options may have equivalent attributes so that the existence of an aggregation function is not trivial.

Additive aggregation functions require that attributes' utilities have some properties of independence. For example, increasing an attribute's utility increases an option's utility and increases it by the same amount whatever are the other attributes' utilities. A nonadditive aggregation function may impose some related properties of independence. According to the function, attributes' utilities may have independent effects on options' utilities. A change in utility with respect to an attribute may produce the same effect on an option's utility no matter how other attributes are fixed. If the method of aggregation is multiplicative, then one attribute's utility is proportional to the option's utility given that other attributes' utilities are held fixed. According to a type of independence that section [Aggregation Functions](#) examines, as an attribute's utility increases, the option's utility increases no matter how other attributes are fixed.

This section focuses on additive aggregation functions because of their prominence in the literature. It considers conditions sufficient for using a sum or weighted sum to represent preferences among options, but argues that an additive utility representation of preferences is not enough to establish genuine additivity of utilities. The section examines first a set of conditions for an additive representation that a theorem of Harsanyi (1955) suggests. The conditions involve coherence of preferences and responsiveness of some preferences to other preferences.

Harsanyi's theorem is about personal and social preferences. Preferences, either personal or social, are *coherent* if and only if they may be represented as maximizing expected utility. Social preferences are *Pareto* if and only if they are responsive to the unanimous preferences of society's members, more precisely, if and only if they conform to the traditional Pareto principle that requires a society to prefer one option to another if all members prefer the first, or some members are indifferent between the options and other members prefer the first. Broome (1991, p. 160) states Harsanyi's theorem this way: "Suppose that each person has coherent preferences, and that social preferences are coherent and Paretoian. Then social preferences can be represented by an expectational utility function that is the sum of expectational utility functions representing the individuals' preferences." An *expectational utility function* is one that takes an option's utility to equal the expected utility of the option's possible outcomes.

Although Harsanyi's theorem treats personal and social preferences, because its proof is formal, it is open to alternative interpretations that replace personal and social preferences with other types of preferences. This section applies Harsanyi's theorem to aggregation of a person's restricted utility functions for options, taken with respect to attributes, to obtain the person's comprehensive utility function for options. Because aggregating personal preferences to form social preferences structurally resembles aggregating a person's restricted preferences to form her comprehensive preferences, the theorem governs aggregation to obtain an option's utility as well as aggregation to obtain an option's social utility.

The definition of coherent preferences applies straightforwardly to an agent's preferences among options. Preferences among options with respect to an attribute are coherent if and only if preferences among options that are equal in all other attributes, and offer chances for various instances of that attribute, may be represented as maximizing expected utility. An agent's

preferences among options are “Paretian” if and only if the agent prefers one option to another given that she prefers the first option to the second with respect to every attribute, or prefers the first option to the second with respect to some attributes and is indifferent between the options with respect to the other attributes.

The theorem implies that if preferences are coherent for each attribute and for options, and if preferences for options follow unanimous preferences with respect to attributes, or more precisely are “Paretian,” then an option’s utility may be represented as a weighted sum of its attributes’ utilities.

Broome uses the traditional probability agreement theorem to object to the usual application of Harsanyi’s theorem. He states the probability agreement theorem this way (p. 160): “Suppose that each person has coherent preferences. Then social preferences cannot be both coherent and Paretian, unless everyone agrees about the probability of every state of nature.” Broome holds that the probability agreement theorem refutes the assumptions of Harsanyi’s theorem because people do not agree about probabilities. Putting the point less contentiously, the probability agreement theorem limits applications of Harsanyi’s theorem to ideal cases involving agents who agree about probabilities. In any case, the probability agreement theorem is no obstacle to this section’s application of the theorem. A single probability assignment governs all of a person’s restricted preferences. So Harsanyi’s theorem applies to an agent’s restricted and comprehensive preferences concerning options.

Does Harsanyi’s theorem, as this section applies it, therefore offer a rationale for additive aggregation of an option’s restricted utilities, taken with respect to attributes, to obtain the option’s comprehensive utility? Keeney and Raiffa ([1976]1993, pp. 527–528) and Ellis (2006, n. 19, n. 22) point out this rationale for additivity. A close look at the theorem and additivity, however, shows that the theorem does not entail the additivity of a rational ideal agent’s utility assignments.

Harsanyi’s theorem is a representation theorem. It shows that preferences meeting certain conditions have a certain type of representation; utility functions with a certain structure may be defined to represent the preferences. The theorem does not show that restricted utility functions stating degrees of desire, when added using weights, yield a comprehensive utility function stating degrees of desire, but only that utility functions representing restricted and comprehensive preferences can be constructed so that adding the functions representing restricted preferences, using weights for them, yields the function representing the comprehensive preferences. Thus, taking utility as section [Multi-Attribute Utility Analysis](#) does, Harsanyi’s theorem does not justify using addition, under an assignment of weights to attributes, to aggregate an option’s utilities with respect to attributes into the option’s comprehensive utility.

The theorem, nonetheless, has an important consequence about the measurement of utility. Assuming that additive aggregation is correct, the theorem justifies inferring attribute weights from preferences among options and preferences among options with respect to attributes. Representation of these preferences generates a function that obtains an option’s utility in the representation as a weighted sum of its utilities with respect to attributes in the representation. The additive function that the representation generates is unique given choices of utility scales for options and attributes. Therefore the function uses the same weights as the additive function that goes from an option’s genuine utilities with respect to attributes to the option’s genuine utility, given that those utilities use the same scales that utilities in the representation use.

Also, although Harsanyi's theorem does not justify addition of utilities with respect to attributes, it justifies comparability of attributes in the cases it treats. Because of Harsanyi's theorem, coherent preferences among options with respect to each attribute, and coherent and "Pareto" preferences among options, entail that the preferences have an additive representation that assigns weights to the attributes and so compares the attributes. Such a representation does not exist if the attributes are incomparable. Given incomparable attributes, a rational ideal agent does not form a complete set of preferences among options and among options with respect to each attribute. As the theorem shows, forming the preferences despite the incomparability results in defective preferences. Section 2 Incomparable Attributes treats rational choice given incomparable attributes and incomparable options.

Some famous representation theorems establish conditions necessary and sufficient for an additive representation of preferences involving multiple attributes. These representation theorems assume in the background a rich set of preferences involving a set of attribute types.

Suppose that  $X_i$  is an attribute,  $x_i$  is a value of the attribute,  $u$  is a utility function for an option taken as a combination of attribute values, and  $u_i$  is a utility function over values of  $X_i$ . Debreu (1960) showed that given attributes  $X_1, X_2, \dots, X_m$ ,  $n \geq 3$ , an additive utility function  $u(x_1, x_2, \dots, x_n) = \sum_i u_i(x_i)$  exists if and only if the attributes are mutually preferentially independent. The attributes are *mutually preferentially independent* if and only if every subset is preferentially independent of its complementary set. A set of attributes  $Y$  is *preferentially independent of its complementary set*  $-Y$  if and only if for some  $z'$ , if  $(y', z') \geq (y', z')$ , then  $(y', z) \geq (y'', z)$  for all  $z, y', y''$ , where  $\geq$  is the relation of *weak preference*, that is, preference or indifference.

Gorman (1968) showed how to reduce the work needed to establish mutual preferential independence. Let  $Y$  and  $Z$  be subsets of the attribute set  $S = \{X_1, X_2, \dots, X_n\}$  such that  $Y$  and  $Z$  overlap, but neither is contained in the other, and such that the union  $Y \cup Z$  is not identical to  $S$ . If  $Y$  and  $Z$  are each preferentially independent of their respective complements, then  $Y \cup Z$ ,  $Y \cap Z$ ,  $Y - Z$ ,  $Z - Y$  and  $(Y - Z) \cup (Z - Y)$  are each preferentially independent of their respective complements. Because preferential independence among some sets entails preferential independence among other sets, showing mutual preferential independence does not require examining every subset and its complement.

Fishburn (1965) established a necessary and sufficient condition for an additive representation when the objects of preferences are lotteries over bundles of attributes. The attributes  $X_1, X_2, \dots, X_n$  are *additive independent* if and only if preferences over lotteries on  $X_1, X_2, \dots, X_n$  depend only on their marginal probability distributions and not on their joint probability distribution. Additive independence is necessary and sufficient for an additive representation. This result is related to Harsanyi's theorem about conditions sufficient for an additive representation, as Keeney and Raiffa ([1976]1993, pp. 527–528) explain.

The representation theorems begin with a set of preferences and present conditions under which the preferences have a representation using an additive utility function. A corresponding normative principle requires utilities to be additive. The conditions for an additive representation do not establish a normative principle of additivity, just as Harsanyi's conditions for an additive representation do not establish a normative principle of additivity. A normative principle of additivity for utilities concerns utilities defined independently of additivity, for example, defined as rational degrees of desire as in section 2 Multi-Attribute Utility Analysis. That preferences have an additive representation does not show that the preferences arise from utilities complying with the normative principle.

Take a decision problem in which an agent has just two salient options, chocolate ( $c$ ) and vanilla ( $v$ ), and he prefers the first. Using the set of attributes, richness ( $r$ ) and smoothness ( $s$ ), the preference has an additive representation. For example, defining utilities as follows works:  $U(c) = U_r(c) + U_s(c) = 3 + 2$  and  $U(v) = U_r(v) + U_s(v) = 1 + 3$ . This representation yields the preference  $c > v$ . However, suppose that the utility function representing the preference does not accurately report the agent's degrees of desire. According to an accurate utility function,  $U_r(c) + U_s(c) = 3 + 2$  and  $U(v) = U_r(v) + U_s(v) = 2 + 3$ . The preference for chocolate holds because the caffeine in the chocolate breaks the tie. Then although the preference has an additive representation using the two attributes, richness and smoothness, the preference does not arise because of addition of utilities with respect to those two attributes. The utilities that the representation introduces are not the utilities that the agent assigns, and the set of attributes omits a relevant consideration.

This example does not fall among the cases that the representation theorems treat; it does not meet the theorems' background assumptions. The theorems apply to a rich set of preferences and not to a single preference. Nonetheless, such examples show that the representation theorems do not establish a normative principle stating that the utility of an option is a sum of its utilities with respect to the attributes in a set, even if they present necessary and sufficient conditions for preferences having an additive utility representation. The step from additive representations to genuine additivity needs argumentation.

## Intrinsic-Utility Analysis

---

Intrinsic-utility analysis divides an option's utility into the utilities of its attributes. The attributes are realizations of basic intrinsic desires and aversions. This section explains these basic intrinsic attitudes and shows how they ground an analysis of an option's utility. It draws on Weirich (2001, Chap. 2). The main principle of intrinsic-utility analysis asserts that when a rational agent knows an option's outcome, the option's utility is a sum of the intrinsic utilities of the objects of the basic intrinsic attitudes realized given the option's realization. The principle is normative because it governs rational degrees of desire. It derives from the additivity of the intrinsic utilities of realizations of basic intrinsic attitudes.

The difference between intrinsic and extrinsic desire arises because of desire's variable scope. Some desires hold all things considered, and others hold given a restricted range of considerations. A person may desire that a proposition obtain because of the proposition's total outcome, including its causal consequences, or because of the proposition's logical consequences alone. In the first case the desire is extrinsic, and in the second case it is intrinsic. A person typically has an intrinsic desire for pleasure and an extrinsic desire for money. Aversion similarly may be either intrinsic or extrinsic.

An intrinsic desire may rest on other intrinsic desires. For example, an intrinsic desire for two pleasures may rest on intrinsic desire for the first pleasure and an intrinsic desire for the second pleasure. An intrinsic desire that does not rest on any other intrinsic desire is basic. A basic intrinsic aversion has an analogous definition. A person's aversion to a risk is apt to be a basic intrinsic aversion.

A proposition's utility for a person is a rational degree of desire that the proposition obtain. Varying the scope of considerations on which desire depends produces different kinds of utility. Intrinsic utility measures desire arising from considerations of limited scope. A proposition's

intrinsic utility for a person is the person's degree of intrinsic desire that the proposition hold. This equals the person's degree of desire that the proposition hold considering only the proposition's logical consequences. Intrinsic utility contrasts with ordinary, comprehensive utility, which unlike intrinsic utility measures desire arising from considerations of unlimited scope. A proposition's ordinary, comprehensive utility for a person is the person's degree of desire that the proposition hold all things considered, including the proposition's causal consequences as well as its logical consequences.

A person's degrees of desire, if rational, meet standards that take account of the person's abilities. This chapter treats ideal agents whose rational degrees of desires meet the highest standards and consequently satisfy principles of utility, such as consistency: if two propositions are logically equivalent, then their utilities are equal. The principles of utility vary with the type of utility. Comprehensive, but not intrinsic, utility obeys the expected utility principle requiring an option's utility to equal the option's expected utility. Intrinsic utility, because it rests on logical consequences, does not respond to chances, and so the expected utility principle does not govern it.

In this section, a basic intrinsic attitude is either a basic intrinsic desire or a basic intrinsic aversion. A proposition that specifies for each basic intrinsic attitude whether it is realized characterizes the relevant aspects of a possible world. It represents the possible world. The proposition's intrinsic utility equals its ordinary, comprehensive utility because the proposition specifies everything that matters. Its logical consequences include all its relevant consequences.

Suppose that an agent is rational and ideal. For the agent, a world's intrinsic utility is a sum of the intrinsic utilities of the objects of the basic intrinsic attitudes that the world realizes. The reasons for this principle of addition are roughly the following. The realization of a basic intrinsic attitude makes the same contribution to the intrinsic utility of any world that realizes the basic intrinsic attitude. Conjunction of objects of basic intrinsic attitudes is a concatenation operation for intrinsic utility, and addition of intrinsic utilities represents that operation. An intrinsic utility assignment therefore is additive with respect to basic intrinsic attitudes. A proposition's intrinsic utility is the sum of the intrinsic utilities of the objects of basic intrinsic attitudes whose realizations the proposition entails.

For example, suppose that an agent has basic intrinsic desires for health and for wisdom and has no other basic intrinsic attitudes. Suppose also that the intrinsic utility of health is 3 and the intrinsic utility of wisdom is 2. Then the intrinsic utility of health and wisdom is 5.

Next, suppose that an agent has a basic intrinsic desire for each of two pleasures during successive intervals. She also has a basic intrinsic desire for continuity of pleasure during the two intervals. Then the intrinsic utility of both pleasures is the sum of the intrinsic utilities of the two pleasures and also the intrinsic utility of pleasure's continuity during the two intervals. The conjunction of the propositions that each pleasure obtains during its interval entails realization of those propositions and also realization of the proposition that pleasure is continuous during the two intervals.

Intrinsic utility grounds a multi-attribute approach to risk because an aversion to risk typically is intrinsic and basic. Intrinsic-utility analysis therefore authorizes dividing the intrinsic utility of a risky option's possible outcome, a world that might be realized if the option were realized, into the intrinsic utility of the option's risk and the intrinsic utilities of other objects of basic intrinsic attitudes that would be realized if the possible outcome were realized. An option's ordinary, comprehensive utility equals the utility of the proposition that the option's world obtains. Given certainty, an agent knows the option's world, the possible

outcome that obtains, and an option's utility equals its world's intrinsic utility. Given uncertainty, an option's utility is the expected value of the intrinsic utility of the proposition that the option's world obtains, that is, a probability-weighted average of the intrinsic utilities of the option's possible outcomes.

## Trustee Decisions

---

Multi-attribute approaches to risk, with risk as an attribute, facilitate decisions in which a trustee decides for a client, for example, decisions in which a physician decides for a patient about a treatment for an illness. This section examines trustee decisions in which the trustee is an expert and a client authorizes the trustee to use expert information to advance the client's basic goals.

The trustee decides for the client, this section assumes, by maximizing utility among options, using the trustee's information and the client's goals. This procedure is appropriate when the trustee's information includes all the client's relevant information and the objective is a decision that the client might make, if rational, given possession of the trustee's expert information.

To implement the procedure, the following steps are effective. For an option, the trustee supplies a probability assignment to possible outcomes, and the client supplies a utility assignment to possible outcomes. The client's utility assignment to a possible outcome depends on his assessment of the option's attributes, including the risk the option generates. The client's assessment of the option's risk is uninformed, and the trustee replaces it with an informed assessment of the risk. Then the trustee recalculates the possible outcome's utility, substituting her informed assessment of the risk for the client's uninformed assessment, but using the client's assessments of the option's other attributes. Finally, the trustee assigns utilities to options applying the expected utility principle with her probability assignment and the recalculated utilities of possible outcomes, and identifies an option of maximum utility in the set of options.

Suppose that a physician has two treatment options that offer a patient equal chances of recovery. Accordingly, the patient takes the options to generate equal risks. The utility of a treatment's possible outcome depends on the attributes of risk and of health. Adding more attributes is easy, but using just these two attributes keeps the illustration simple. Because the first treatment promises slightly faster recovery, its possible outcomes have slightly greater utilities than their counterparts with the second treatment. Using for possible outcomes the physician's probability assignment and the client's utility assignment, the first treatment's utility is superior. However, the physician knows that the second treatment has undergone more extensive testing than has the first treatment. Hence, the second treatment generates less risk than does the first treatment. Substituting the physician's assessments of the treatments' risks, utilities for the second treatment's possible outcomes are slightly greater than for their counterparts with the first treatment. The second treatment's utility is therefore greater than the first treatment's utility. Thus, using expert assessments of risk in the multi-attribute calculation of possible outcomes reverses utility maximization's recommendation.

To illustrate, suppose that  [Table 20.2](#) represents the patient's utilities for the two treatments given success and also given failure. Each cell represents a treatment's possible outcome. The first number in a cell evaluates the possible outcome with respect to risk, and the second evaluates it with respect to health, including recovery time.

Assuming that a possible outcome's utility equals the sum of the utilities of its attributes, **Table 20.3** shows the utilities of each treatment's possible outcomes.

Because the first treatment's utilities are higher in each column, their probability-weighted sum is greater than the probability-weighted sum of the utilities of the second treatment's possible outcomes. Therefore the first treatment maximizes expected utility, and so utility.

The comparison reverses, however, after substituting informed assessments of risks in place of the patient's assessments. **Table 20.4** shows the change.

**Table 20.5** displays utilities of possible outcomes after recalculating their utilities from their informed utilities with respect to the attributes of risk and of health.

Using informed assessments of risks and so informed utilities of possible outcomes, the second treatment has greater expected utility, and hence greater utility, than has the first treatment. The physician should therefore recommend the second treatment to the patient. In this example, informed assessments of risks reverse utility maximization's original recommendation.

**Table 20.2**  
**Patient's assessments of attributes**

	Success	Failure
First treatment	2, 11	2, 6
Second treatment	2, 10	2, 5

**Table 20.3**  
**Utilities of outcomes**

	Success	Failure
First treatment	13	8
Second treatment	12	7

**Table 20.4**  
**Informed assessments of attributes**

	Success	Failure
First treatment	2, 11	2, 6
Second treatment	4, 10	4, 5

**Table 20.5**  
**Informed utilities of outcomes**

	Success	Failure
First treatment	13	8
Second treatment	14	9

This example assumes, as section [Risk as an Attribute](#) argues, that risk is an attribute of risky options and their possible outcomes. Granting this, multi-attribute utility analysis is plainly a valuable tool for trustee decisions. In particular, it assists government regulatory decisions of the sort section [Government Regulation](#) reviewed. In those decisions the government agency is a collective trustee, and the public is the client that the agency serves. The agency uses its expert information to assess risks, and it uses its informed assessments of risks to make decisions on the public's behalf.

## Further Research

---

Multi-attribute approaches to risk are still under construction. Research on the approaches tackles unfinished tasks. Among the tasks to be completed are detailed justifications of the approaches and generalizations of the approaches so that they cover realistic and not just idealized decision problems.

## Aggregation Functions

---

The justification of a multi-attribute approach to risk derives an option's utility from the utilities of the option's relevant attributes. The utilities of the option's attributes are comparable if an option's utility is a function of its attributes' utilities, and each attribute's utility affects the option's utility. A typical multi-attribute assessment of an option's utility entails the comparability of the utilities of the option's relevant attributes. So its justification requires establishing their comparability. Section [Incomparable Attributes](#) treats comparability, and this section treats other issues pertaining to justification of multi-attribute assessments of options.

In some decision problems, it is convenient to compare options using selected attributes if the options are alike with respect to other attributes. For example, a financial planner may compare options alike in risk by comparing their expected returns. A multi-attribute utility function justifies this simplification if utilities of attributes are separable. Separability is a matter of independence of attributes' utilities. The utilities of attributes are *separable* if and only if holding constant all attributes but one while increasing the utility of that attribute increases an option's utility. Varian (1984, Sect. 3.14) calls this feature of attributes' utilities *functional separability*.

Separability rules out a certain type of complementarity between attributes, that is, cases in which increasing utility with respect to one attribute while holding other attributes constant lowers an option's utility. Such complementarity holds between wealth and security, for instance, if, assuming poor security measures, increasing wealth lowers comprehensive utility because it makes kidnapping more likely.

Traditional utilitarianism treats the well-being of each individual in a group as an attribute affecting collective utility. It takes collective utility to be a function of the utilities of the individuals' levels of well-being, or, more briefly, utilities for individuals. Utilities for individuals are separable, in fact, additively separable, according to utilitarianism. That is, adding utilities for individuals yields collective utility.

The utility of equality raises an objection to utilitarianism. According to the objection, an option that promotes equality in a group benefits the group but does not distribute a benefit to each member of the group. Consequently, increasing a member's utility while holding other members' utilities constant may lower collective utility by destroying equality in the group. This lowering of collective utility is contrary to the separability that utilitarianism advances. A defense of utilitarianism argues that a group's members benefit from equality so that destroying equality by raising utility for one member also lowers utility for the other members. Because utilities for the other members change during the lowering of collective utility, that lowering is compatible with separability. Hence, the utility of equality does not discredit a utilitarian separation of individuals' utilities.

Value holism argues that the moral value of a whole does not equal the sum of the moral values of its parts. Suppose that an individual suffers. Adding to the situation a second individual who takes pleasure in the first's suffering makes the situation worse, not better, although pleasure is a good. This case counts against the separability of moral values, because increasing pleasure while holding suffering constant decreases total value. The counterexample works, however, only if all pleasures count as good. Value theory may distinguish types of pleasure and deny that all are good. Because pleasure at another's suffering is bad, its lowering the situation's value does not refute the separability of moral values.

These examples from moral theory illustrate attacks on and defenses of separability. Multi-attribute utility theory's reliance, in some applications, on the separability of attributes' utilities faces similar attacks and may marshal similar defenses.

Multi-attribute utility theory does not claim that every set of attributes offers a way of deriving an option's utility. It selects attributes that permit the derivation. Also, it selects the function that combines attributes' utilities to obtain an option's utility. It need not select an additive function, or even a function that makes utilities of attributes separable. A multi-attribute utility analysis needs only one set of attributes and one function that together permit deriving an option's utility from its attributes' utilities. Because of an analysis's modest requirements, the prospects of justifying a multi-attribute utility analysis of an option's utility are good in many cases.

## Realism

---

This chapter adopts several idealizations to facilitate presentation of multi-attribute approaches to risk. For example, it assumes that agents are ideal and so have no cognitive limits. It also assumes that decision problems are ideal so that every option has a utility with respect to each attribute and also has a comprehensive utility; attributes and options are compared, and comparisons are precise.

Realistic agents in realistic decision problems cope with cognitive limits, imprecision, and incomparability. Theorists seek to remove idealizations and extend to realistic cases multi-attribute approaches to risk. Perhaps some idealizations are indispensable and so impose limits on managing risk by weighing pros and cons. Nevertheless, the multi-attribute approach to risk should extend as far as those limits allow. It should relax as many idealizations as possible. For discussion of realistic decision principles and their limits, see in this handbook, [Chap. 21, Real-Life Decisions and Decision Theory](#).

Consider the idealization that an agent in a decision problem assigns, for every option, a probability and a utility to each possible outcome with respect to every attribute. This idealization is strong even for a rational agent with ample resources for reflection. Such an agent may lack evidence that warrants a precise probability assignment or may lack experience that warrants a precise utility assignment. For a tourist in Paris, a rational assignment of probability to rain tomorrow may be imprecise, and so may a rational assignment of utility to visiting the Louvre tomorrow. Even given full rationality and ample computational resources, the tourist may fail to remove all imprecision in probability and utility assignments.

In some decision problems imprecision does not prevent identifying an optimal option. Perhaps no matter the precise probability of rain tomorrow and no matter the precise utility of visiting the Louvre tomorrow, that visit is optimal for a tourist in Paris. Other options have less utility under every refinement of probabilities and utilities. A sensitivity analysis may establish the robustness of the visit's position at the top of a ranking of options.

A topic for further research is whether an option's optimality under some refinement of probabilities and utilities suffices for the option's rationality. Good (1952, p. 114) advances the view that it suffices, but Elga (2010) challenges that position, arguing that given unsharp probabilities it condones incoherent sequences of decisions, for example, rejecting each of a pair of gambles that together guarantee a gain.

Some idealizations concern the options in a decision problem. In a standard problem some option has maximum utility, and the agent has a stable basis for comparing options. The agent has stable basic goals, and assuming an option's realization does not alter the basis of its comparison with other options. Moreover, weights for attributes and utilities of possible outcomes are independent of both the option realized and the state of the world that obtains.

To handle the dependence of weights and utilities on options and states, utility theory may take an option's possible outcomes to be possible worlds. Then possible outcomes include everything an agent cares about. Their utilities, because inclusive, are independent of options and states. The main drawback of the broad view is that possible outcomes, if comprehensive, do not occur in multiple contexts. That complicates measurement of their utilities.

Game theory generates decision problems in which assuming an option's realization alters the option's comparison with other options. Consider a two-person game with a unique Nash equilibrium, that is, an assignment of strategies to agents such that each agent's strategy is a best response to the other agent's strategy. An agent's supposition that she departs from her Nash strategy may carry information that her opponent departs from his Nash strategy. That information affects the utility of her departure from her Nash strategy.

Because decisions in games have special features, the principle of straightforward utility maximization may need refinement to handle those decisions. For example, it may give way to the principle of ratification. That principle recommends an option that maximizes utility on the assumption that the option is realized, as Weirich (2007, Chap. 8) explains.

The next section considers relaxing the idealization that attributes and options are compared. It examines a generalization of the principle of utility maximization designed to accommodate decision problems with uncomparable options.

## Incomparable Attributes

---

For a person, two objects of desire or aversion are incomparable if the person cannot compare the two. For example, a connoisseur may like both music and wine yet be unable to compare the two. The connoisseur neither prefers one to the other, nor is indifferent between the two, and, moreover, despite ample time for reflection, cannot form a preference or become indifferent between them. In a decision problem, if a person has options with incomparable attributes, then the options may be incomparable, too. If the options are incomparable, then the ranking of options is incomplete. Choosing from the top of the ranking may be unwarranted.

Helzner (2009) argues that multi-attribute assessments of options should accommodate incomplete orderings of options. In some decision problems, for two options, the agent neither prefers one option to the other, nor is indifferent between them. The agent's preference is indeterminate. Indeterminacy of preferences between options may arise from incomparable attributes of options. It may also arise because of indeterminacy in the weighting of attributes, that is, the incommensurability of the attributes. Two attributes may be comparable but not commensurable because although the first is weightier than the second, it is not weightier by a precise amount.

An agent in a decision problem may be at fault for not having a determinate preference between a pair of options. Perhaps he should have reflected and formed a preference. In some cases, however, a failure to form a preference is excused. This section takes it for granted that a rational ideal agent may face a decision problem in which the relevant attributes of options are incomparable or incommensurable so that for good reason the agent does not compare all options. It considers a method of evaluating the agent's decision despite an incomplete ranking of options.

Not all decision problems in which options have incomparable attributes create complications. In some decision problems, options are comparable although attributes are not. Suppose that a decision problem has two salient options, and the first is better than the second with respect to every attribute. Then the first is better than the second and makes a rational choice. The options' comparison does not require that the attributes be comparable. Incomparable attributes trouble evaluations of decisions only when the attributes' incomparability blocks comparison of options.

Also, in some decision problems a preference ranking of options need not be complete to be useful. Suppose that an option is at the top of the agent's ranking of options although the ranking omits some options available in the decision problem. A plausible decision principle permits that option because the agent prefers no other option. The permission is uncontroversial if the ranking omits only one option because it is incomparable with some options in the ranking, and the agent prefers the option at the top of the ranking to the option that the ranking omits.

This section targets decision problems in which incomparable attributes create incomparable options that make the preference ranking of options incomplete. The ranking omits an option because it is incomparable to some options in the ranking. However, no rival in the incomplete ranking defeats it. In particular, the agent does not prefer the option at the top of the ranking.

For example, a new engineer may have two job offers, and may use salary and location as attributes to evaluate the offers. Suppose that for the engineer the two attributes are incomparable. She cannot compare for either job its salary with its location and so cannot settle the attributes' relative weights and the job's overall utility. Suppose also that the job with the greater

salary has a less attractive location than has the other job, and the engineer cannot settle whether the greater salary compensates for the less attractive location. Incomparability of attributes blocks multi-attribute assessments of options. The engineer does not assign a utility to either job, and the jobs are incomparable. Her ranking of options omits them, but no option in the ranking defeats them. Resolving such decision problems requires generalized decision principles. Can multi-attribute utility theory formulate principles that handle such decision problems?

Etzioni (1986) introduces multiple utility scales to handle incomparable attributes that do not fit on the same scale. He proposes two utility scales, one for pleasure and one for morality, but is open to adding other utility scales. He rejects combining an option's assessments with respect to the two utility scales to form the option's comprehensive utility, but does not explain how to resolve decision problems without combining the two sorts of assessment of an option.

A general problem with using multiple utility scales to handle incomparable attributes is that eventually an agent must move from an assessment of options using attributes to a choice. Suppose that in a decision problem, instead of putting morality and pleasure on the same scale, a decision procedure puts morality on one scale and pleasure on another scale. It does not compare morality and pleasure. Then it aggregates an option's utilities on the two scales to obtain an overall evaluation of the option. Its aggregation of utilities with respect to attributes is unjustified because it does not compare attributes. Incomparability thwarts justified aggregation of utilities with respect to attributes and thus blocks the standard multi-attribute approach to decisions.

How do agents resolve decision problems despite such obstacles? One possibility is that an agent attends to only one utility scale in a decision problem, and that scale directs the agent's decision. Sometimes an agent attends to morality, and other times to pleasure. This possibility moves away from evaluative to descriptive decision theory. It treats an agent's motivation rather than an agent's justification for a decision. This chapter, which treats evaluative decision theory, puts aside that method of resolving a decision problem with incomparable options.

A second possibility is that an agent uses a lexicographical ordering of options to reach a decision. Perhaps morality has absolute priority over pleasure. Pleasure's role may be limited to breaking ties between options that are morally permissible.

The lexicographic method of using attributes to reach a decision takes an option's choiceworthiness to be a nonadditive function of its evaluation with respect to each attribute. It dispenses with options' utilities, the mainstay of the standard multi-attribute approach to decisions. This revised version of the multi-attribute approach assigns utilities to options with respect to attributes but does not assign comprehensive utilities to options. It uses utilities with respect to attributes to reach decisions without the intermediary of options' comprehensive utilities and without comprehensive comparisons of options. As in the example, it ranks options according to a primary attribute and then breaks ties using a secondary attribute.

Levi (1986, pp. 28–34, 80–82) describes two-step and multi-step decision procedures that use options' comparisons with respect to attributes. He considers a two-step procedure that begins with an agent's identification of options that are best according to at least one of the agent's principal values. In the second step, from these options, the agent selects an option that is best according to a tie-breaking, secondary value. For example, suppose that an employer ranks one job candidate best according to education and another candidate best according to experience. If education and experience are the primary values, then those two candidates are the finalists. The employer may then choose between the two finalists according to their performance during an interview, a secondary value.

A problem confronts this two-step procedure. In the example, suppose that a third candidate is second according to education and also experience, best according to interview, and so best all things considered. The decision procedure fails to select that candidate despite her overall optimality. If options have an overall ranking, a decision procedure ought to use it. For the two-step decision procedure to be plausible, it must be restricted to cases in which options lack an overall ranking.

On the other hand, given the absence of an overall ranking, the decision procedure seems too strict. In some cases, it requires an agent to select an option even though the agent does not prefer it to a rival option. For example, it requires the employer to select the candidate who gave the better interview even though the employer, without any failure of reflection, does not prefer that candidate to the others. It seems that if rationality does not require an agent to prefer one option to all others, then it does not require the agent to choose that option.

A common alternative to lexicographic methods is less demanding and also more broadly applicable. It applies to cases in which options are incomparable, not only all things considered, but also considering just a single attribute. For example, it applies to the employer's decision problem even if the job candidates are incomparable with respect to education, experience, and performance during an interview.

Suppose that in a decision problem two options in contention are incomparable. Rather than insist on an option whose utility is at least as great as any other option's utility, either overall or with respect to some attribute, the alternative principle declares that each incomparable option is a rational choice. Does rationality in fact permit either option? Is the permissive decision principle correct?

To begin answering, consider a crucial difference between incomparability and indifference. If an agent is indifferent between two options, adding a small benefit to one option breaks the tie. This is not so with incomparable options. If  $x$  and  $y$  are incomparable options, so are  $x+$  and  $y$ , where  $x+$  is a small improvement of  $x$ . This disanalogy between indifference and incomparability makes the permissive decision principle condone incoherent sequences of choices, Peterson (2007) argues.

Suppose that a safety measure has incomparable attributes such as a reduction in wages and a reduction in risk to health. The same holds for inaction. As a result, a decision about the safety measure surveys incomparable options. The same holds for subsequent decisions about similar safety measures. Following the permissive decision principle may produce an incoherent sequence of decisions about safety measures.

To show this, consider options  $x$ ,  $x+$ , and  $y$ . Suppose that rationality, assuming the permissive decision principle, permits the following three choices. (1) The agent may choose option  $x$  over option  $y$ , because  $x$  is better than  $y$  with respect to one attribute and worse than  $y$  with respect to another, incomparable attribute so that the options are incomparable. (2) The agent may choose option  $x+$  over option  $x$ , because  $x+$  is slightly better than  $x$  with respect to one attribute and is the same as  $x$  with respect to other attributes. (3) The agent may choose option  $y$  over option  $x+$ , because, as with  $x$  and  $y$ , the options are incomparable. Then rationality condones a cycle of choices from  $y$  to  $x$ , from  $x$  to  $x+$ , and from  $x+$  to  $y$ .

The cycle makes the agent a money pump, Peterson (2007) observes. A person ready to make the choices in the cycle may be led through the cycle many times, each time paying a sum to make the switch from  $x$  to  $x+$  until he is bankrupt. The possibility of a money pump makes

a case against the rationality of the choices in the cycle and thus against the permissive decision principle. The principle condoning any choice among incomparable contenders is mistaken, Peterson concludes.

Some ways of defending the permissive decision principle are available, however. A method of preventing incoherent choices given incomparable options is for an agent to keep a record of past choices and evaluate current choices in light of past choices so that an aversion to incoherent choices blocks cycles. For instance, an agent after choosing  $x$  over  $y$  and  $x+$  over  $x$  should revise evaluation of  $y$  and  $x+$  so that they are no longer incomparable. In light of past choices, the agent should prefer  $x+$  to  $y$  because of an aversion to cyclical choices, and to the particular cycle realized by a choice of  $y$  over  $x+$ .

A standard rebuttal is that sunk costs, or in this case past choices, do not count. All that counts is the current utility assignment to options. This rebuttal is not decisive. A rejoinder contends that past choices count if an agent is averse to cyclical choices. Past choices settle whether a current choice completes a cycle of choices. Given an aversion to cycles, past choices influence current utility assignments to options. The choices lower an option's current utility assignment if because of them the option's realization completes a cycle. Because of an aversion to cycles, it is rational to have a utility assignment to options that is attuned to a current option's consequences given past choices. Moreover, it is rational to have an aversion to cyclical choices. In fact, rationality requires such an aversion in cases where cyclical choices lead to sure losses. So a rational ideal agent following the permissive decision principle does not make an incoherent sequence of choices.

Because the permissive decision principle does not lead to incoherent sequences of choices, it is defensible. It gives multi-attribute approaches to risk a way of handling incomparable attributes.

## Outlook

Despite unresolved issues, multi-attribute approaches to risk have attractive features, such as the transparency they bring to assignments of utilities to options. Because of these attractive features, many decision theorists are motivated to refine multi-attribute approaches to meet challenges rather than to abandon these approaches in the face of challenges. Decision theorists' continuing investigations give multi-attribute approaches to risk a bright future.

**Abstract:** Some decisions result in cognitive consequences such as information gained and information lost. The focus of this study, however, is decisions with consequences that are partly or completely noncognitive. These decisions are typically referred to as “real-life decisions.” According to a common complaint, the challenges of real-life decision making cannot be met by decision theory. This complaint has at least two principal motives. One is the maximizing objection that to require agents to determine the optimal act under real-world constraints is unrealistic. The other is the precision objection that the numeric requirements for applying decision theory are overly demanding for real-life decisions. Responses to both objections are aired in the section [History](#) of this chapter. The maximizing objection is addressed with reference to work by Weirich and Pollock, while the precision objection is countered via a proposal by Kyburg and another by Gärdenfors and Sahlin. However, the section [Current Research](#) urges a different response to the precision objection by introducing a comparative version of decision theory. Drawing on Chu and Halpern’s notion of generalized expected utility, this version of decision theory permits many choices to be based on merely comparative plausibilities and utilities. Finally, the section [Further Research](#) undertakes an open-ended exploration of three of the assumptions upon which this form of decision theory (and many others) is based: transitivity, independence, and plausibilistic decision rules.

## Introduction

---

Decisions can be classified by their consequences. The consequences of some decisions are cognitive, such as information gained or information lost; the consequences of other decisions are noncognitive, such as economic gain, political embarrassment, esthetic enjoyment, legal imbroglio, or military advantage. Where the consequences of concern to the agent are purely cognitive, the agent confronts a *cognitive decision*; where the situation is mixed, with relevant consequences that are both cognitive and noncognitive, the agent must make a *partly cognitive decision*; and where the relevant consequences are purely noncognitive, the agent faces a *noncognitive decision*.

The concept of a *real-life decision* is both irremediably vague and undeniably useful. Rather than attempt to define the concept in abstract terms, I will simply note that the contrast class for real-life decisions appears to be cognitive decisions (despite the fact that cognitive decisions are, strictly speaking, just as real and just as much a part of life as partly cognitive and noncognitive decisions). Hence most real-life decisions are either partly cognitive or noncognitive. Examples of real-life decisions can be suggested by questions such as these: Whom should I vote for? Would it be better to cancel this trip? Must I tell the truth to my nosy neighbor? Do I need a second medical opinion? How should I invest this windfall?

Decision theory has been dogged by complaints that it is inapplicable to real-life decisions. There appear to be two standard objections. The maximizing objection takes issue with the decision-theoretic directive to maximize, that is, to choose the optimal act. Though this anti-maximizing approach can take different forms (Elster 1979; Levi 1986; Slote 1989), the best-known appears to be Herbert Simon’s advocacy of satisficing (Simon 1982). Given the complexity of our environment and our limitations in gathering and processing information, the goal of maximizing is unattainable, according to Simon. Instead, we should aim to satisfice by seeking results that are merely good enough relative to some threshold of expected utility. The second complaint about decision-theoretic realism is the precision objection: decision

theory exacts numerical precision that we can very rarely supply. Strict Bayesian decision theorists take the probability and utility functions that underlie expected utilities to determine sharp numeric values (de Finetti 1937; Savage 1972). But real-life decision makers usually operate without nearly as much numeric data; they are characterized, in fact, by numeric poverty. Hence, the objection goes, decision theory cannot be applied to most real-world decisions.

This chapter explores the prospects for obtaining decision-theoretic guidance for real-life decisions. It proceeds in three stages. The section [History](#) reviews several perspectives on the maximizing and precision objections. The section [Current Research](#) presents the author's proposal for meeting the precision objection. Finally, the section [Further Research](#) offers suggestions on how this proposal might be solidified by future investigation.

In keeping with this volume's focus on risk, I will concentrate on decisions under risk, that is, decisions for which the decision maker can estimate the probability (or plausibility) of states of the world relevant to the decision. I will say nothing further about decisions under ignorance, that is, decisions for which the decision maker is unable to make such probabilistic (or plausibilistic) determinations.

## History

### The Maximizing Objection

We begin with two well-known perspectives on maximizing. Despite areas of agreement, Paul Weirich and John L. Pollock hold positions that are fundamentally opposed. Weirich claims that rationality requires maximization; Pollock demurs.

Weirich's defense of maximization unfolds against the backdrop of a theory of idealizations. An idealization simplifies by focusing on some explanatory factors and excluding others. In physics, for example, a theory of motion may idealize by excluding the explanatory factor of air resistance – in effect, assuming it is zero.

Historically, decision theory has developed by employing a full complement of idealizations. Weirich's *Realistic Decision Theory* identifies and classifies these idealizations (2004, Chap. 3). It then performs a sort of controlled demolition by subtracting them one by one. Idealizations of the agent are eliminated in Chaps. 4–7; idealizations of the situation, in Chaps. 8–9. With each jettisoned idealization, decision theory becomes both more realistic and more general.

What turns out to be a lengthy and complex process can be illustrated by a few examples from its inception. Weirich initially assumes agents who are perfect and fully informed. Such godlike agents would not engage in deliberation and decision, for “they can maximize utility spontaneously” (2004, p. 22). Specifically, they would maximize informed utility by complying with the *principle of utility maximization for acts*: “Among the acts you can perform at a time, perform one whose utility is at least as great as any other’s utility” (2004, p. 20).

Removing the idealization of perfect agents but retaining that of full information leaves us with imperfect agents for whom it would make sense to deliberate and compare utilities. For these agents, the foregoing principle for acts is generalized as the *principle of utility maximization for decisions*: “Among the decisions you can make at a time, make one whose utility is at least as great as any other’s utility” (2004, p. 23).

Casting off the idealization of full information carries us one step further in the direction of realism and generality. Agents who are uncertain of the outcomes of acts under consideration must consider the probabilities of states of the world as well as the utilities of outcomes. They do this by taking an act's utility to be its expected utility, that is, a weighted average of the act's outcome utilities in which the relevant state probabilities are the weights. Suppose that an agent equipped with a probability function  $\mu$  and a utility function  $v$  is considering the performance of an act  $a$ . Relevant to the decision are a finite number of attributable states of the world  $s_1, s_2, \dots, s_n$  with corresponding state probabilities  $\mu(s_1, e), \mu(s_2, e), \dots, \mu(s_n, e)$  based on the evidence  $e$ . In addition, performance of  $a$  when exactly one of  $s_1, s_2, \dots, s_n$  obtains would produce outcomes  $o_1, o_2, \dots, o_m$ , respectively, and these outcomes have utilities  $v(o_1), v(o_2), \dots, v(o_n)$ . The expected utility  $E$  of  $a$  given  $e$  can then be defined as follows:

$$E_{a,e} = \sum_{i=1}^n v(o_i)\mu(s_i, e).$$

For imperfect, partially informed agents, the principle of utility maximization for decisions would be generalized as the *principle of expected utility for decisions*: “Among the decisions you can make at a time, make one whose expected utility is at least as great as any other’s expected utility.”

The three maximization principles cited in the three preceding paragraphs are all treated in Chap. 2 of *Realistic Decision Theory*. But the process of stripping away idealizations continues throughout the work until Weirich finally proposes a *principle of comprehensive rationality*: “A rational decision maximizes self-conditional utility among self-supporting options with respect to a quantization of conscious beliefs and desires after a reasonable effort to form and become aware of relevant beliefs and desires, acquire pertinent *a priori* knowledge, and correct unacceptable mistakes” (2004, p. 191). Technical terms such as “quantization,” “unacceptable mistakes,” “self-supporting options,” and “self-conditional utility” will not be defined here. Readers interested in further detail are advised to consult the relevant sections of the work (2004, pp. 69–70, 119–123, 147–154, and 155–158, respectively). Even without these definitions, however, it is evident that Weirich remains committed to a highly general form of maximization.

Pollock’s *Thinking about Acting* (2006) rejects the goal of maximization. Its point of departure is the thesis that theories of ideal decision makers tell us little about how real decision makers, whether humans or machines, should make decisions. Theories of ideal decision makers are theories of *warranted choice*, that is, choices that “would be justified if the agent could complete all possibly relevant reasoning.” By contrast, theories of real decision makers are theories of *justified choice*, choices that “a real agent could make given all the reasoning it has performed *up to the present time* and without violating the constraints of rationality” (Pollock 2006, p. 6). Because of cognitive limitations, real decision makers often make choices that are justified but not warranted.

In Pollock’s view, subjective expected utility theory is a theory of ideal rationality. One of its principal departures from realism is the optimality (or maximizing) principle: choose optimal (or maximal) solutions to problems. Pollock objects to it on a number of grounds. In classical decision theory, the optimality principle is formulated in terms of actions: choose the action that maximizes expected utility. But Pollock argues that actions must be chosen as parts of plans; hence the basic alternatives faced by decision makers are plans, not actions. If we attempt

to reformulate the optimality principle in terms of plans, Pollock raises three further objections: “Although plans are evaluated in terms of their expected utilities, they cannot be chosen on the basis of a pairwise comparison because plans can differ in scope.... [Furthermore,] there are always potentially infinitely many plans that compete with a given plan. An agent cannot be expected to survey them all, so it is unrealistic to expect the agent to choose optimal plans. There may not even be optimal plans. For every plan, there may be a better plan” (2006, p. 167). In short, alternative plans may not be comparable because they differ in scope; the injunction to choose an optimal plan from an infinity of possible plans is unrealistic; and optimal plans may not even exist.

What Pollock proposes instead is a theory of real rationality that he calls “locally global planning.” Normal planning is local planning – a plan for getting to Vienna, say. But local plans can be merged to create a global or master plan – to write a definitive book on the *Wiener Kreis*, for example. Local plans are often just good enough to get the agent started, but they can be improved in the attempt to implement them. Even in their improved versions, however, they can be expected to be less than optimal. Yet this does not mean that they are less than rational, for the rationality of real decision makers consists in continually bettering these plans. In short, “a rational decision maker should be an *evolutionary planner*, not an *optimizing planner*” (2006, p. 187).

Pollock recognizes the kinship between locally global planning and satisficing. But he distinguishes them as follows: “Satisficing consists of setting a threshold and accepting plans whose expected utilities come up to the threshold. The present proposal requires instead that any plan with a positive expected utility is defeasibly acceptable, but only defeasibly. If a better plan is discovered, it should supplant the original one. Satisficing would have us remain content with the original” (2006, p. 187 note 4). In Pollock’s view, locally global planning is more adaptable, more responsive to changing circumstances, than satisficing.

Though the debate between maximizers and anti-maximizers rages on (Byron 2004), this is no place for an exhaustive treatment. Nevertheless, since the  Current Research section’s proposal for applying decision theory to real-life decisions is a maximizing proposal, I feel obliged to comment very briefly on Pollock’s critique of maximizing.

The point that some plans cannot be pairwise compared because they have different scopes is well-taken. Someone who is thinking about attending either a 2-year community college or a 4-year college is not considering plans of equal scope. I would suggest, however, that the plans can be compared in either of two ways. One is to supplement the community college plan with whatever additional plan the agent might consider as an alternative to the third and fourth years in a 4-year college. When packaged with this additional plan, the community college plan can be compared to the 4-year college plan with an eye to maximizing. The other approach is to compare only the first and second years at a 4-year college with 2 years at a community college, looking once again for the optimal plan. Evidently, these maneuvers can be adapted to other plans with incongruent scopes.

Pollock also charges that the injunction to choose the optimal plan is unrealistic because “there are always potentially infinitely many plans that compete with a given plan.” The key point here is that a plan is optimal relative to other plans. For an ideal agent, these other plans constitute an infinite set. For a real agent, however, the other plans form a finite subset of the infinite set (cf. Giere 1985, p. 87; Weirich 2004, p. 142). Granted, then, that since a real agent lacks an ideal agent’s ability to evaluate an infinite number of plans, it would be unrealistic to expect her to choose the optimal plan relative to this set. But it would not be unrealistic to

expect her to choose the optimal plan relative to the finite subset she can consider. To fend off this charge of unrealism, then, we only need to ensure that “optimal plan” is realistically understood.

Still, Pollock contends, there may not be optimal plans. A well-known example is Leonard J. Savage’s problem of choosing your income to be some figure less than \$100,000 per year (Savage 1972, p. 18). Since there are an infinite number of options, each with an alternative that has greater utility, there is no optimal plan. As Savage points out, however, the supposition of an infinite number of options requires “abstracting from the indivisibility of pennies”; that is, any system of currency will divide the income continuum between \$0 and \$100,000 into a finite number of intervals, exactly one of which is optimal. But if we ignore the wet blanket of realism and simply postulate an infinite number of options, none of which is optimal, what would that mean for a strategy of maximization? Weirich responds that “The [maximization] rule needs generalization, not correction” (2004, p. 144). In such cases, maximization should be generalized to satisficing. The principle of utility maximization for decisions cited above would become the *principle of utility satisfaction for decisions*: “Among the decisions you can make at a time, make one whose expected utility is satisfactory.” In other words, satisfice.

Note, however, that Weirich’s use of satisficing is different than Simon’s (Weirich 2004, p. 145). Simon proposes satisficing as a decision procedure, whereas Weirich uses it (like the more specific concept of utility maximization) as a standard of evaluation. A decision procedure is, as it were, first person: to make this decision, I will apply this rule. But a standard of evaluation may be first, second, or third person: anyone at all can evaluate a decision by appealing to this standard.

Though no one will confuse the foregoing remarks with a vindication of maximization, I hope that they suffice to show that the maximizing strategy remains a live option. That, at least, is my intention, and I propose to employ this strategy in the quest for decision-theoretic realism below. In order to do this, however, we first need to investigate alternative grounds for the claim that decision theory is unrealistic.

## The Precision Objection

---

As noted in the section [Introduction](#), classical decision theory assumes probability and utility functions that determine sharp numeric values. This is an idealization, however (Weirich 2004, Chaps. 4 and 5); real-life decisions must usually be made with far less numeric information. Inevitably, then, decision theorists face the objection concerning precision: decision theory demands numbers that real-life decision makers rarely possess.

The present subsection canvasses two responses to this objection: one by Henry E. Kyburg, the other by Peter Gärdenfors and Nils-Eric Sahlin. We can set the stage for both responses with a remark by Savage: “One tempting representation of the unsure is to replace the person’s single probability measure  $P$  by a set of such measures, especially a convex set” (1972, p. 58 note +). A convex set of probability measures ensures that, for any probability measures  $p$  and  $p'$  that belong to the set and for  $0 \leq \alpha \leq 1$ ,  $\alpha p + (1 - \alpha)p'$  also belongs to the set. For example, for a state  $s$  where  $p(s) = 0.2$ ,  $p'(s) = 0.4$ , and  $\alpha = 1/2$ ,  $(\alpha p + (1 - \alpha)p')(s) = 0.3$ . In other words, a convex set of probability measures defines a probabilistic interval. Though convex sets of probability measures may not always be appropriate (Kyburg 2006), one approach to the problem of numeric poverty is to retrench by dropping back from point-valued to interval-valued functions.

Drawing on earlier work on interval-valued probability functions (Kyburg 1961; Good 1962; Levi 1974), Kyburg proposes that expected utility is interval valued as well (1979). The gist of the proposal can be conveyed by a simple numeric example. Suppose that the only states relevant to a decision to perform act  $a_1$  or act  $a_2$  are  $s_1$  and  $s_2$ . If the probability of  $s_1$  is the closed interval (0.25, 0.50), then the probability of  $s_2$  is the closed interval (0.75, 0.50). Assume that the outcome utility of performing  $a_1$  when  $s_1$  obtains is 0.80 and the outcome utility of performing the same act when  $s_2$  obtains is 0.40. Then the expected utility of  $a_1$  is:

$$(0.25 \times 0.80, 0.50 \times 0.80) + (0.75 \times 0.40, 0.50 \times 0.40) = (0.50, 0.60).$$

The expected utility of  $a_2$  would be an interval as well.

The expectation intervals for  $a_1$  and  $a_2$  will either overlap or not. If they do not, the principle of maximizing expected utility would require that the act associated with the rightmost interval be chosen. If the intervals do overlap, on the other hand, the coincidence is either total or partial. If total, there is no decision-theoretic reason to choose one act over the other; they are equally choiceworthy. But if the coincidence is partial, the maximizing principle breaks down. In these cases, Kyburg suggests the adoption of an additional rule such as minimax or maximax to complete the decision (Kyburg 1979, p. 434).

Consistent with Savage's remark above, Gärdenfors and Sahlin regard the strict Bayesian assumption that decision makers' beliefs about states can be represented by a single probability measure as unrealistic. They choose to rely on a set  $P$  of epistemically possible probability measures instead (Gärdenfors and Sahlin 1982). They do not insist that  $P$  be convex, though they do discuss the convex special case where probability measures establish probabilistic intervals (1982, pp. 365–366). In this respect, then, their approach is more general than Kyburg's.

Even though Gärdenfors and Sahlin utilize a set of probability measures to represent decision makers' beliefs about states, they claim that not all such beliefs can be represented in this way. In particular, beliefs about the epistemic reliability of the probability measures in  $P$  elude the representation. To illustrate this point, take a spectator who is considering bets on the outcomes of three tennis matches. In the first, the spectator is extremely well informed about the two players and regards them as evenly matched; in the second, the spectator has only heard that one of the players is far superior to the other without hearing which player this is; and in the third, the spectator knows nothing whatever about the tennis skills of the two players. Gärdenfors and Sahlin point out that, relative to the spectator's information, each player has a 50% chance of winning. But the epistemic reliability of these probabilities is different in each case. Specifically, her probability measure for the first match is much more reliable than the probability measures for the other two matches. Gärdenfors and Sahlin propose to take epistemic reliability into account by specifying a real-valued measure  $\rho$  of the epistemic reliability of probability measures.

To do this, they describe a two-step decision procedure. The first step is to restrict the set of epistemically possible probability measures to a subset of epistemically reliable probability measures. Let  $\rho_0$  represent the decision maker's desired level of epistemic reliability. Then  $P/\rho_0$ , the set of epistemically possible probability measures  $P$  given the level  $\rho_0$  of epistemic reliability, is the subset of epistemically reliable probability measures. The members of this set are the probability distributions that the decision maker actually takes into account. The second step of the procedure is to apply the maximin criterion for expected utilities: Choose the act with the highest minimal expected utility. That is, the decision maker calculates the

expected utility of each act for each probability measure in  $P/\rho_0$ , identifies the minimal expected utility for each act, and chooses the act with the highest minimal expected utility.

## Current Research

---

Like the previous section, the present section seeks a more realistic decision theory. In fact, it takes its cue from the interval-based approaches just reviewed. Interval decision theory retrenches by dropping back from point-valued to interval-valued functions. The approach to be floated here attempts to retrench even further by dropping back from interval to comparative functions. The issue to be addressed is the possibility of comparative decision theory: Could decision theory be applied with merely comparative values for probabilities and utilities?

I will suggest an answer to this question in three stages. First of all, the principal assumptions to be employed are laid out in the subsection [● Preliminaries](#). These assumptions are then invoked to develop a comparative approach to binary choices between acts. Finally, this comparative approach is extended to choices among any finite number of acts. Throughout, the focus will be on the partly cognitive and noncognitive decisions characteristic of real-life decision making.

### Preliminaries

---

Due to space limitations, I will introduce the main assumptions underlying the theory baldly, with little or no justification. Only the final assumptions concerning decision rules and relative disutility will require fuller initial treatment. Three of these main assumptions, however, will receive further scrutiny in the section on [● Further Research](#).

*Propositions:* Decision-theoretic acts, states, and outcomes can be thought of as propositions (Jeffrey 1983, pp. 82–85).

*Finitude:* Because real-life decision makers can consider only a finite number of items at a given decision point, acts, states, and outcomes are assumed to be finite (cf. Gärdenfors and Sahlin 1982, p. 364; Weirich 2004, pp. 24, 28, 142).

*Transitivity:* If  $a$  is strictly preferred to  $b$  and  $b$  is strictly preferred to  $c$ , then  $a$  is strictly preferred to  $c$ . (Transitivity is treated in more detail in the first part of the section on [● Further Research](#).)

*Independence:* Let act  $a$  have outcomes  $x$  and  $y$  and act  $b$  have outcomes  $x$  and  $z$ . Then the choice between  $a$  and  $b$  should be made by ignoring the common outcome  $x$  (cf. Maher 1993, pp. 10, 12, 63–83). That is, the decision should be made independently of  $x$ . (Independence is discussed more fully in the second part of the section on [● Further Research](#).)

*Plausibility:* A probability measure may map propositions about states to numbers in the unit interval. But real-life decision makers are often unable to provide reliable numeric probabilities for states. Consequently, I will work with the more general notion of plausibility. A plausibility measure can map propositions about states to members of any partially ordered set (Friedman and Halpern 1995). Though plausibility values can be restricted to the special case of the unit interval (e.g., Klir 2006, p. 166), they can also include qualitative values like high, likely, and impossible provided they are partially ordered. In one influential conception

(Friedman and Halpern 1995), a plausibility function  $\pi$  returns values that are bounded by nonnumeric limits  $\top$  and  $\perp$ , where  $\top$  represents the maximum plausibility and  $\perp$  the minimum plausibility. So conceived,  $\pi$  satisfies the following requirements for propositions  $q$  and  $r$  (cf. Chu and Halpern 2004, pp. 209–210):

- Pl1. If  $q$  is contradictory,  $\pi(q) = \perp$ .
- Pl2. If  $q$  is tautologous,  $\pi(q) = \top$ .
- Pl3. If  $q$  implies  $r$ ,  $\pi(q) \leq \pi(r)$ .

Comparing Pl1–Pl3 to the standard Kolmogorov axioms for probability shows that probability is a special case of plausibility.

*Order:* Classic formulations of decision theory assume that beliefs, desires, and preferences for acts have representations that are totally ordered: either  $a$  is strictly preferred to  $b$ , or  $b$  is strictly preferred to  $a$ , or  $a$  and  $b$  are equally preferred. Even von Neumann and Morgenstern were uneasy about this assumption: “It is very dubious, whether the idealization of reality which treats this postulate as a valid one, is appropriate or even convenient” ([1944]1953, p. 630; cf. Aumann 1962, p. 446; Ok 2002; Ok et al. 2004). I take it to be a simple fact that agents are sometimes unable to reasonably determine whether one utility, plausibility, or preference for an act is greater than, equal to, or less than another. In the interest of realism, therefore, I assume that utilities, plausibilities, and preferences for acts can be incomparable.

To express relations of order in a realistic way, the nonstrict comparative term “ $\preceq$ ” will be drafted as primitive. The  $\preceq$  relation establishes a partial order; that is, it is reflexive, antisymmetric, and transitive.

In the context of plausibility, “ $\preceq$ ” can be read as “is less plausible than or equally plausible to” or “is not more plausible than.” The following plausibility relations are straightforwardly definable in terms of it, conjunction (“ $\wedge$ ”), and negation (“ $\neg$ ”):

$$\begin{aligned} \text{Infraplausibility } [\pi(s_1, e) < \pi(s_2, e)] &=_{\text{df}} [\pi(s_1, e) \preceq \pi(s_2, e)] \wedge -[\pi(s_2, e) \preceq \pi(s_1, e)] \\ \text{Supraplausibility } [\pi(s_1, e) > \pi(s_2, e)] &=_{\text{df}} -[\pi(s_1, e) \preceq \pi(s_2, e)] \wedge [\pi(s_2, e) \preceq \pi(s_1, e)] \\ \text{Equiplausibility } [\pi(s_1, e) = \pi(s_2, e)] &=_{\text{df}} [\pi(s_1, e) \preceq \pi(s_2, e)] \wedge [\pi(s_2, e) \preceq \pi(s_1, e)] \\ \text{Incomparability } [\pi(s_1, e) \mid \pi(s_2, e)] &=_{\text{df}} -[\pi(s_1, e) \preceq \pi(s_2, e)] \wedge -[\pi(s_2, e) \preceq \pi(s_1, e)]. \end{aligned}$$

The primitive “ $\preceq$ ” will be used in different settings, and its context will determine its sense. In addition to the plausibilistic usage just described, “ $v(o_1) \preceq v(o_2)$ ” can be read as “the utility of outcome  $o_1$  is no greater than the utility of outcome  $o_2$ ” and “ $PE(a_1) \preceq PE(a_2)$ ” as “the plausibilistic expectation of act  $a_1$  is no greater than the plausibilistic expectation of act  $a_2$ ” (plausibilistic expectation is defined just below). With these nonstrict relations as primitives, relations of utility and plausibilistic expectation analogous to infraplausibility, supraplausibility, equiplausibility, and incomparability can be easily defined.

*Decision rules:* To have a single, all-purpose decision rule would be ideal. Unfortunately, the prospects for finding one are not very good. The principal reason for this is the hard fact of incomparability. Situations in which plausibilities or utilities are incomparable are so different from situations in which both plausibilities and utilities are comparable that I think we are unlikely to find a single rule that suits all occasions. However, the prospects are good, I think, for finding a suite of decision rules that cover the spectrum of comparable and incomparable data. In fact, it is possible to find three cognate decision rules to carry out this task. These three rules will be introduced in the following paragraphs.

Before these rules are stated, I will sketch the general framework that relates them to each other. Savage famously showed that preferences for one act over another can be represented by

comparative relations between expected utilities (1972, pp. 69–82). Savage's representation theorem has a plausibilistic generalization, as Francis Chu and Joseph Halpern have demonstrated (2008, pp. 12–13). To sketch this result, we assume states of the world  $s_1, s_2, \dots, s_n$  and corresponding state plausibilities  $\pi(s_1, e), \pi(s_2, e), \dots, \pi(s_n, e)$  based on the evidence  $e$ . We also assume that performing act  $a$  when exactly one of  $s_1, s_2, \dots, s_n$  obtains would produce outcomes  $o_1, o_2, \dots, o_n$ , respectively, and that these outcomes have utilities  $v(o_1), v(o_2), \dots, v(o_n)$ . In addition, we rely on Chu and Halpern's notion of generalized expected utility. This generalization of expected utility is defined for an expectation domain  $D = (U, P, V, \oplus, \otimes)$ , where  $U$  is a set of utility values ordered by a reflexive binary relation  $\leq_u$ ;  $P$  is a set of plausibility values ordered by a binary relation  $\preceq_p$  that is reflexive, antisymmetric, and transitive;  $V$  is a set of expectation values ordered by a reflexive binary relation  $\leq_v$ ; the multiplication-like operation  $\otimes$  maps  $U \times P$  to  $V$ ; and the addition-like operation  $\oplus$  maps  $V \times V$  to  $V$  (2004, pp. 209–211; 2008, pp. 6–10). Then the generalized expected utility  $GEU$  of  $a$  given  $e$  can be expressed as:

$$GEU_{a,e} = \bigoplus_{i=1}^n v(o_i) \otimes \pi(s_i, e).$$

Chu and Halpern show that, where  $\leq_A$  is a preference relation over a set  $A$  containing a finite number of acts  $a_1, a_2, \dots, a_n$ ,

$$a_1 \leq_A a_2 \text{ iff } GEU(a_1) \leq GEU(a_2)$$

That is, preferences for acts can be represented by comparative relations between generalized expected utilities.

The decision rule associated with  $GEU$  is to maximize generalized expected utility. As Chu and Halpern point out, this rule is universal in the following sense: it establishes the same ordinal rankings as any decision rule that satisfies a trivial condition. The condition is that the rule weakly respect utility, that is, that act preferences track outcome utilities for all constant acts (2004, pp. 216, 219, 226–227). Constant acts are constant in the sense that their outcomes do not depend on states of the world (Savage 1972, p. 25).

For the purposes of real-life decision making, I propose to adopt three special forms of Chu and Halpern's decision rule. The principal rule is the first; the other two cover very special cases. To introduce this first rule, let  $D = (U, P, T, V, \oplus, \otimes)$  be an expectation domain whose elements are defined as follows.  $U$  is the set of utility and disutility values  $\{U, u, -u, -U\}$  such that  $-U < -u < u < U$ .  $P$  is the set of plausibility values  $\{p, P\}$  such that  $p < P$ .  $\otimes$  is the multiplication-like operation that maps  $U \times P$  to  $T$ .  $T$  is therefore the set of product values  $\{-UP, -uP, -Up, -up, up, uP, Up, UP\}$  to be used in calculating plausibilistic expectation. These values are ordered according to the following specifications, where “|” is used analogously to its prior function in expressing incomparable plausibilities, utilities, and plausibilistic expectations:

1. Positive values:  $up < uP < UP; up < Up < UP; uP | Up$
2. Negative values:  $-UP < -uP < -up; -UP < -Up < -up; -uP | -Up$
3. Mixed values: for all  $x, y \in T$ ,  $(x < 0 \wedge y > 0) \rightarrow (x < y)$ .

$\oplus$  is the addition-like operation that maps  $T \times T$  to  $V$ . This operation, which is commutative, is defined for all  $x, y \in T$  and their absolute values  $|x|, |y|$  as follows:

1.  $(x < 0 \wedge y < 0) \rightarrow ((x \oplus y) = -)$ .
2.  $(x < 0 \wedge y > 0 \wedge |x| < |y|) \rightarrow ((x \oplus y) = +)$ .

3.  $(x < 0 \wedge y > 0 \wedge |x| = |y|) \rightarrow ((x \oplus y) = 0).$
4.  $(x < 0 \wedge y > 0 \wedge |x| > |y|) \rightarrow ((x \oplus y) = -).$
5.  $(x > 0 \wedge y > 0) \rightarrow ((x \oplus y) = +).$

The operation remains undefined for the sums “ $Up \oplus -uP$ ” and “ $-Up \oplus uP$ ” since the absolute values of the addends are incomparable. Finally,  $V$  is the set of plausibilistic expectation values  $\{-, 0, +\}$  ordered in the obvious way so that  $- < 0 < +$ .

Relative to  $D$ , we assume attributable states  $s_1, s_2, \dots, s_n$  and a plausibility function  $\pi$  that maps these states onto the values of  $P$ . In addition, we assume outcomes  $o_1, o_2, \dots, o_n$  and a utility function  $v$  that maps these outcomes onto the values of  $U$ . Then, the plausibilistic expectation ( $PE$ ) of an act  $a$  given evidence  $e$  can be defined as follows:

$$PE_{a,e} = \bigoplus_{i=1}^n v(o_i) \otimes \pi(s_i, e).$$

The right-hand side of  $PE$  is typographically identical to that of  $GEU$ , but their meanings are quite different;  $PE$  is a highly specific instance of  $GEU$ . The decision rule associated with  $PE$  is to maximize plausibilistic expectation.

To introduce the second and third decision rules, we need to pay closer attention to the consequences of order. In the foregoing remarks on order, we assumed that the  $\preceq$  relation establishes a partial order on utilities, for example. This permits a utility to be neither less than, equal to, or greater than another. Such utilities are therefore incomparable. The upshot is that, in such cases,  $PE$  cannot be applied. Let  $?_1$  and  $?_2$  be incomparable utilities and  $p_1$  and  $p_2$  comparable plausibilities. Then, the products in

$$(?_1 \otimes p_1) \oplus (?_2 \otimes p_2)$$

are incomparable, and the summation cannot be carried out (cf. Weirich 2004, p. 59). Like applications of  $E$  for expected utility, applications of  $PE$  require that outcome utilities be comparable. For analogous reasons,  $E$  demands comparable state probabilities and  $PE$  comparable state plausibilities. But utilities, probabilities, and plausibilities are sometimes incomparable in real-life decision making.

How might we deal with these incomparabilities in a rational way? One possibility is to shelve decision theory in any situation with incomparable plausibilities or utilities. A second possibility is to adapt the decision rule based on  $PE$  to the situation. Unfortunately, adopting the first option requires an answer to the question “What decision rule should be used instead?” Since I do not have a viable answer to this question, I favor the second option: adapt the decision rule to the situation.

There are actually two types of situation that call for adaptation. The first is where utilities are comparable while plausibilities are not; the second, where plausibilities are comparable but utilities are not. I will refer to the first type of situation as “utility-comparable” and to the second as “plausibility-comparable.” In both types of situation, I suggest, we should be guided by a common-sense notion: where just two criteria are relevant to a decision but one is inapplicable, we rely on the other criterion instead. Adherence to this notion in making real-life decisions would require ignoring any incomparable values, since nothing useful can be obtained from them, and relying on the comparable values.

In utility-comparable situations, the expectation domain  $D$  would become  $D_u = (U, P, T, V, \oplus, \otimes)$  with elements defined as follows.  $U$ ,  $V$ , and  $\oplus$  have the same meanings as for  $PE$ .  $P$  is the set of incomparable plausibility values  $\{p_1, p_2, \dots, p_n\}$ .  $\otimes$  is defined so that incomparable

plausibilities become right-identity elements; that is, for all  $u \in \mathbf{U}$  and all  $p \in \mathbf{P}$ ,  $u \otimes p = u$ . As a consequence,  $\mathbf{T} = \mathbf{U}$ .  $PE$  then reduces to the following definition of utility-comparable expectation ( $UCE$ ):

$$UCE_{a,e} = \bigoplus_{i=1}^n v(o_i).$$

The corresponding decision rule is to maximize utility-comparable expectation.

In plausibility-comparable situations, the expectation domain  $\mathbf{D}$  would become  $\mathbf{D}_p = (\mathbf{U}, \mathbf{P}, \mathbf{T}, \mathbf{V}, \bigoplus, \otimes)$ , defined analogously to  $\mathbf{D}_u$ .  $\mathbf{P}, \mathbf{V}$ , and  $\bigoplus$  retain their original meanings.  $\mathbf{U}$  is the set of incomparable utilities and disutilities  $\{u_1, u_2, \dots, u_n, -u_1, -u_2, \dots, -u_n\}$ .  $\otimes$  is defined so that incomparable utilities are left-identity elements and incomparable disutilities are negative left-identity elements; that is, for all  $u, -u \in \mathbf{U}$  and all  $p \in \mathbf{P}$ ,  $u \otimes p = p$  and  $-u \otimes p = -p$ . Therefore,  $\mathbf{T} = \{-P, -p, p, P\}$ , ordered in the obvious way. Accordingly,  $PE$  contracts to this definition of plausibility-comparable expectation ( $PCE$ ):

$$PCE_{a,e} = \bigoplus_{i=1}^n \pi(s_i, e).$$

The associated decision rule is to maximize plausibility-comparable expectation.

What I am proposing, then, is a suite of three decision rules: for fully comparable situations, maximize  $PE$ ; for utility-comparable situations, maximize  $UCE$ ; and for plausibility-comparable situations, maximize  $PCE$ . All three senses of expectation are special cases of Chu and Halpern's  $GEU$ . All three rules are motivated by the common-sense injunction "Use comparable data!"

*Relative disutility:* Jaakko Hintikka and Juhani Pietarinen propose to treat the epistemic utility of a hypothesis  $h$  and its contradictory  $\neg h$  as follows: "If  $h$  is true, the utility of his [the agent's] decision is the valid information he has gained. ... If  $h$  is false, it is natural to say that his disutility or loss is measured by the information he lost because of his wrong choice between  $h$  and  $\neg h$ , i.e., by the information he would have gained if he had accepted  $\neg h$  instead of  $h$ " (Hintikka and Pietarinen 1966, pp. 107–108; cf. Hintikka 1970, p. 16). This proposal for the utilities  $u$  of  $h$  and  $\neg h$  can be summed up by  $\circledast$  Table 21.1, where  $s_h$  and  $s_{\neg h}$  are states of the world posited by  $h$  and  $\neg h$ , respectively.

We are not concerned here with epistemic utility, but the Hintikka–Pietarinen proposal can be extended in the direction of our present interests. Because the choice of a hypothesis is an act, the proposal might be generalized for acts  $a_1$  and  $a_2$ , states  $s_1$  and  $s_2$ , and the outcome  $o_1$  of choosing  $a_1$  when  $s_1$  obtains and the outcome  $o_2$  of choosing  $a_2$  when  $s_2$  obtains. The generalized proposal can be summarized by  $\circledast$  Table 21.2.

We gain perspective on this generalization by noting the distinction between intrinsic utility and relative utility. (An analogous distinction can be drawn between intrinsic and

**Table 21.1**  
The Hintikka–Pietarinen proposal

	$s_h$	$s_{\neg h}$
$h$	$u(h)$	$-u(\neg h)$
$\neg h$	$-u(h)$	$u(\neg h)$

**Table 21.2****The Hintikka–Pietarinen proposal generalized**

	$s_1$	$s_2$
$a_1$	$u(o_1)$	$-u(o_2)$
$a_2$	$-u(o_1)$	$u(o_2)$

relative probability [Levi 1967, p. 98]). The intrinsic utility of some outcome is its utility considered in itself, without reference to other utilities. By contrast, the relative utility of an outcome is its utility compared to another utility. The intrinsic utility of an information outcome of 2 kb, say, would typically be small and positive because, considered in itself, it would be valued slightly. But the relative utility of the same outcome would be large and negative if we have to forego 1,000 kb of information in order to obtain it; that is, we would not prefer 2 kb of information but would greatly prefer 1,000. Hintikka and Pietarinen operate along the same relative lines. To say that the disutility of choosing  $h$  given  $s_h$  is  $-u(-h)$  and the disutility of choosing  $-h$  given  $s_h$  is  $-u(h)$  is to rely on relative disutilities.

Further perspective can be gained by underlining the distinction between the Hintikka–Pietarinen proposal and its foregoing generalization. Though the generalization is inspired by the Hintikka–Pietarinen proposal, there are several crucial differences. Here I mention only three.

The first is that Hintikka and Pietarinen's application of decision theory assumes numeric values for probabilities and utilities; by contrast, the decision theory outlined in these pages is comparative. It relies on comparative relations of plausibility, utility, and plausibilistic expectation. The practical import of this difference would be difficult to overstate. Because plausibilities and utilities can be specified using a bare minimum of comparative values, comparative decision theory can be applied in real-life situations that are just too amorphous for numeric forms of decision theory. It therefore signals an advance in the quest for a more realistic theory of decision recapped in the section  [Introduction](#).

The scope of the respective proposals constitutes a second difference. Hintikka and Pietarinen apparently meant for relative disutilities to be used in any choice between contradictory hypotheses. What I am proposing, by contrast, is spot duty. Relative disutilities can be useful in situations that are repeated over and over again in real-life decision making, situations in which utilities are only comparable in nonnumeric terms. That is, we may estimate one utility to be greater than another without being able to estimate how much greater it is. Relative disutilities are meant to be used in these situations. If, on the other hand, we can compare utilities in numeric terms, it goes without saying that we should use the more precise numeric comparison instead.

A third difference is that comparative decision theory generalizes the Hintikka–Pietarinen proposal in a sense we have yet to notice. Hintikka and Pietarinen were concerned with the binary case of contradictory hypotheses, but many options are not so neatly related. The propositions associated with nonidentical acts are often contraries instead of contradictories. Hence the comparative decision theory below generalizes Hintikka and Pietarinen's approach to cover more typical cases of choice where the propositions in play may be contraries as well as contradictories. This generalization is carried out as follows.

We begin by distinguishing total outcome, shared outcome, and unique outcome. An act's *total outcome* is its full set of consequences. An act's *shared outcome* is any part of its total

outcome that can be obtained by performing another act under consideration. An act's *unique outcome* is any part of its total outcome that cannot be obtained by performing other acts under consideration. Here is a simple example: if one act results in a share of stock and a samovar while another results in the same share of stock and a stone, the stock is the shared outcome of both acts; the samovar is the unique outcome of the first act; and the stone is the unique outcome of the second.

To expand the notion of relative disutility to options that may be contraries as well as contradictories, we note that the outcomes of acts  $a_1$  and  $a_2$  either overlap or not. If they do not, the total outcome of an act is identical to its unique outcome. This case would differ only slightly from the contradictory options of the Hintikka–Pietarinen scenario. That is, the outcome of choosing  $a_1$  would have any utility  $u_1$  produced by that act or the loss of any utility  $u_2$  provided by  $a_2$ . Alternatively, the outcome of choosing  $a_2$  would have utility  $u_2$  or disutility  $-u_1$ . Unlike the Hintikka–Pietarinen scenario, however, the propositions identified with  $a_1$  and  $a_2$  may be contraries, not contradictories, and so not jointly exhaustive. There may be a third option  $a_3$ . If so, we proceed as follows. Say that comparative decision theory permits the determination that  $a_1$  is inferior to  $a_2$ . The procedure can then be repeated for  $a_2$  and  $a_3$ . Like the outcomes of  $a_1$  and  $a_2$ , the outcomes of  $a_2$  and  $a_3$  either overlap or not. If they do not, we proceed as in this paragraph; if they do, we proceed as in the next one.

If the outcomes do overlap, the overlap may be total or partial. If total, there is no unique outcome because the acts lead to exactly the same outcome. Regardless of which act is chosen, then, the utility or disutility of this outcome would be the same:  $u$  or  $-u$ . If the overlap is partial, on the other hand, there are shared and unique outcomes. Because the shared outcome would be obtained whether the agent chooses  $a_1$  or  $a_2$ , it could not motivate the choice of one act rather than the other. According to the principle of independence, we would disregard the shared outcome and focus on unique outcomes. Suppose that  $a_1$  and  $a_2$  are acts whose associated propositions are contraries and that a unique outcome of  $a_1$  has utility  $u_1$  and a unique outcome of  $a_2$  has utility  $u_2$ . If the agent chooses  $a_1$ , she loses any utility offered by  $a_2$  but not by  $a_1$ ; she could have obtained this utility by choosing  $a_2$  instead. The disutility of this choice would be  $-u_2$ . Alternatively, if the agent chooses  $a_2$ , the disutility of this choice would be the loss of any utility uniquely provided by  $a_1$ . This disutility is  $-u_1$ .

In summary, even if the propositions associated with  $a_1$  and  $a_2$  are contraries, the outcomes of  $a_1$  and  $a_2$  are either completely distinct or not. If they are completely distinct, the situation is fundamentally no different for contraries than for contradictories. If the outcomes are not completely distinct, the overlap is total or partial. If total, the outcomes have the same utility or disutility; but if partial, the principle of independence authorizes choice based on unique outcomes alone. In cases of partial overlap, choice of one act relinquishes any unique outcome that would result from choice of the other. Hence any utility of an unattained unique outcome would also be lost. If the unique outcome of choosing one act has utility  $u$ , the relative disutility of the outcome of choosing the alternative act is  $-u$ . We can therefore generalize the Hintikka–Pietarinen proposal to include options that are contraries as well as contradictories.

## The Binary Case

Suppose that we are faced with a binary choice: act  $a_1$  or act  $a_2$ . Some of the states relevant to this choice may invite  $a_1$  in the sense that performing the act when these states obtain would

**Table 21.3****Binary cases for comparative decision theory**

13		<
14		>
15		=
16		

produce desirable outcomes – desirable relative to other possible outcomes. Other states may invite  $a_2$  in an analogous sense. For example, if you are debating whether to take your umbrella or not, the state of rain today invites taking the umbrella and the state of no rain today invites leaving it at home. The plausibilities of these relevant states exhibit relations of infraplausibility ( $<$ ), supraplausibility ( $>$ ), equiplausibility ( $=$ ), or incomparability ( $|$ ). Structurally analogous relations hold among the utilities of the outcomes given the various act-state pairs. Hence there are 16 possible cases.

These cases are summarized in [Table 21.3](#). In order to highlight essentials, the table employs abbreviations. For example, “ $<$ ” in the plausibility column abbreviates “ $\pi(s_1, e) < \pi(s_2, e)$ ,” which says that the plausibility of the  $s_1$  states that invite  $a_1$  given the total evidence  $e$  is less than the plausibility of the  $s_2$  states that invite  $a_2$  given  $e$ . In other words, plausibility considerations favor  $a_2$ . Similarly, “ $<$ ” in the utility column is short for “ $v(o_1) < v(o_2)$ ,” which says that the utility of outcome  $o_1$  from choosing  $a_1$  is less than the utility of outcome  $o_2$  from choosing  $a_2$ . In this case, utility considerations favor  $a_2$ .

These cases fall naturally into seven groups, the first of which is formed by cases 1 and 6. Let “ $U$ ” and “ $u$ ” express higher and lower utility while “ $P$ ” and “ $p$ ” stand for higher and lower plausibility. In case 1,  $a_1$  provides utility  $u$  with plausibility  $p$  and disutility  $-U$  with plausibility  $P$ , but  $a_2$  yields utility  $U$  with plausibility  $P$  and disutility  $-u$  with plausibility  $p$ . To choose between the acts, we employ the decision rule of maximizing plausibilistic expectation. Where plausibilistic expectation is defined by  $PE$ , the plausibilistic expectation of  $a_1$  is

$$PE_1 = up \oplus -UP = -.$$

Similarly,  $PE$  determines the plausibilistic expectation of  $a_2$ :

$$PE_2 = -up \oplus UP = +.$$

Because the plausibilistic expectation of  $a_1$  is negative while that of  $a_2$  is positive,  $a_1$  is inferior to  $a_2$ . A parallel argument for case 6 shows that  $a_2$  is inferior to  $a_1$ .

The second group includes cases 3, 7, 9, and 10, which have one relation that is  $=$  while the other is either  $<$  or  $>$ . Suppose that there are two routes to a vacation destination and that the only relevant criteria for choice are cost and comfort. Suppose also that the routes are equally costly but one is more comfortable than the other. Then the more comfortable route should be chosen. Generally, in any choice with two relevant criteria and a tie with respect to one of them, common sense recommends that the other criterion be decisive. Case 3 follows this advice. Here  $a_1$  offers utility  $U$  with plausibility  $p$  and disutility  $-U$  with plausibility  $P$ ; for  $a_2$ , the plausibilities are reversed. Because the acts are tied with respect to utility, the tie is broken by plausibility. According to  $PE$ , the plausibilistic expectation of  $a_1$  is

$$PE_1 = Up \oplus -UP = -,$$

while that of  $a_2$  is

$$PE_2 = -Up \oplus UP = +.$$

Since the plausibilistic expectation of  $a_2$  is positive and that of  $a_1$  is negative,  $a_2$  is superior to  $a_1$ .

The sparsely populated third group is made up of case 11 alone. This case differs from those of the second group because not just one but both relations are  $=$ .  $PE$  would give the plausibilistic expectation of both acts as

$$PE = UP \oplus -UP = 0.$$

Note that an expectation of 0 does not imply that the associated act has no intrinsic utility or disutility. Like our other expectations, this expectation is comparative. Hence there is no comparative advantage for either act – a tie.

Cases 13, 14, and 15 comprise a fourth group, whose members have a plausibility relation that is  $\mid$  and a utility relation that is not  $\mid$ . Since these cases are utility-comparable, the relevant sense of expectation is  $UCE$ . We thereby ignore the incomparable plausibilities and base the decision on utility alone. In case 13, for example, the utility-comparable expectation of  $a_1$  would be

$$UCE_1 = u \oplus -U = -,$$

while that of  $a_2$  would be

$$UCE_2 = -u \oplus U = +.$$

Because the utility-comparable expectation of  $a_1$  is negative while that of  $a_2$  is positive,  $a_2$  is the better choice.

A fifth group contains cases 4, 8, and 12, which have a utility relation that is  $\mid$  and a plausibility relation that is not  $\mid$ . Because the members of this group are plausibility-comparable, the appropriate definition of expectation is  $PCE$ . Applying it to case 4 gives the plausibility-comparable expectation of  $a_1$  as

$$PCE_1 = p \oplus -P = -$$

and that of  $a_2$  as

$$PCE_2 = -p \oplus P = +.$$

Since the plausibility-comparable expectation of  $a_2$  is positive and that of  $a_1$  is negative, the choice should be  $a_2$ .

Cases 2 and 5 constitute a sixth group. Its members are heterogeneous in that each act compares favorably in one respect but unfavorably in the other. Consider case 2, for instance. Where  $a_1$  has more utility but less plausibility, its plausibilistic expectation would be

$$PE_1 = Up \oplus -uP.$$

By contrast, the plausibilistic expectation of  $a_2$  would be

$$PE_2 = -Up \oplus uP.$$

As noted in the [Preliminaries](#) subsection of [Current Research](#), the  $\oplus$  operation is undefined in both cases. There is no way to compare the plausibilistic expectations without knowing how much more desirable the outcomes of  $a_1$  are and how much more plausible the states that invite  $a_2$  are. In these cases, therefore, we can reach no decision.

Only case 16 remains. Like cases 2 and 5, it results in no decision, but it does so for a different reason. In cases 2 and 5, comparative decision theory breaks down. In case 16, however, it cannot even start up; since both plausibility and utility are incomparable, comparative decision theory – like any other form of decision theory – can say nothing at all.

These three problem cases are not equally problematic. Unlike case 16, cases 2 and 5 can sometimes be resolved on a case-by-case basis. Take a decision about whether or not to attend an academic conference, for example. Although serious accidents can happen at home, venturing out onto the highways and airways of the conference circuit most likely increases the plausibility of a serious accident. Hence plausibilistic considerations would encourage us to stay home, yet many of us decide not to do so. Why? Because we take the far greater utility of a conference to outweigh the slightly greater plausibility of a travel accident. On the other hand, if we were to judge the plausibility of a travel accident to be significantly higher than the plausibility of an accident at home, we would choose to stay home. This is a rational choice provided we assign a normal (very great) disutility to serious bodily harm. The writer once opted out of a conference in Turkey because he estimated the plausibility of war spilling over from northern Iraq to Turkey to be decidedly higher than the plausibility of an accident at home.

Note that our results acknowledge the difference between indifference and indecision. Cases 11, 12, and 15 result in indifference: there is a good decision-theoretic reason to choose  $a_1$  and a good decision-theoretic reason to choose  $a_2$ . But cases 2, 5, and 16 terminate in indecision: there is no decision-theoretic reason to choose  $a_1$  and no decision-theoretic reason to choose  $a_2$ .

It is sometimes overlooked that even though the indifference judgments in cases 11, 12, and 15 do not assert that  $a_1$  is superior to  $a_2$  or vice versa, they do make an assertion. They assert that  $a_1$  is as good as  $a_2$ . This is a disjunctive judgment, analogous to the disjunctive solutions proposed in the literature on moral dilemmas (Greenspan 1983, pp. 117–118; Gowans 1987, p. 19; Zimmerman 1996, pp. 209, 220–221). Disjunctive judgments do valuable cognitive work. Consider the four basic possibilities for binary choice of any kind: option 1, option 2, both option 1

■ **Table 21.4**  
Binary cases with resolutions

Case	Plausibility	Utility	Resolution
1	<	<	$a_2$
2	<	>	No decision
3	<	=	$a_2$
4	<		$a_2$
5	>	<	No decision
6	>	>	$a_1$
7	>	=	$a_1$
8	>		$a_1$
9	=	<	$a_2$
10	=	>	$a_1$
11	=	=	$a_1$ or $a_2$
12	=		$a_1$ or $a_2$
13		<	$a_2$
14		>	$a_1$
15		=	$a_1$ or $a_2$
16			No decision

and option 2, neither option 1 nor option 2. An agent who forms the judgment “ $a_1$  or  $a_2$ ,” as in cases 11, 12, and 15, has already rejected the neither option. And, since the acts cannot be chosen simultaneously, the agent *might* feel compelled by circumstances to choose one of them even though she has no reason to choose it over the alternative. The agent would have made a disjunctive judgment that excludes two of the four basic options: neither and both.

The results of our discussion can now be summarized in ▶ **Table 21.4**. Of the 16 cases represented there, 13 are resolvable in comparative terms; only 3 are not.

## The Finite General Case

One of the assumptions in the ▶ **Preliminaries** subsection is that real-life decision makers can consider only a finite number of acts at a given moment. This makes the foregoing analysis of the binary case critical. For if it is possible to choose between  $a_1$  and  $a_2$  such that  $a_2$ , say, is the winner, then it is also possible in principle to choose between  $a_2$  and any act  $a_3$ . The winner can then be compared with any act  $a_4$ , and so on.

Here we rely on the additional assumption that act preference is transitive. The transitivity of preference is routinely affirmed by decision theorists (Savage 1972, p. 18; Jeffrey 1983, pp. 144–145; Maher 1993, p. 60), yet this affirmation has been repeatedly challenged (e.g., Hughes 1980; Black 1985; Baumann 2005). Since transitivity is discussed in greater depth in the section on ▶ **Further Research**, for the moment I will limit myself to the two following claims. First, even if act preference should turn out to be intransitive, binary choice could still be

completed on comparative grounds, for transitivity is irrelevant when there are only two options. Comparative decision theory can always be applied to any two acts under consideration. Second, the assumption that act preference is transitive, if properly understood and suitably employed, does in fact hold. The main consideration is to restrict transitive inference to the same sense of “preference.” That is, we need to avoid equivocation.

To see the damage that equivocation can wreak, let us consider a relatively transparent instance. Max Black attempted to show that intransitive preferences can be rational by instancing job candidates A, B, and C who are rated for expertise, congeniality, and intelligence on a scale of 1–3, where 3 is high (1985). Their scores for each characteristic in the order mentioned are as follows:

A: 3, 2, 1

B: 1, 3, 2

C: 2, 1, 3.

Given these scores, an employer would prefer A to B (for expertise), B to C (for congeniality), and C to A (for intelligence). Hence, it appears, transitivity is violated but not rationality.

That transitivity is violated is a mere appearance, however, thrown up by simple equivocation. We have cycled from preferred-for-expertise to preferred-for-congeniality to preferred-for-intelligence. Jumbling these three senses of preference together can create problems in much the same way as mixing binary, decimal, and hexadecimal numerals. Decision-theoretic preference is not preference for one characteristic and then another; it is preference overall. “I am concerned with preference *all things considered*, so that one can prefer buying a Datsun to buying a Porsche even though one prefers the Porsche *qua* fast (e.g., since one prefers the Datsun *qua* cheap, and takes that desideratum to outweigh speed under the circumstances)” (Jeffrey 1983, p. 225). If an employer were to have an *overall* preference for A to B, B to C, and C to A, we would have a genuine violation of transitivity. But we would also have a violation of rationality.

The moral: equivocation can produce apparent violations of transitivity. This issue is treated in more detail in the section on [Further Research](#).

## Further Research

The comparative decision theory just outlined is based on the assumptions identified in the [Preliminaries](#) subsection of [Current Research](#). However, most of these assumptions were simply postulated without any attempt at justification. Though this cannot be remedied completely here, I do want to inquire into three of these assumptions in particular: transitivity, independence, and the proposed decision rules. These assumptions mark choice nodes even for those working within alternative decision-theoretic frameworks. Hence the following remarks are offered as suggestions for further research.

## Transitivity

Within the confines of comparative decision theory, transitivity can be an issue at three different levels. At the most basic level, if plausibility  $p_1$  (or utility  $u_1$ ) is greater than plausibility

$p_2$  (or utility  $u_2$ ), and  $p_2$  (or  $u_2$ ) is greater than plausibility  $p_3$  (or utility  $u_3$ ), then we might infer that  $p_1$  (or  $u_1$ ) is greater than  $p_3$  (or  $u_3$ ). Such inferences, including analogous inferences with the relations of equal to, less than, and incomparable to, exhibit *factor transitivity*. At a second level, whenever a product  $r_1$  of utility and plausibility is equal to another such product  $r_2$  and  $r_2$  is equal to a third such product  $r_3$ , we may conclude that  $r_1$  is equal to  $r_3$ . Along with similar inferences involving the relations greater than, less than, and incomparable to, these inferences instantiate *product transitivity*. Finally, if the plausibilistic expectation of act  $a_1$  is less than the plausibilistic expectation of act  $a_2$  and that of  $a_2$  is less than that of act  $a_3$ , then we may deduce that the plausibilistic expectation of  $a_1$  is less than that of  $a_3$ . Such inferences, including parallel inferences with the relations of greater than, equal to, and incomparable to, display *expectation transitivity*.

Factor transitivity and product transitivity are both relatively transparent and relatively peripheral to our present concerns. They are relatively transparent because the inferences involve a single, clearly articulated relation:  $>$ ,  $<$ ,  $=$ , or  $\mid$  as already defined for factor relata (in the [Preliminaries](#) subsection of [Current Research](#)) and analogously definable for product relata. For example, if one plausibility is greater than a second and this second is greater than a third, the plausibility of the first must be greater than the third. Nevertheless, factor transitivity and product transitivity are relatively peripheral for our purposes because the extension of comparative decision theory from the binary to the finite general case appeals to expectation transitivity, not factor or product transitivity. We want to be able to infer, say, that the expectation of act  $a_1$  is equal to that of act  $a_3$  simply because the expectation of  $a_1$  is equal to that of act  $a_2$  and that of  $a_2$  is equal to that of  $a_3$ . The inference permits a comparative evaluation of  $a_1$  and  $a_3$  without having to compare them directly.

Let us therefore turn to expectation transitivity. Our discussion requires attention to three types of *homogeneous groups*. *Fully comparable groups* are composed of one or more binary comparisons in which the utilities and plausibilities are comparable in terms of greater than, equal to, or less than. For example, a comparison of act  $a_1$  and act  $a_2$  where all utilities are comparable and all plausibilities are comparable would constitute a fully comparable group. *Utility-comparable groups* are formed by one or more binary comparisons in which the utilities are comparable while the plausibilities are incomparable. *Plausibility-comparable groups* consist of one or more binary comparisons in which the plausibilities are comparable but the utilities are incomparable.

Fully comparable groups appear to pose no problems for transitivity. The relata, which are plausibilistic expectations ( $PE$ ), form a homogeneous set. If we are considering acts  $a_1$ ,  $a_2$ , and  $a_3$  where  $PE(a_1) < PE(a_2)$  and  $PE(a_2) < PE(a_3)$ , then  $PE(a_1) < PE(a_3)$ .

The other homogeneous groups are similarly transparent. Consider acts  $a_1$ ,  $a_2$ , and  $a_3$  with outcome utilities that are comparable but state plausibilities that are incomparable. Since this is a utility-comparable group, the appropriate decision rule is based on utility-comparable expectation ( $UCE$ ). Let  $UCE(a_1) > UCE(a_2)$  and  $UCE(a_2) > UCE(a_3)$ . Then, straightforwardly,  $UCE(a_1) > UCE(a_3)$ . Parallel remarks apply to plausibility-comparable groups.

Unfortunately, not all groups are as well behaved. The decision rules based on  $PE$ ,  $UCE$ , and  $PCE$  all assume homogeneity: for a given choice, all the utilities and plausibilities are fully comparable, or they are all utility-comparable, or they are all plausibility-comparable. At times, however, some utilities and plausibilities may be fully comparable while others can be either utility-comparable or plausibility-comparable. These heterogeneous decision problems are characterized by *mixed groups*.

**Table 21.5** **$a_1$  or  $a_3$ ?**

	$\pi(s_1) = p$	$\pi(s_2) = P$
$a_1$	$v(o_1) = U$	$v(o_2) = -u$
$a_3$	$v(o_3) = -U$	$v(o_4) = u$

Watch what can happen when we attempt transitive inference across mixed groups. Let acts  $a_1$  and  $a_2$  be utility-comparable such that  $UCE(a_1) > UCE(a_2)$ . In addition, acts  $a_2$  and  $a_3$  are utility-comparable such that  $UCE(a_2) > UCE(a_3)$ . But let  $a_1$  and  $a_3$  be fully comparable. Their comparison is represented by [Table 21.5](#), where  $\pi$  is a plausibility function;  $s_1$  and  $s_2$  are relevant states;  $p$  and  $P$  are state plausibilities such that  $p < P$ ;  $v$  is a utility function;  $o_1, o_2, o_3$ , and  $o_4$  are outcomes of act-state pairs; and  $U, u, -u, -U$  are outcome utilities such that  $-U < -u < u < U$ . According to the analysis in the section [Current Research](#), the comparison of  $a_1$  and  $a_3$  should result in no decision because the decision-theoretic verdict is split: utility considerations favor  $a_1$ , but plausibility considerations favor  $a_3$  (cf. case 2 of [Table 21.4](#)). But, having noted that the expectation of  $a_1$  is greater than that of  $a_2$  and that of  $a_2$  is greater than that of  $a_3$ , we might venture the transitive inference that the expectation of  $a_1$  is greater than that of  $a_3$ . This would be inconsistent with the conclusion that the pairwise comparison of  $a_1$  and  $a_3$  results in no decision.

What has gone wrong? The answer, in a word, is equivocation. The transitive inference that the expectation of  $a_1$  is greater than that of  $a_3$  is fallacious. It equivocates by conflating the utility-comparable expectations of  $a_1$  relative to  $a_2$  and  $a_2$  relative to  $a_3$  with the fully comparable expectation of  $a_1$  relative to  $a_3$ . Instead, we should conclude that even though  $a_1$  is decision-theoretically superior to  $a_2$  and  $a_2$  is decision-theoretically superior to  $a_3$ , there is no decision-theoretic reason to prefer  $a_1$  over  $a_3$  or vice versa – unless, of course, we are willing to place more weight on either plausibility or utility.

Clearly, then, we need to restrict expectation transitivity. The restriction is that expectation transitivity must be limited to homogeneous groups. Transitivity can be invoked if all the comparisons are fully comparable, or if they are all utility-comparable, or if they are all plausibility-comparable. In insisting on this restriction, we are merely insisting on the same sense of “expectation” in each case. Fully comparable expectation, utility-comparable expectation, and plausibility-comparable expectation are different, though closely related, concepts. Mixing them up can generate fallacies.

The foregoing remarks make no claim to have proved the transitivity of preference; the issue is far too complex for that. But the transitivity assumption seems to be as widely accepted as any normative principle of rational choice; it is common to both the Anglo-American and Franco-European schools of decision theory, for instance (Fishburn 1991, p. 115). Nevertheless, this is a topic for further research.

## Independence

Another main assumption of the decision theory outlined in the section on [Current Research](#) is the principle of independence. This principle, which licenses ignoring shared

outcomes and concentrating on unique outcomes, is controversial. It figured as one of Savage's postulates under the guise of "the sure-thing principle" (1972, p. 21), was targeted by the Allais and Ellsberg paradoxes (Allais 1953, 1979a, b; Ellsberg 1961), and continues to be affirmed in one form or another by Jeffrey (1983, p. 23), Levi (1986, pp. 129, 144), and Maher (1993, pp. 12, 83). While a full-blown investigation would be out of place, I do want to acknowledge the controversy and say just a few words about it. The discussion proceeds through three stages: a brief exploration of the Allais and Ellsberg paradoxes; a search for solid ground for the principle of independence; and a suggestion about porting trickier cases to this solid ground.

Some adherents of the principle of independence objected to Allais' original counter-examples because they unrealistically require ordinary people to make hypothetical choices with potential payoffs of hundreds of millions of dollars (e.g., Morgenstern 1979, pp. 178, 180; Amihud 1979, pp. 151–152). In response, Allais pointed out that maximizing expected utility can also create problems in realistic situations. The paradox introduced in the following paragraph is an instance. Even though it does not rely directly on independence, I concentrate on it because of its simplicity and proximity to ordinary reasoning. The treatment of this simple example can be extended in obvious ways to more complicated scenarios that do rely directly on independence, but there is no need to carry out this extension here.

Allais claims that "a person who is not generally considered as irrational, faced with a single, non-renewable choice, may well take ten dollars in cash rather than gamble on an even chance of winning \$22 or nothing" (1979b, p. 539). Such a person, that is, might choose the sure \$10 despite the fact that the choice is not the expected utility winner, and such a choice need not be irrational. In this and other examples, Allais' point is that maximizing expected utility neglects "the impact of the greater or lesser propensity for risk-taking or security, the consequence of which is, in particular, a complementarity effect in the neighbourhood of certainty" (1979b, p. 442). In short, the maximizing approach ignores "the considerable psychological importance attaching to the advantage of certainty as such" ([1953]1979a, p. 88).

The first thing to be noticed about this example is that it trades on a mistake: the conflation of monetary outcomes and utilities. In order to make the point that the choice of \$10 is not the expected utility winner, Allais assumes outright that the utilities of the outcomes of \$0, \$10, and \$22 are 0, 10, and 22, respectively. At least since the time of Daniel Bernoulli, however, economists have recognized that the relation between money and its utility is not necessarily linear (cf. Levi 1986, p. 142). Hence the monetary outcomes of the example may or may not have utilities of 0, 10, and 22. For the sake of the argument, however, I will assume that they do.

The notion that acts should be evaluated by their consequences has been called a decision-theoretic "pre-axiom" by Peter Hammond (1988, p. 73), who argues that this consequentialist presupposition implies a number of standard axioms, including some forms of the principle of independence. Hence non-consequentialist preferences – preferences for a state or an act, for example – can lead to violations of these axioms. An example of a state-dependent preference is a favorable view of a state of financial crisis because the Joneses would be poorer and the task of keeping up with them less onerous (cf. Hirshleifer 1965, p. 532). Perhaps, then, the security motivating those who would choose the sure \$10 is a state-dependent preference.

However, as one writer on state-dependent preferences observed, "states may vary in respect to 'nonpecuniary income'" (Hirshleifer 1965, p. 532). This is a revealing observation. If income is a decision-theoretic consequence and there are nonpecuniary incomes, then such preferences may actually be consequence-dependent rather than state-dependent. Suppose we explore this idea in the context of the Allais paradoxes (cf. Maher 1993, p. 82). Consider our

**Table 21.6****An Allais problem with outcomes**

	$s_1$	$s_2$
Accept the \$10	\$10, FA	\$10, FA
Accept the gamble	\$22, FA	\$0, -FA

example with the sure \$10 from the point of view of someone for whom \$10 would be extremely important – someone who would urgently need the money for first aid, for example. In such a case, we would need to include the outcomes of first aid (FA) and no first aid ( $-FA$ ) in addition to the already-specified monetary outcomes. The agent's predicament could then be represented by [Table 21.6](#).

What would be the utilities of these four outcomes? If we adapt the comparative resources developed in the section on [Current Research](#), the answer is straightforward: For a utility function  $v$  with values  $U > u > -U$ ,

$$\begin{aligned} v(\$22, \text{FA}) &= U \\ v(\$10, \text{FA}) &= u \\ v(\$0, -\text{FA}) &= -U. \end{aligned}$$

The third utility assignment is based on the consideration that all utility from the outcome (\$22, FA) would be lost by accepting the gamble when  $s_2$  obtains. This is actually a variation on the theme of relative disutility introduced in the section on [Current Research](#). The original concept of relative disutility could be called *column disutility*: disutility relative to other values in the column that represent what the agent might have enjoyed if she had acted differently. By contrast, the relative disutility employed in the third utility assignment would be *row disutility*: disutility relative to other values in the row that represent what the agent might have obtained had the world been different. Note that since there is no overlap between the outcomes (\$22, FA) and (\$0,  $-FA$ ), there is no call to apply the principle of independence here.

Substituting these utilities for their associated outcomes in [Table 21.6](#) yields [Table 21.7](#).

We can now calculate the expected utilities  $E$  of the two acts. Since the probability of each state is  $\frac{1}{2}$ ,  $E(\text{accept the } \$10) = u$ , and  $E(\text{accept the gamble}) = 0$ . The security-conscious agent we are considering should therefore accept the \$10 (though other agents faced with other outcomes might reasonably accept the gamble). We have arrived at the secure Allais result, but we have done so by simple maximization of expected utility.

Let us turn briefly to the Ellsberg paradox (1961, pp. 653–656). Imagine an urn known to contain 30 red balls and 60 black and yellow ones; the proportion of black to yellow is unknown. One ball is to be drawn at random from the urn. You are faced with two choices. Choice 1 is between act  $a_1$ , to bet on red with payoffs of \$100 if you win and \$0 if you lose, and act  $a_2$ , to bet on black with payoffs of \$100 if you win and \$0 if you lose. Choice 1 is summarized by [Table 21.8](#). Choice 2 is between act  $a_3$ , to bet on red or yellow with payoffs of \$100 if you win and \$0 if you lose, and act  $a_4$ , to bet on black or yellow with payoffs of \$100 if you win and \$0 if you lose. Choice 2 is summarized by [Table 21.9](#).

Unlike the Allais problem we have just discussed, the Ellsberg problem directly challenges the principle of independence. According to it, the yellow column in both choices should be

**Table 21.7****An Allais problem with utilities**

	$s_1$	$s_2$
Accept the \$10	$u$	$u$
Accept the gamble	$U$	$-U$

**Table 21.8****The Ellsberg paradox: choice 1**

	Red	Black	Yellow
$a_1$ bet on red	\$100	\$0	\$0
$a_2$ bet on black	\$0	\$100	\$0

**Table 21.9****The Ellsberg paradox: choice 2**

	Red	Black	Yellow
$a_3$ bet on red or yellow	\$100	\$0	\$100
$a_4$ bet on black or yellow	\$0	\$100	\$100

ignored since its payoffs in Choice 1 are the same and its payoffs in Choice 2 are the same. If that is done, Choice 1 and Choice 2 become numerically identical. Hence anyone who prefers  $a_1$  over  $a_2$  should also prefer  $a_3$  over  $a_4$ . But Ellsberg reports that many people prefer  $a_1$  to  $a_2$  yet also prefer  $a_4$  to  $a_3$ . Others, though fewer, prefer  $a_2$  to  $a_1$  yet also prefer  $a_3$  to  $a_4$ . Both preference patterns violate the principle of independence.

I submit that the twist in the Ellsberg problem is that both Choice 1 and Choice 2 are instances of what I will call *laminated choice*. Each choice is constituted by a superposition of two layers, but one of these layers is explicit while the other is implicit. In Choice 1, the explicit layer is fully accounted for by [Table 21.8](#) above. But the implicit layer is a further choice.

This further choice hinges on the difference between definite probabilities, such as the probability of drawing a red ball in this situation, and indefinite probabilities, such as that of drawing a black ball. The acts under consideration are to bet with definite probabilities and to bet with indefinite probabilities. The possible outcomes for this choice are a better chance, a worse chance, and an unchanged chance to win the bet. States, as we have noted, can be thought of as propositions, and the states relevant to the choice at hand are states that affect the world's predictability. Of particular interest in this case are the states that definite probabilities facilitate accurate prediction more than indefinite probabilities, that indefinite probabilities facilitate accurate prediction more than definite probabilities, and that neither type of probability facilitates accurate prediction more than the other. For brevity, I will refer to these states of the world as "favors definite," "favors indefinite," and "favors neither." The choice in the implicit layer of the problem can then be summarized by [Table 21.10](#).

**Table 21.10****The Ellsberg paradox: choice 1's implicit layer**

	Favors definite	Favors indefinite	Favors neither
$a_5$ bet with definite probabilities	Better chance to win	Worse chance to win	Unchanged chance to win
$a_6$ bet with indefinite probabilities	Worse chance to win	Better chance to win	Unchanged chance to win

What I am suggesting, then, is that Choice 1 can be summarized by two decision tables:

➊ [Table 21.8](#), which features  $a_1$  and  $a_2$ , and ➋ [Table 21.10](#), which features  $a_5$  and  $a_6$ . An analogous point holds for Choice 2. These laminated choices are possible because acts are subject to multiple true descriptions. One act can be truly described as both  $a_1$ , a bet on red, and  $a_5$ , a bet with definite probabilities. The decision tables for choices defined in these alternative terms are, as it were, superposed.

The superposition of choices can be made more transparent by noting the distinction that Ellsberg builds his entire analysis around: Frank Knight's distinction between measurable uncertainty or risk, which can be expressed by numerical probabilities, and unmeasurable uncertainty, which cannot ([1921]1971, pp. 19–20). The statistical probabilities of 1/3 for a red ball and 2/3 for a black or yellow ball are measurable uncertainties, but Ellsberg thinks that the problem's residual uncertainty is not probabilistic and not measurable (1961, p. 659).

Ellsberg is right, I believe, to think that there are two types of uncertainty here, but I would develop the contrast differently. All probabilities are plausibilities, as we have noted, but not all plausibilities are probabilities. Hence there are probabilistic and nonprobabilistic plausibilities. Both are present in the Ellsberg problem: the numerical probability of states like the drawing of a red ball and the comparative plausibility of states like favoring bets made with definite probabilities. The explicit layer of the problem relies on numerical probabilities; the implicit layer, on comparative plausibilities.

Looked at in this way, the Ellsberg problem no longer appears to violate the principle of independence. Take Choice 1, understood as a superposition of the choice between  $a_1$  and  $a_2$  and the choice between  $a_5$  and  $a_6$ . The choice between  $a_1$  and  $a_2$  cannot be made by maximizing expected utility ( $E$ ). Although  $E$  of  $a_1$  could be determined, that of  $a_2$  could not, for  $E$  requires a definite probability for drawing a black ball, and that we do not have. Although it would be possible to estimate the probability of black in various ways – by defining upper and lower probability measures, for instance (Halpern 2003, pp. 25–28) – unless we are prepared to work with multiple probability measures and to recast our decision rule to accommodate them, there is no solution at the explicit layer.

But there is a solution at the implicit layer. Given that the utilities of the outcomes of  $a_5$  and  $a_6$  are evenly balanced, those who would prefer  $a_5$  can do so reasonably if and only if they hold a plausibility function  $\pi$  that returns these comparative plausibilities of states:

$$\pi(\text{favors definite}) > \pi(\text{favors indefinite}).$$

That is, they would choose  $a_5$  because they believe it offers them a better chance of winning the bet, and they believe this because, in effect, they are maximizing plausibilistic expectation ( $PE$ ). Given  $\pi$ ,  $a_5$  turns out to maximize  $PE$ . Analogously, Choice 2 cannot be made by maximizing  $E$ .

**Table 21.11****Grounds for the principle of independence**

	$s_1$	$s_2$	$s_3$
$a_1$	$o_1$	$o_2$	$o_3$
$a_2$	$o_4$	$o_5$	$o_3$

for the choice between  $a_3$  and  $a_4$ , but it can be made by maximizing  $PE$  for the choice between  $a_5$  and  $a_6$ . In both cases, those who opt for  $a_5$  could do so for the same plausibilistic reason. And they could do so without violating the principle of independence.

The second stage of our discussion of the principle of independence is a search for solid ground for the principle. To initiate this search, consider the usual decision-theoretic case where state probabilities are independent of acts. As a simple illustration, take a case that is structurally similar to the Ellsberg problem. The possible outcomes  $o_1$ – $o_5$  of acts  $a_1$  and  $a_2$  given states  $s_1$ ,  $s_2$ , and  $s_3$  are reflected in [Table 21.11](#), where  $o_1$  and  $o_4$ , on the one hand, and  $o_2$  and  $o_5$ , on the other, are assumed to be nonidentical. Since the outcomes in the  $s_3$  column are identical, their utilities are identical also. Provided that the probability of  $s_3$  does not vary with the choice of  $a_1$  or  $a_2$ , the products  $r_3$  formed by  $o_3$ 's utility and  $s_3$ 's probability must therefore be identical as well. Where the remaining products of utility and probability are expressed in the obvious way, the expected utility  $E$  of the two acts would be:

$$\begin{aligned} E(a_1) &= r_1 + r_2 + r_3 \\ E(a_2) &= r_4 + r_5 + r_3. \end{aligned}$$

Consequently, the relative magnitude of the acts' expected utilities is independent of the products  $r_3$  – just as the independence principle says. The same point holds for plausibilistic expectation. In these cases, then, independence is no more than elementary algebra. When state probabilities do not vary with acts, the principle of independence is on entirely solid ground (cf. Jeffrey 1983, p. 23).

The final stage of our discussion of independence concerns the remaining question: What if state probabilities do vary with acts? Here, of course, independence need not hold. Michael D. Resnik describes a decision about whether or not to smoke where the relevant states are contracting lung cancer and not contracting lung cancer (1987, pp. 15–16). Evidently, the probabilities of these states do vary with the acts of smoking and not smoking. But Resnik thinks the problem should be reformulated. Since not all smokers get lung cancer, there must be some protective factor that some people have and others do not. So Resnik proposes replacing the states of getting lung cancer and not getting lung cancer with four states related to this protective factor: having the protective factor and getting lung cancer from nonsmoking causes; having the protective factor and not getting lung cancer from nonsmoking causes; not having the protective factor and getting lung cancer from nonsmoking causes; and not having the protective factor and not getting lung cancer from nonsmoking causes (1987, p. 16). The probabilities of these states do not vary with the acts of smoking and not smoking.

I also think that the problem should be reformulated, but my suggestion is different. From the point of view of the person trying to decide whether to smoke, getting lung cancer and not getting lung cancer are not states at all. They are outcomes. The relevant states, on the other

hand, can be very roughly described as having a predisposition to lung cancer and not having a predisposition to lung cancer. The probabilities of these states, like the probabilities of Resnik's states, do not vary with the acts of smoking and not smoking. Consequently, when the decision is conceptualized in these terms, the principle of independence can be unproblematically applied.

In sum, the suggestion for dealing with states whose probabilities vary with acts is to attempt to reformulate them as states whose probabilities do not vary with acts. Whether this strategy can always be employed, or if not, when it can and cannot be employed, are questions for further research.

## Decision Rules

The suite of decision rules proposed in the [Preliminaries](#) subsection of [Current Research](#) keyed on plausibilistic expectation (*PE*), utility-comparable expectation (*UCE*), and plausibility-comparable expectation (*PCE*). As we have noted, all three rules assume homogeneity: for a given choice, all the utilities and plausibilities are fully comparable, or they are all utility-comparable, or they are all plausibility-comparable. But our discussion of transitivity has already adduced one instance of a mixed group. In mixed groups, some utilities and plausibilities may be fully comparable while others may be either utility-comparable or plausibility-comparable. Suppose, for example, that an agent is considering an act whose relevant states  $s_1$ ,  $s_2$ , and  $s_3$  have plausibilities  $p_1$ ,  $p_2$ , and  $p_3$ , respectively. Performing the act will result in one of the outcomes  $o_1$ ,  $o_2$ , and  $o_3$ , which have utilities  $u_1$ ,  $u_2$ , and  $u_3$ , respectively. Assume that  $p_1-p_3$  are comparable,  $u_1$  and  $u_2$  are comparable, but  $u_3$  is incomparable to  $u_1$  and  $u_2$ . What decision rule(s) should be used?

One possibility is to adopt the norm "For mixed groups, mix the rules." That is, use the rule based on *PE* whenever possible and the rules based on *UCE* and *PCE* whenever necessary. In the case just described, this would require calculating *PE* for the fully comparable possibilities with  $u_1$  and  $u_2$  but *PCE* for the plausibility-comparable possibility with  $u_3$ . The act's expectation would turn out to be a compound of the form  $PE, PCE = u_1p_1 + u_2p_2, p_3$ . This approach would have the advantages of retaining the distinctions among the different senses of expectation and permitting comparative judgments among the fully comparable, utility-comparable, and plausibility-comparable components of alternative expectations. In addition, the approach could be defended on grounds of coherence with the rationale for the other three decision rules: "Use comparable data!" But how successful such an approach might be is unexplored territory, so far as I know. It must be left here as a topic for further research.

**Abstract:** Economic research on risk attitudes has traditionally focused on individual decision-making issues, without any consideration for potential social influences on preferences. This has been changing rapidly over the last years, with economists often taking inspiration from earlier psychological research in their increasing consideration of social aspects in decision-making under risk. We provide a broadly conceived overview of the recent literature, defining four different categories of social influences on economic decisions under risk: (1) the observation of other agents' outcomes; (2) the observation of the decision maker's outcomes by other agents; (3) the direct effect of the decision maker's choices on other agents' outcomes; and (4) the direct dependency of the decision maker's outcomes on other agents' choices. While many promising insights have been gained over the last few years, several shortcomings and inconsistencies in our current understanding of social influences on decision-making under risk are pointed out. The overview concludes with a discussion of two real-world applications – agency in financial markets and climate change – that prominently show the importance of furthering our knowledge in this area. In order to achieve such increased knowledge, a much deeper integration of currently dispersed disciplinary knowledge in the social sciences seems crucial.

## Introduction

---

Decision-making under risk has traditionally been considered an *individual* decision problem in the economics literature. The decision maker considers the outcomes in the uncertain possible future states of the world for different courses of action available, and then chooses the alternative that maximizes some function of the outcomes and the probabilities involved. While individual preferences will always be central for decisions under risk, we argue that *social influences* are also crucial in many economic decisions. Most economic decisions involve situations where agents interact in markets, or strategic situations where the decision maker's own actions affect others, and, vice versa, her actions are affected by others' choices. Even when an agent's outcomes are not directly affected by, or do not directly affect, others, more subtle social issues may play a role. Indeed, the observation of others as well as the awareness of (potentially) being observed by others may influence the agent's actions. Nevertheless, social influences on the evaluation of risky alternatives have not been studied or formalized by economists until recently.

Before delving any deeper into the topic, it appears imperative to introduce some elementary distinctions and definitions. While the concept of risk is taken in a broad sense in keeping with the spirit of this handbook, it may not always be obvious what studies can be considered as *economic* in a sprawling social science literature in which traditional boundaries between disciplines are becoming increasingly blurred. In first approximation, we can define as economic studies all those that have as their primary object of study transactions that affect an agent's wealth: monetary and non-monetary. This, in turn, entails a necessary focus on *outcomes* of decisions – as opposed, for instance, to the focus on the decision-making *processes* themselves, typical of the psychology literature. Indeed, this explains at least in part the different conceptions of rationality that serve as normative benchmarks in different disciplines. While these issues also produce methodological differences, we will be as inclusive as possible, considering any studies on decisions that may result in the creation or transfer of value or wealth.

In this chapter, we will first illustrate the traditional neglect of social issues in risky decisions in economics, and discuss some earlier contributions in neighboring fields, especially

psychology, that have influenced the more recent attempts in economics to model decisions under risk as a social decision task (section [History](#)). We then turn to current research in economics. Various social aspects of risky decisions have received attention in recent years, and we suggest a classification within which to discuss the different approaches and organize the quickly growing literature. We distinguish four broad classes of social influences, based on the relationship between the parties involved and the means by which the influence is transmitted. Each of these classes subsumes different theoretical and empirical approaches. The four classes can be summarized as follows:

1. The decision maker observes other agents' outcomes.
2. The decision maker's outcomes are observed by other agents.
3. The decision maker's choices affect other agents' outcomes.
4. The decision maker's outcomes depend on other agents' choices.

In the first class, where the decision maker observes other agents' outcomes and her own choices depend on this observation, there is generally no direct interdependency between agents. For instance, Paul's choice between a job with a sure annual income of \$50K and a job with a risky income between \$40K and \$65K may be influenced by whether Peter, his brother-in-law, earns \$48K or \$52K. Such social influence is purely psychological, and involves factors like fairness, social reference points, social regret, or conformity. A similar, yet more explicit, situation may be the one in which an agent is given explicit advice on actions to take (e.g., investment advice). Both experimental studies and theoretical models have been advanced to include these factors in models of risky decisions.

The second class, encompassing cases in which the decision maker's outcomes are observed by others, also concerns psychological mechanisms, and mainly relates to *accountability* – the implicit or explicit expectation on the side of the decision maker that she may have to justify her decisions to somebody else. For instance, a risky investment that looks attractive from an individual decision perspective may be less acceptable when anticipating the possibility that negative outcomes are observed by others. To the extent that people care about their reputation, a potential observer's possible judgment of the agent's decision making competence becomes a crucial aspect in the decision between risky alternatives. This, in turn, may lead to deviations from the type of behavior observed in the isolated and purely individual decisions typical of laboratory experiments, in which subjects are assured as much anonymity as possible. Since such isolated decisions will rarely be found outside the economist's or psychologist's laboratory, a thorough understanding of the impact of such social influences seems crucial for our ability to generalize laboratory findings to the real world.

The third and the fourth class of influences refer to situations in which there exists true interdependence between agents, which goes beyond their influences on prices and the functioning of markets. Normatively, these situations may still be, and have been, studied as an individual decision problem. Both empirical research and recent real-world events strongly suggest, however, that explicitly modeling the social aspects of these decisions is warranted. The third class summarizes situations where an agent's decision affects not only her own outcomes, but also those of another agent or group of agents. Financial intermediation and delegation of decision-making power when ownership of assets is diffuse constitute an important class of situations in real-world decision making under risk, for which many problems have been revealed during the recent financial turmoil. Economists have become interested in the question how risk taking on

behalf of others differs from risk taking for oneself, and have begun to study these situations in more controlled environments that allow for the examination of different sorts of influences, which may all be important in the real world.

The fourth class of situations looks at the other side of the relationship in the third class, with the decision maker assuming the role of a principal delegating the final decision power to an agent. This class of influences is also important in strategic interactions and for the empirical analysis of game theoretical models, where agents move simultaneously and hold beliefs about the likelihood of the opponent's strategies. Empirical research has shown that in such situations, choices deviate from those in which the agent faces the same outcomes and probabilistic beliefs, in which however the uncertainty is due to nature rather than another agent. Findings in this category also concern the kind of incentives that a principal can put in place in order to make the agent's decisions coincide as much as possible with her own preferences. This principal–agent issue has attracted much interest in economics, and a host of models, as well as an increasing number of empirical studies, exist on how the risk attitude of agents can be influenced by the principal.

The state of the economics literature on social influences in risk taking is summarized under the Current Research heading according to the four classes of situations just described. While this conceptual separation will be maintained as much as possible, this is done for expositional clarity and it should be well understood that the four classes of influences will not be strictly separate in empirical applications. In particular, in the latter two classes with true interdependence, the purely psychological motives deriving from observation of other agents, or by other agents, will also affect decision making, leading to interesting interactions of motives. When applicable, we will discuss research studying such interaction effects.

In the final section of this chapter, open questions will be identified, as well as applications of the new insights on social influence to economic problems (in the broadest sense) involving risk. Particular attention is devoted to the issue of agency in risky decision making, with a focus on financial decisions. The latter involves all four classes of social influences and has not been widely explored so far. We will point out applications to common resources problems in environmental and climate policy. This section will also discuss how the related fields that provided the initial insights inspiring the study of social influences in economics may contribute additional inputs to improve the first generation of models and empirical studies in economics.

Finally, a warning is in place. While we have attempted to provide a broad overview of the existing economics literature on social influences, this study cannot aspire to being comprehensive. The speed at which new research emerges, as well as the space limits imposed by the current format, forced us to make some difficult choices both on the number of studies to be included and on the level of detail to be reported on those studies. This chapter is thus driven at least in part by the particular interests of the authors, as well as the desire for providing a wide-spun overview rather than an in-depth analysis of some particular aspects.

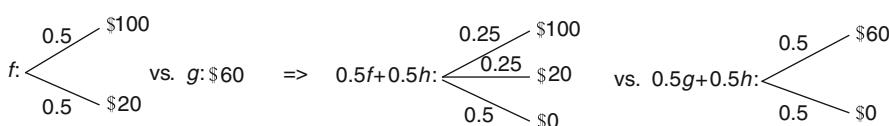

## History

Economists have long studied risk in the tradition of Bernoulli (1738), who introduced the idea of expected utility. A prospect (or lottery) representing a probability distribution over possible outcomes is evaluated by a weighted sum of a function of the outcomes, often called utilities, the weights being the probabilities with which the different outcomes are expected to occur

(expected utility theory) (Chap. 15, A Rational Approach to Risk? Bayesian Decision Theory and Chap. 5, The Economics of Risk: A (Partial) Survey). In the mid-twentieth century, behavioral foundations were laid for the expected utility model that defined the model in terms of axioms describing simple observable preferences between risky prospects (von Neumann and Morgenstern 1947; Herstein and Milnor 1953). For instance, the so-called independence condition has proved crucial for preferences to be describable by expected utility theory. It stipulates that the preference between two prospects  $f$  and  $g$  should not be affected if we probabilistically mix both of these prospects with a third prospect  $h$ . (Figure 22.1) illustrates the independence condition.

Foundations have also been given for the technically distinct case in which no objective probabilities are known, a situation often referred to as *uncertainty* (Knight 1921). In this case, the decision maker evaluates a prospect by using her own, subjective estimates of the relevant probabilities (Anscombe and Aumann 1963; Savage 1954). Such behavioral foundations of decision-making models have typically focused on observable individual preferences, and have made no reference to social influences. More generally, dependence of decisions on a particular context has usually been excluded from the economic definitions as well as being avoided in empirical investigations, because it may give rise to ad hoc explanations and lack of predictability. In the case of social context, a model that allows for different behavior for each possible social context was long considered unfalsifiable and empirically useless.

Remarkably, social influences have also been excluded when studying situations explicitly concerned with social decisions. The well-known foundation of utilitarianism laid by Harsanyi (1955) employs individual agents' expected utilities over risky distributions of their own social positions to derive the social planner's utilitarian welfare function. While explicitly concerned with social comparisons, individual evaluations of risky social allocations are assumed to exclude any social comparisons (Diamond 1967; Trautmann 2010). Similarly, game theoretic analyses of strategic interactions involve both risk due to nature and risk due to the decisions made by other players. No distinction between such different types of risks has been made until recently, even though these two kinds of risks may be perceived very differently by the decision maker (Fox and Weber 2002). Von Neumann and Morgenstern (1947) introduced their expected utility model of individual risk taking to analyze strategic game situations and mixed equilibria, where randomization of strategies by other players introduces an element of risk into each player's decision problem. As we will show in the next section, the economics literature has only recently started to capture the systematic aspects of social influences and to improve the realism of such models, while maintaining predictive power and empirical refutability.

**Fig. 22.1**

**Mixing and independence.** Notes: Independence stipulates that the preference between the left-hand prospects  $f$  and  $g$  should not be affected if both prospects are probabilistically mixed with the same prospect  $h$ . The figure shows a 0.5 mix with a prospect  $h$  resulting in a sure zero payoff

In contrast to the economics literature, psychologists have long been aware of social influences and tried to take these explicitly into account in their theorizing. Indeed, the issue of social influences is important enough as to have given rise to the whole subfield of social psychology. A host of different forms and shades of social influences have thus systematically been explored in social psychology, ranging from the conformity paradigm (Asch 1955), to social facilitation or mere presence (Bond and Titus 1983; Zajonc 1965), accountability in its various forms (Lerner and Tetlock 1999; Shafir et al. 1993), and many more (Cialdini 1993). This long research tradition on social influences has produced over the years a huge pool of knowledge from which economists can draw inspiration. One aspect of this research tradition that has complicated the interdisciplinary exchange is the divisive nature of many of the research efforts in social psychology, often aimed at further subdividing established effects rather than at searching for commonalities between existing research paradigms. Such aggregation could indeed benefit the dialogue between disciplines in the social sciences. Furthermore, while a huge body of evidence has been produced on social influences on decisions in general, the case of decisions under risk appears to play a relatively minor role in this tradition.

There are exceptions, however, and a non-negligible body of psychological evidence on social aspects influencing behavior under risk has emerged over the years. A prominent example is *risky shift*, which is defined as a level of risk tolerance in a group that is larger than the average level of individual risk tolerance of its members (Stoner 1961). Wallach et al. (1964) examine the causes of the risky shift phenomenon, and find that the diffusion of responsibility in the group leads to increased risk taking. They also find the opposite effect, a *cautious shift*, however. The latter occurs if individual members are personally responsible for the welfare of the group. A very similar result is obtained by Weigold and Schlenker (1991), who examine these effects through the lens of the social facilitation paradigm. Having elicited subjects' risk attitude, they found that subjects became more extreme in their original positions when they were told that they would be required to justify their choices, with risk-averse subjects becoming more risk averse, and risk seekers increasing their preference for risk. Below, we show that there is converging evidence from the more recent economics literature that responsibility for others often leads to reduced risk tolerance, as would be predicted if people are predominantly risk averse in isolated decisions.

Other approaches in psychology have been closer to economics in the sense that their focus centered on individual preferences, accounting for individual-level biases. Kahneman and Tversky's (1979) prospect theory, for instance, unmasks various deviations in risky choices from those predicted by expected utility theory (● Chap. 25, Risk Perception and Societal Response and ● Chap. 19, Paradoxes of Rational Choice Theory). These deviations, however, are explained through individual-level psychophysical aspects like diminishing sensitivity, reference dependence, and a larger impact of negative outcomes (losses) than of positive outcomes (gains), in comparison to some reference points. Nevertheless, social aspects can be incorporated naturally into this framework, for instance, through the undetermined origin of the reference point or various editing processes. Boles and Messick (1995) showed that the selection of the decision maker's reference point in the presence of multiple possible reference points depends on social comparisons. These authors find that social reference points are often more influential than individual reference points, like the status quo. In one experiment, compared to the status quo of \$0, people preferred a gain of \$90 when another person simultaneously received a gain of \$500 less than a much smaller gain of \$10 when the other person experienced a loss of \$100.

Psychologists have also studied how the anticipation of being evaluated by others can affect attitudes under uncertainty. We have already mentioned Weigold and Schlenker's (1991) result showing how accountability amplifies pre-existing risk attitudes, making risk averters more risk averse and risk seekers even more risk prone. Mere formulation differences or frames have often been found to influence decisions under risk and uncertainty. Takemura (1993, 1994) showed that making subjects accountable by announcing that they will have to justify their decisions in front of somebody else reduced incoherence between different frames, thus increasing the consistency of preferences. Similar effects were obtained by Miller and Fagley (1991) and Sieck and Yates (1997). Studying a problem in which subjects' decisions had consequences for others, Tetlock and Boettger (1994) found that subjects were more reluctant to approve a risky drug for a hypothetical market when held accountable. Indeed, accountability pushed subjects to procrastinate as well as to try to pass the responsibility on to others, so that potentially useful drugs were not approved for use in a timely manner because of the idiosyncratic risks they entailed.

Ambiguity aversion – the preference of known-probability outcome generating processes over normatively equivalent processes entailing unknown probabilities (Fox and Tversky 1995; Frisch and Baron 1988) – is a classic example of how economists often arrive late to the study of social-decision aspects. The phenomenon itself has been of interest to economists ever since the publication of the famous Ellsberg paradox in 1961 (☞ Chap. 18, [Unreliable Probabilities, Paradoxes, and Epistemic Risks](#)). While economists have studied the issue as a purely individual problem, psychologists have taken a wider approach to the issue. Curley et al. (1986) studied a wide array of potential causes of ambiguity aversion. They found that being observed by a group of people when making a choice between a bet on a known-probability prospect and a bet on an ambiguous prospect, decision makers became more ambiguity averse (a similar finding was reported by Taylor (1995)). Economists became interested in social influences on ambiguity attitudes only very recently. This parallels developments in the literature on the effects of social reference points and other influences, in which economists did not develop an interest until more than a decade later than psychologists. For this reason, the psychological findings often form the basis for economic studies. It should be noted however that – in addition to having a different focus deriving from the different underlying research paradigm – economists studying social influences in decisions under uncertainty are not always aware of previous work by psychologists. In the following section, we will therefore also refer to findings in the psychological literature that are of direct relevance to problems studied more recently in economics.

## Current Research

---

In this section, we review current research in economics. We follow the structure laid out in the introduction and discuss any overlaps between the classes of influence where applicable.

### The Decision Maker Observes Other Agents' Outcomes

---

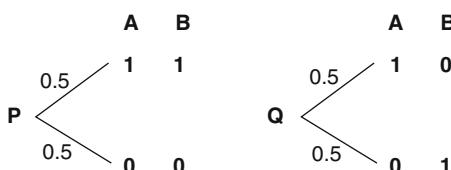

A variety of social influences fall into this class. We discuss three different types of models. First, fairness motives have been shown to interact with uncertainty if the decision maker observes the payoffs of other agents whose outcomes she considers relevant. Second, the

outcome of another person may act as a social reference point even in the absence of fairness considerations. And third, conformity with the behavior of their peers has been shown to affect people's decisions under risk.

**Process Fairness.** Fairness motives may alter a decision maker's risk attitude when other people's decisions and outcomes are observable. Consider the risky decision for person A shown in [Fig. 22.2](#). Person A faces a choice between two risky lotteries P and Q. For person A, each lottery gives a payoff of 1 or a payoff of 0, with equal probability of 0.5. If player A considered only her own payoffs in her decision, she would be indifferent between the two lotteries – indeed, they would be exactly the same. If, however, the outcome of person B is observed and equality concerns matter to person A, then lottery P will be strictly preferred to lottery Q. For either state of the world, equality obtains for prospect P and inequality obtains for prospect Q, even though the expected value of the two prospects is equal for both agents.

The importance of such fairness motives in risky decisions was illustrated empirically by Kroll and Davidovitz (2003), Bolton et al. (2005), and Krawczyk and Le Lec (2010). Zizzo (2004) and Cappelen et al. (2009), on the other hand, show the inverse effect, namely that individual risk-taking influences fairness evaluations. Interestingly, the interaction of risk and fairness has also led to the new concept of *process fairness* in economics. Process fairness explicitly considers the risk borne by all agents and does not evaluate the equality of outcomes, but the equality of expected outcomes. In the above example, person A is indifferent between prospects P and Q if she is motivated by process fairness because her own payoff is identical under both prospects, and the expected payoffs of both agents are equal and identical under both prospects. Theoretical models accounting for allocation of risk and process fairness have been proposed by Bolton et al. (2005), Trautmann (2009), Sebald (2010), Krawczyk (2011), and Borah (2010). Trautmann (2010) discusses an application of individual-level process fairness to social choice problems involving risk. Bolton and Ockenfels (2009) report experimental evidence for the relevance of process fairness considerations in choice situations similar to those in [Fig. 22.2](#), where person A makes choices for herself and for a passive person B (see below). Aldashev et al. (2010) show process fairness effects in real-world settings. In the risky allocation of more or less desirable tasks to workers, they show that process fairness influences the effort that these workers exert in their task.

Social influences due to process fairness concerns can be employed to justify the concept of *resolute choice* in risky decisions, introduced by Machina (1989) to restore dynamic consistency of non-expected utility preferences. If their choices violate the independence axiom, non-expected utility maximizers may change their preference after the resolution of the uncertainty, violating dynamic consistency. Trautmann and Wakker (2010) show that process fairness preferences imply a similar rejection of consequentialism and lead to dynamic inconsistency. In [Fig. 22.2](#), process fairness implies indifference between prospects P and Q. Let us assume

**Fig. 22.2**

Risky decision for Person A who observes the risky outcome of Person B

that Q is chosen and resolved. Obtaining the poor outcome under prospect Q after the resolution of uncertainty, however, the agent faces a sure allocation and may reconsider her preference. In particular, she may now prefer the poor outcome under prospect P rather than prospect Q, because of ex-post fairness concerns. Under process fairness, however, resoluteness becomes convincing, because agents explicitly consider risks borne in the past and will not adjust their preferences ex-post. Trautmann and Wakker (2010) argue that process fairness can thus give a justification of resolute risky choice in social settings. Under process fairness, the risks borne in the past by the players become meaningful in terms of social comparison and should be considered also ex-post, enforcing dynamic consistency.

*Social reference points.* A related but slightly different view holds that another agent's outcome may act as a reference point in a risky choice, similarly as in the psychological work by Boles and Messick (1995). Linde and Sonnemans (2009) and Rohde and Rohde (2009) provide theoretical models and empirical tests of this paradigm. Consider prospect P in [Fig. 22.2](#), but now assume that agent B receives an outcome of at least 1 in both states (instead of the given numbers). Linde and Sonnemans call this a social loss frame for agent A. On the other hand, if B receives an outcome smaller than 0 in both states, the prospect is evaluated in a social gain frame for agent A. The situation depicted in [Fig. 22.2](#) for prospect P, with a stochastic outcome for B equal to the outcome of A is called a neutral frame. In contrast to fairness-based influences on risk attitude, here the social comparison is thought to influence risk attitude by providing a reference point. Building on prospect theory's reference-dependent evaluation function, risk seeking is predicted in loss frames while risk aversion is expected to prevail in gain frames.

The empirical evidence does not support this prediction unequivocally, however. Linde and Sonnemans observe more risk aversion when decision makers find themselves in a social loss frame than under the gain frame, reversing the typical prospect theory pattern. In contrast, in a field experiment devised to test this idea, Haisley et al. (2008) found that poor people are more likely to buy lottery tickets after being shown income brackets that place them at the bottom of the income distribution, as compared to when the income brackets employed place them somewhere in the middle ground. That is, these people become more risk seeking when their placement in a perceived peer group puts them in a social loss frame. These different findings may be explained by the role of the reference point as an aspiration level (Diecidue and van de Ven 2008). People put additional value on outcomes that help them to achieve their aspiration level, for instance, a social comparison outcome. While a simple loss frame may not elicit risk seeking per se, it may do so if the aspiration level can be met or surpassed by assuming greater risks, which is surely the case for the lottery ticket in the Haisley et al. study.

A related concept, introduced by Delgado et al. (2008), is social loss aversion. Delgado et al. studied social loss aversion for first-price auctions in the presence of multiple social reference points. Consider once more prospect Q in [Fig. 22.2](#). This allocation lottery can be interpreted as a situation where either person A or person B receives a desirable item (with 1 indicating the person obtaining the item). Auctions provide an example of such situations, with uncertainty deriving from other bidders' behavior. The auction winner receives the item while all other bidders receive nothing. Bidding behavior in auctions has widely been studied in economics, both theoretically and empirically. An empirical phenomenon that has attracted much interest is the fact that people tend to overbid in first-price auctions with respect to the theoretical prediction of the Nash equilibrium. In the first-price sealed bid auction, each bidder simultaneously submits a bid, and the winner with the highest bid wins the auction and has to pay her

bidding price. To make a positive profit, the buyers have to submit bids that are lower than their valuation of the good. The lower the bid submitted, the higher the profit but also the higher the risk that another bidder will submit a larger bid. Nash equilibrium predicts the optimal tradeoff between these two forces, but empirically people usually bid too high relative to the Nash prediction. Risk aversion has sometimes been used to explain this overbidding. More recently, using both behavioral and neuroeconomic evidence, Delgado et al. (2008) showed that it is mainly the perception of non-winning of the auction (lower branch of prospect Q) as a *social loss* that influences overbidding.

These examples show that straightforward extrapolation from individual to social reference points is not always warranted. Some individual effects may be amplified in social contexts as was the case with loss aversion; others may be reversed as in the risk aversion for social loss frames. Furthermore, by moving from individual to social reference points, complexity increases because of the multiplying of reference points (individual and social reference points usually coexist), and stochastic reference points if other agents also face risky prospects resulting in different outcomes in different states of the world. The development of descriptive models with social reference points will therefore have to draw upon psychological insights about the aggregation of multiple references points (e.g., Kahneman and Miller 1986) and theoretical work in economics on stochastic reference points (Sugden 2003; Schmidt et al. 2008).

*Conformity and Peer Effects.* Recent research has shown that conformity with the behavior of relevant others is an important driver of economic decisions (Sacerdote 2001; Duflo and Saez 2002; Falk and Ichino 2006). An early theoretical model is provided by Bernheim (1994). There is no clear-cut evidence in economics on the effect of conformity on risky decisions yet. Goeree and Yariv (2006) study situations where agents have to predict the distribution of colors in an urn after either observing one sample from the urn or observing other agents' predictions. In particular, either an urn with three red and seven blue balls, or an urn with seven red and three blue balls is randomly selected, but subjects do not know which urn was chosen. Before predicting the distribution, subjects can either draw a sample ball with replacement from the selected urn at zero cost, or observe the betting choices of four other persons who had no information before making their bet. That is, while a sample draw is informative from a Bayesian viewpoint, observing the uninformed choices of the other four people does not reveal any information about the distribution in the urn. Goeree and Yariv observe clear preferences for observing the uninformed choices of others. Between 30% and 50% of the subjects preferred observing others' choices, and this pattern is robust if the authors control equality and efficiency concerns. Further, conformity with the uninformed majority choice becomes stronger for larger majorities, consistent with the psychology of social impact (Latane 1981). Goeree and Yariv therefore interpret their result as a preference for conformity.

While this interpretation seems the obvious explanation in the simple setting used by Goeree and Yariv, the result may obtain even under rather weak conformity preference if subjects have no clear concept of the Bayesian learning from sampling with replacement. A recent study by Trautmann and Zeckhauser (2010) indeed suggests that many people have no proper understanding of the concept of learning under uncertainty and do, consequently, often completely neglect learning opportunities. If people are offered a chance to observe others, they may choose to do so even if conformity preferences are weak, or out of pure curiosity.

Another study finding strong peer effects was conducted by Cooper and Rege (2008). These authors asked subjects to make a set of simple choices between risky prospects. The whole set of choices was made three times. In the first instance, subjects made simple individual choices.

In the second and third repetition, they were either informed only about their own past choices or additionally about the past choices of five other people in their group. The authors found strong effects of the additional peer group information on risk attitudes. Two theoretical accounts were put forth: one based purely on conformity pressures, and another one based on social regret. Under pure conformity, the option chosen initially by a majority of peers yields an additional social utility component, such that groups are predicted to converge toward the initial majority choice over time.

The social regret model for peer effects on the other hand is based on the assumption that decision makers anticipate regret in risky decisions (Loomes and Sugden 1982; Bell 1982). Consider the right-hand situation Q in  Fig. 22.2, and assume that A and B represent the outcomes of two distinct prospects. If a person has to decide between prospects A and B, she may anticipate that after choosing prospect A she feels regret in case the lower branch should obtain. In this case, prospect B would have been the better choice ex-post. Similarly, after choosing prospect B, the upper branch outcome would lead to decision regret.

In many situations, prospects are asymmetrically affected by regret, which then strongly influences choice behavior. Cooper and Rege assume that subjects evaluate risky prospects by an evaluation function that consists of an “inherent utility” term, for instance, the expected utility of the prospect, and an additive punishment for anticipated regret. Importantly, the weight of the regret term in the evaluation inversely depends on the expected number of people choosing the same gamble – misery loves company. This model is similar in spirit to the above-discussed amplification of individual-level biases in social circumstances.

Studying the dynamic behavior in their experiment, Cooper and Rege find evidence for the social regret model of peer effects and reject the pure preference for conformity model. There is no simple convergence toward the initial majority as predicted by conformity, but rather a bias against more risky prospects in the peer choice information treatments compared to the individual information-only treatments. This bias is predicted by social regret, because the risky options involve more potential for regret than safer options. Thus, in contrast to Goeree and Yariv (2006), this study does not find a pure conformity effect in risky choices. Another study that does not support conformity is that of Corazzini and Greiner (2007). In their study, subjects choose between two identical gambles A and B one after the other. That is, by definition, individual attitudes toward risk cannot imply a strict preference between the gambles, allowing conformity to potentially exert as strong an influence as possible. Subjects making decisions later in the sequence should thus tend to the majority choice of subjects who previously revealed their preference. Corazzini and Greiner report significant non-conformity: observing a sequence of choices of one type by other subjects, subjects are more likely to choose the other prospect. This pattern is also observed if prospect A is strictly better than prospect B. Still about 25% of the subjects prefer to choose B after observing a sequence of A choices. Corazzini and Greiner’s result is consistent with earlier evidence in psychology reported by Arkes et al. (1986), who executed a experiment on learning under uncertainty in which subjects were given a decision-making rule, which would allow them to maximize their payoff. They found that subjects displayed a strong tendency not to follow that rule, but rather tried to beat the system – with the consequence of a substantial loss in payoffs as compared to subjects who did follow the rule.

On the whole, the existing evidence on the role of conformity is thus inconclusive and more research is needed to uncover the reasons underlying the widely differing results. As Cooper and Rege show, it is often difficult to separate different explanations with purely behavioral data. New methods in economics, including data from brain-scans executed while decisions are

taken may help to study such difficult-to-identify social influences. For example, Engelmann et al. (2009) conducted a neuro-economic study of advice in financial decision making under risk. They found that brain regions involved in the value tradeoffs typical for decision making under risk become less activated if advice by an expert is given. On the other hand, regions involved in strategic thinking and mentalizing others' intentions become more active (see also Bossaerts 2009, Sect. 6). This shift in processes results in behavioral changes. Identifying underlying neurological processes can thus help identify changes in social decision-making under risk where behavioral observations are inconclusive.

## The Decision Maker's Outcomes Are Observed by Others

---

Situations in which a decision maker is observed by others, and the effects that such observation may conjure about, has been widely studied in social psychology. Once again, the interest for the topic in economics surfaced much more recently. In early studies of the issues of observability of donations, Hoffman et al. (1996) showed that in a dictator game subjects offered lower sums of money when nobody could observe the amount donated than when donations were to some degree observable. Even under complete anonymity, however, donations remained superior to the predicted zero result implied by the selfishness assumption typical of economics. While subsequently other experiments used similar concepts of social observability (referred to with a variety of names such as justification need, anonymity, and double blind procedures), they were mostly concerned with behavior in interactive games rather than individual decisions under risk (e.g., Bohnet and Frey 1999; Dufwenberg and Muren 2006).

The overall evidence on the effect of being observed on the decision maker's choices under risk is mixed. In an early psychological study, Weigold and Schlenker (1991) found that subjects' original risk attitudes were enhanced when they anticipated the need to justify them – with risk averters becoming more risk averse and risk lovers becoming more risk seeking. The economic consequences of this are difficult to pin down, however. Vieider (2009) found an effect of accountability on loss aversion, which was decreasing when subjects were held accountable. In this case, economic consequences are clear, since loss aversion is commonly perceived as a decision bias that may lead people to pass over potentially lucrative opportunities. Excessive loss aversion is often thought to occur because of narrow bracketing of decision problems, whereby decisions are considered one by one rather than in the larger perspective of lifetime decisions (Read et al. 1999; Rabin and Weizsäcker 2009). Accountability seems effective inasmuch as subjects realize the irrationality of their instinct to avoid losses, and try to correct it when they anticipate having to justify their decision. In contrast, in an experiment on framing, Vieider (2011) presents evidence that accountability may not be effective at changing risk attitudes either in the gain or the loss domain. This is an issue that is conceptually separate from the loss aversion results just discussed, which require mixed prospects over gains and losses to be addressed. These results do, however, contradict the earlier results by Weigold and Schlenker if one accepts that a majority of subjects is typically risk averse for gains. Weigold and Schlenker's results would then lead us to predict an overall increase in risk aversion for gains under accountability. Overall, the verdict is thus not clear.

Accountability, on the other hand, has been found to increase the coherence between different decision frames – thus increasing the alignment of risk attitudes for gains and for losses. In the same spirit, accountability has been found to push decisions closer to the normative economic

prediction when subjects are called to choose between different prospects, one of which is clearly superior to the other. The commonly observed failure of rational decision making in such choice problems derives generally from the differential complexity of the prospects, so that subjects seem to forego potential gains in expected utility to avoid the cognitive effort required for the discovery of the optimal decision (Huck and Weizsäcker 1999; for a psychological perspective see Inbar et al. 2010). Accountability has been found to increase cognitive effort in such situations, and thus to improve decision making (Kruglanski and Freund 1983). Vieider (2011) showed that improvements due to accountability also occur when at the same time financial incentives are provided for the decisions, so that the effect is not due to particularly low cognitive effort when decisions do not carry real consequences. Rather, he found that the provision of monetary incentives may, paradoxically, sometimes impair the decision-making process, pushing them farther away from the benchmark of economic rationality.

As mentioned in the  History section, accountability has also been found to have effects on ambiguity aversion (Ellsberg 1961). Curley et al. (1986) compared a group for which the decision was performed in relative privacy in front of the experimenter only to one in which the decision was performed in front of the experimenter and the whole group of subjects partaking in the experiment. They found a significant increase in ambiguity aversion when a group of subjects could observe the choice and the outcome of the choice. More recently, Muthukrishnan et al. (2009) successfully used the accountability effect to induce increased ambiguity aversion as a treatment variation in a marketing study.

To test whether social influences may in some settings be necessary for ambiguity aversion, Trautmann et al. (2008) implemented the opposite manipulation by completely excluding the possibility of observation of the decision maker's preferences over outcomes, and thus ultimately of whether the decision maker ends up winning or losing. This was done by using outcomes over which the typical decision maker exhibits a clear preference (in this case, two movies on DVD), whilst such preferences cannot be guessed by the experimenter. The authors found that subjects who had to declare their preference before making their decision exhibited the usual pattern of ambiguity aversion, while subjects who did not reveal their preference beforehand were no longer ambiguity averse. On top of the results obtained by Curley et al., this shows on the one hand that the potential observability of outcomes is sometimes necessary for ambiguity aversion to be strong. On the other hand, it also shows a more subtle fact. Indeed, in Curley et al.'s experiments, the size of the audience was increased, while both the decision itself (i.e., the decision-making process) and the outcomes that obtained from that decision were observable in both conditions. Trautmann et al., on the other hand, vary the observability of *outcomes* alone (or of preferences over outcomes to be precise) across conditions, while the decision-making *process* was always observed by the experimenter. This goes to show that the effect is indeed produced by a focus on outcomes.

Field evidence also points in the direction of increased ambiguity avoidance under observability. In financial investment, the advent of online brokerage has provided an environment of increased anonymity compared with traditional forms of brokerage. Barber and Odean (2001, 2002) showed that people invest more heavily in growth stocks and high-tech companies, investments that are associated with higher ambiguity in the finance literature, when they use online brokerage rather than traditional brokerage. Similarly, Konana and Balasubramanian (2005) found that many investors use both traditional and online brokerage accounts, and hold more speculative online portfolios. Consistent with the proposed accountability effect on ambiguity attitude, one of the investors they interviewed noted in the context

of online trading (p. 518): "I don't have to explain why I want to buy the stock." Barber et al. (2003) showed that group decisions (investment clubs) similarly lead to a stronger preference for easy-to-justify investments.

Economists have just begun to study accountability effects in decisions under risk. While so far we have considered purely psychological accountability effects, in economics, accountability often takes the form of incentive structures in agency problems. We discuss risk taking in such situations in more detail in the following sections.

## The Decision Maker's Choices Determine or Influence Other Agents' Outcomes

---

A relatively common situation is the one in which a decision maker's choices and actions determine not only her own outcomes, but also the outcomes of others – beyond any influence they may have on market prices (a fact that has always been studied in economics, and that we do not consider a social issue). This happens for instance whenever the decision maker is hired to make decisions for someone else, or makes decisions for a group of people as in a business decision affecting various stakeholders. This category also includes decision making within the family regarding such issues as saving and investment, pension and life insurances, or buying a house. The social aspects of such decisions are often overlooked. Decisions for others furthermore occur in strategic game settings where the choices of players affect each other's outcomes, and therefore constitute a risk in the sense that choices are made simultaneously and chosen strategies are unobservable *ex-ante*. We first discuss the literature on decisions with responsibility for others' outcomes under risk due to nature, and then under the more implicit risks stemming from strategic interactions in games. Potential differences in behavior between situations of risk due to nature and of risk due to other people's choices in strategic settings will be dealt with in the following section. We do not review group decision making in detail in this section, but focus on situations of responsibility. Group decisions are complex and involve voting rules and dynamic decision processes that make it potentially difficult to identify effects on risk attitudes. For details on group decisions, we refer the reader to Conradt and List (2010) for a broad overview, and to Isenberg (1986) for a focus on risky decisions.

*Risky decisions on behalf of others.* Risky decisions on behalf of others have been studied in a number of different contexts recently, including household and group decisions. An example is the study by Bolton and Ockenfels (2009) on fairness effects on risk taking discussed above. A problem with this type of studies is that the pure effect of responsibility for others often cannot easily be separated from other influences. If people decide for others as well as themselves, fairness or spitefulness issues become important. If people make decisions in groups, the preference aggregation and joint decision process influence behavior irrespective of potential social influences (De Palma et al. 2010; Wallach et al. 1964). We can nevertheless draw some initial conclusions about the effects of responsibility for others from the literature.

Bolton and Ockenfels (2009) included one set of questions in their study where fairness aspects are held constant although the risk affects both the decision maker and another person. They find increased risk aversion in this situation of responsibility relative to the individual benchmark, even though their result falls short of statistical significance. This finding is consistent with evidence from two studies from the financial management literature, which explicitly ask subjects to make decisions for others that do not affect their own outcomes.

Eriksen and Kvaloy (2010) study amounts invested in a risky asset using a task popularized by Gneezy and Potters (1997), and Reynolds et al. (2009) study simple choices between risky and safe lotteries. Both studies find increased risk aversion in decisions for clients compared with the benchmark of decisions for oneself. Interestingly, Eriksen and Kvaloy find myopic loss aversion, a violation of the expected utility model that has been shown for individual investors (Gneezy and Potters 1997), also in decisions for others. This evidence is consistent with findings in Bateman and Munro (2005) that joint household decision making suffers from the same violations of expected utility as individual decisions do, as well as with the finding that professional traders incur this bias more than the typical student populations employed in experiments (Haigh and List 2005).

While these results support the idea of more cautious decision making under conditions of responsibility, there are also studies that obtain the opposite finding of less risk aversion in decisions for others than for oneself. Chakravarty et al. (2010) find more risk seeking by people who make decision for others in lottery choices and bidding in auctions when decisions do not affect the agent's own payoff. Sutter (2009) finds that teams invest more in the Gneezy and Potter's investment task than individuals, thus pointing in an opposite direction than the findings by Eriksen and Kvaloy (2010), although these differences may be affected by the group decision features of Sutter's experiment. Relatedly, Lefebvre and Vieider (2010) found that compensation through stock options made experimental executives take risks that were excessive from their shareholders' point of view, with a substantial loss of revenue for the latter. When executives, however, knew that they might be called to justify their decisions in front of a shareholder reunion, they sacrificed their own payoff to act in the interest of shareholders, whose returns were increased considerably. The latter study differs from the ones described previously on the point that the compensation of agents and principals is determined through different mechanisms – an important class of relationships in the real world, on which little clear evidence exists to date (see [Further Research](#) section for a discussion).

An interesting variant of risk taking for others was studied in Haisley and Weber (2010). These authors offered subjects choices between more or less selfish allocations between themselves and a passive other person, with the latter affected by uncertainty. In particular, the passive person's payoff depended on either a risky or an ambiguous lottery ([Table 22.1](#)).

If subjects choose the other-regarding option, they receive \$2 while the other person receives \$1.50. This decision problem effectively puts a price of \$.25 on the morally more acceptable choice of providing a higher payoff to the other person. It is thus interesting to see whether the type of uncertainty affecting the other person's payoff influences the moral decision. Haisley and Weber reported an increase in selfishness if the probability with which the payoff of the other person obtains is ambiguous rather than a known 50% chance to win \$1, or else nothing.

**Table 22.1**

Social allocations with risk or ambiguity (Adapted from Haisley and Weber 2010)

	Self	Other
Option A (selfish)	\$2.25	Risky lottery (50–50% chance to win either \$0 or \$1.00)
		Ambiguous lottery (unknown probabilities of winning either \$0 or \$1.00)
Option B (other- regarding)	\$2	\$1.50

They found evidence that in the ambiguous situation, the decision maker assumes an optimistic interpretation of the risk, thus in fact making a tradeoff between (\$2, \$1.50) and (\$2.25, “most likely” \$1.00). Under the known 50% chance to receive nothing, the moral constraint is much stronger because self-serving interpretations are not as easy in that case. Interestingly, if subjects first make a simple choice between an ambiguous and a risky gamble of the kind proposed by Ellsberg (see [History](#) section) before making the social allocation choice, the effect is eliminated. In the initial choice, many subjects reveal ambiguity aversion, thus lower evaluations of an ambiguous chance to win \$1.00. The self-serving positive interpretations thus cannot as easily be constructed in the subsequent moral decision.

*Strategic decisions for others.* A different class of phenomena is the one of decisions that affect others, whereby the risk derives from strategic uncertainty in games (this form of social risk is discussed in more detail also below for the case of individual decision makers). Gong et al. (2010) and Sutter et al. (2010) studied how individuals versus teams act in games in which they had to choose between a low payment Nash equilibrium strategy and a more profitable, but also more risky, non-equilibrium strategy. Both papers find more coordination, and thus risk seeking, for individuals than for groups. As discussed before, from group decisions we cannot easily draw conclusions regarding social influences on risk preferences per se, because of the influence of the joint decision-making process. Charness and Jackson (2009) study coordination in Rousseau’s famous stag hunt game by players who individually choose their strategy, which will affect not only themselves but also the individual paired with them. Because the stag hunt game nicely illustrates how risk obtains from strategic uncertainty, we show the normal form of the game in the following table ([Table 22.2](#)).

As can be seen from the table, both players would prefer to coordinate on hunting stag together. However, decisions are made simultaneously and anonymously. Hence, for each player, it is very costly should the other player choose hunting hare instead, possibly because of spitefulness, or simply because she makes a mistake. Depending on player 1’s beliefs about the probability of player 2 choosing stag, denoted  $p$ , she has to make a choice between a sure payoff of 8 for strategy *Hare* and an uncertain payoff of  $p \times 9 + (1 - p) \times 1$  for strategy *Stag*, thus constituting a decision under uncertainty.

Charness and Jackson let people play the game individually or accompanied by an anonymous and passive dependent other person whose payoffs are identical to the decision maker’s payoffs. They find that people on average become more risk averse, and thus cooperate less, when they are responsible not only for themselves but also for the other person’s payoff. Using within-person observations, they also find that this shift is mainly due to one third of the population who are strongly affected by the responsibility, while two third are not affected at all, suggesting systematic heterogeneity in risky decision making for others. Notice also how

**Table 22.2**  
Payoffs in the stag hunt game (Charness and Jackson 2009)

Player 1 \ Player 2	Stag	Hare
Stag	(9,9)	(1,8)
Hare	(8,1)	(8,8)

( $x,y$ ) refers to player 1’s payoff of  $x$  and player 2’s payoff of  $y$

this effect is consistent with the findings on ambiguity aversion discussed in the previous section, where accountable subjects have been found to shy away from the ambiguous option, which is generally perceived as “riskier” by subjects. The following subsection examines in more detail the effect of risks due to strategic uncertainty if compared with risks caused by neutral events.

## The Decision Maker’s Outcomes Depend on Other Agents’ Choices
